409 12th STREET, SW
WASHINGTON, DC 20024
(202) 863-2476

Dear Colleagues:

The 1992 SPO Meeting, like the 1991 SPO Meeting, had a record number of abstracts submitted. This year we had a total of 881 abstracts, which is 93 (11%) more than 1991. A total of 664 abstracts or 75% of those submitted were accepted compared to 86% last year. Of special interest was the fact that we had a large number of abstracts (69) submitted from outside the continental United States. The breakdown of the 881 abstracts submitted for the 1992 SPO Annual Meeting is summarized below:

Abstracts submitted	881
Oral presentations	44 (5%)
Poster presentations	491 (56%)
Published, not presented	129 (15%)
Rejected	217 (25%)*

* Includes those not published at the authors' request.

In accordance with guidelines established over the last two years, each abstract was judged by four qualified reviewers, selected from the regular SPO membership. In no case was a reviewer's evaluation used to judge his/her own abstract for the final scoring and in no case was there an institutional conflict. As has been our policy, the abstracts were judged without knowledge of the authors or institutions. My personal thanks to the reviewers for their carefully considered judgments and speedy responses (although a gentle nudge was sometimes required). I would also like to personally thank whoever invented the FAX machine.

Very special thanks and gratitude go to Lynne McDonnell, Administrative Assistant for Maternal-Fetal Medicine, for her skillful organization and hundreds of hours of work which went into preparing this syllabus. I would also like to give personal thanks to Laurie Daniels and Terry Daniels who assisted Lynne in this endeavor. Ms. Patricia Stahr of our SPO Headquarters in Washington, D.C. is deserving of special recognition for all of her hard work and wonderful advice in planning and preparing for this meeting. These four key individuals have made being the 1992 Program Chair a pleasure instead of a nightmare! Finally, I would like to give thanks to our President, Dr. Thomas Garite, and all of the members of the Board of Directors for their enthusiastic support and assistance in planning this meeting.

As a final note, it would appear that our "crisis" regarding future meeting sites has ended. In 1993 the SPO Meeting will be held at the San Francisco Hilton, San Francisco, CA and in 1995 it will be held at the Atlanta Hilton in Atlanta, GA. The 1994 meeting will remain in Las Vegas at the Las Vegas Hilton.

Sincerely,

Larry C. Gilstrap, III, M.D.

Acknowledgements

The Society of Perinatal Obstetricians wishes to express thanks and deep appreciation to the following organizations for their generous support of the 1992 Annual Meeting(*):

SPONSORS

Acuson
Caremark
Corometrics Medical Systems/Wyeth-Ayerst
Healthdyne Perinatal Service
Humana, Inc.
Tokos Medical Corporation

CONTRIBUTORS

Adeza Biomedical
ADR Ultrasound
Carelink
Genetics & IVF Institute
Genetrix
Hewlett-Packard
Medical Data Systems
Multigon Industries
Nellcor
Ross Laboratories
Toshiba Medical Systems
Upjohn Company
Vivigen
Wiley-Liss

(*) This list reflects known contributors as of press deadline.

Awards

n behalf of the Society of Perinatal Obstetricians, the 1992 Program Committee will announce the following awards as outstanding contributions to this meeting at the Annual Banquet on Thursday, February 6:

Society of Perinatal Obstetricians Award

$1000

Outstanding Research by a Fellow-in-Training

Sponsored by the Society of Perinatal Obstetricians
$1000

Best Genetics Research in the Field of Perinatal Medicine

Sponsored by Vivigen
$500

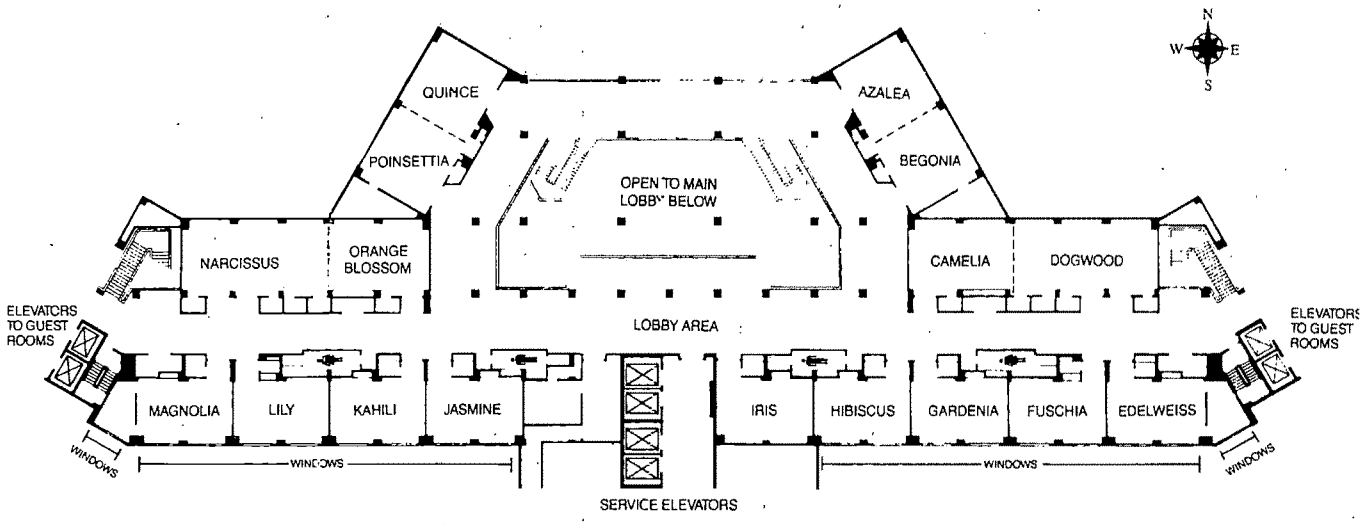
Best Doppler Research in the Field of Perinatal Medicine

Sponsored by Multigon Industries
$500

****

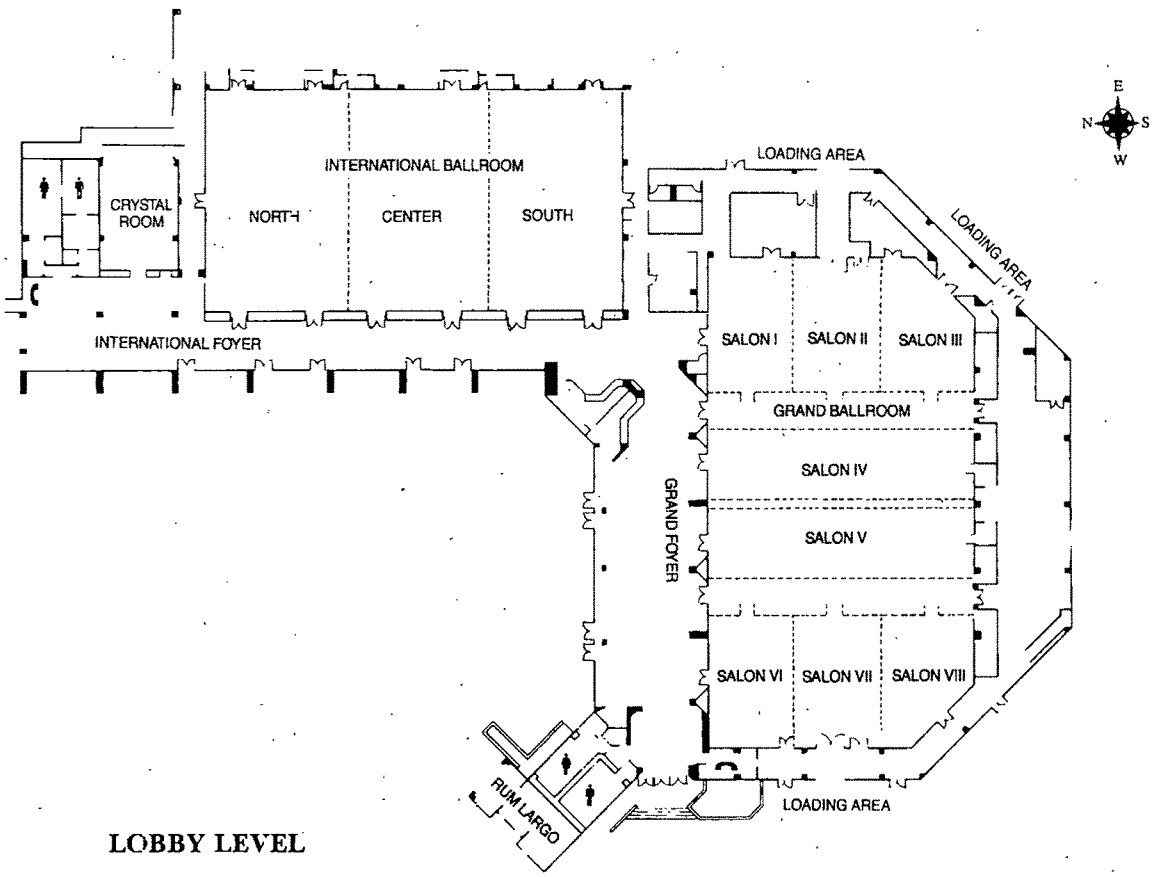
Awards for the Best Poster Presentations

Sponsored by the Society of Perinatal Obstetricians
$500



award will be given to the best poster presented at each of the five sessions. These awards will be announced during the closing ceremony on Saturday, February 8, 1992.

****



Humana Award for Excellence

iis award is for the physician who is extensively involved with the direct care of patients, and who also has the ive and energy to conduct clinical research resulting in a significant advance in diagnosis and treatment. The recipient, selected by the SPO, will be announced at the Thursday Banquet.

SOCIETY OF PERINATAL OBSTETRICIANS

Orlando, Florida – February 3-8, 1992

Schedule of Oral Presentations

Thursday, February 6, 1992

8:00am-10:30am	Oral Session I: Prematurity; Labor; Neonatology Moderator: *Thomas J. Garite, M.D.* *President, SPO*	Grand Salons V-VIII

8:00-8:15am	1	ONCOFETAL FIBRONECTIN IN PATIENTS AT INCREASED RISK FOR PRETERM DELIVERY	*Michael P. Nageotte, K.A. Hollenbach, B.A. Vanderwahl, K.M. Hutch* Long Beach Memorial Womens Hospital, Long Beach, CA and University of California, Irvine
8:15-8:30am	2	NATURAL INTERLEUKIN-1 RECEPTOR ANTAGONIST BLOCKS INTERLEUKIN-1-INDUCED PROSTAGLANDIN PRODUCTION BY HUMAN INTRAUTERINE TISSUES: THE BASIS FOR A NOVEL APPROACH TO THE TREATMENT OF PRETERM LABOR IN THE SETTING OF INFECTION	*Roberto Romero, W. Sepulveda, M. Mazor, C. Dinarello, M. Mitchell* Yale University, New Haven, CT and University of Utah, Salt Lake City, UT
8:30-8:45am	3	KETEROLAC BLOCKS RITODRINE-STIMULATED PRODUCTION OF $PGF_{2\alpha}$ IN PREGNANT SHEEP	*Phillip N. Rauk, Steven A. Laifer* University of Pittsburgh, Magee Women's Hospital Pittsburgh, PA
8:45-9:00am	4	CESAREAN SECTION FOR FETAL INDICATIONS AT THE LIMITS OF FETAL VIABILITY (1986 TO 1991)	*Erol Amon, Sam Moyn* St. Louis University, St. Mary's Health Center St. Louis, MO
9:00-9:15am	5	NEONATAL INTRAVENTRICULAR HEMORRHAGE (IVH) FOLLOWING MATERNAL BETA-SYMPATHOMIMETIC TOCOLYSIS	*Lynn J. Groome, Robert L. Goldenberg, S.P. Cliver, R.O. Davis, R.L. Copper* University of Alabama Birmingham, AL
9:15-9:30am	6	THE CANADIAN MULTICENTRE RCT OF EARLY AMNIOTOMY	*William D. Fraser, S. Marcoux, J.M. Moutquin, A. Christen, B.A. Armson, J.P. Verreault, N. Okun, C. Nimrod, A.K. Joshi, H. Cohen, L. Bayer, T. Doran, P. Bernstein, J. Carroll, S. Bottoms, F. Galerneau* Laval University Quebec, Canada
9:30-9:45am	7	EXPRESSION OF PARATHYROID HORMONE-RELATED PEPTIDE (PTHrP) mRNA IN PLACENTAL MEMBRANES AND AMNIOTIC FLUID (AF)	*J.E. Ferguson II, J. Gorman, D.E. Bruns, M.R. Pandian, M.E.H. Bruns* University of Virginia, Charlottesville, VA and Nichols Institute, San Juan Capistrano, CA

9:45-10:00am	8	COMPARISON OF INDUCTION METHODS FOR PREMATURE RUPTURE OF MEMBRANES AT TERM	*J.F. McCaul, L.M. Williams, R.W. Martin, E.F. Magann, L. Gallagher, J.C. Morrison* University of Mississippi Jackson, MS
10:00-10:15am	9	DOES ANTENATAL MATERNAL BETAMETHASONE ADMINISTRATION REDUCE NEONATAL MORBIDITY FOLLOWING IMMEDIATE SURFACTANT THERAPY AT DELIVERY?	*Andrew W. Davey, David M. Sherer, Jacques S. Abramowicz, Christopher Cox, James W. Kendig* University of Rochester Rochester, NY
10:15-10:30am	10	UMBILICAL ARTERY CREATINE KINASE BRAIN BAND % PREDICTS MAJOR INTRAVENTRICULAR HEMORRHAGE	*R. Figueroa, L. Gonzalez, U. Verma, R. Carter, I. Argani, N. Tejani* New York Medical College Valahalla, NY

Thursday, February 6, 1992

2:00pm-4:00pm		**Oral Session II: Medical Complications of Pregnancy; Hypertensive Disease of Pregnancy** **Moderator:** ***Julian T. Parer, M.D., Ph.D.*** ***Program Chair, 1991 SPO***	**Grand Salons V-VIII**
2:00-2:15pm	11	THRESHOLD VALUES FOR GLUCOSE TOLERANCE TEST (GTT) IN PREGNANCY NEED TO BE MODIFIED	*Nina Boe, J. Dacus, B. Mercer, K. Schulz, B. Sibai* University of Tennessee Memphis, TN
2:15-2:30pm	12	NEONATAL OUTCOME IN PREGNANCIES COMPLICATED BY HYPERTHYROIDISM	*Lynnae Millar, D. Wing, P. Koonings, M. Montoro, J. Mestman* University of Southern California Los Angeles, CA
2:30-2:45pm	13	ANTIPHOSPHOLIPID SYNDROME. OUTCOME OF TREATED PREGNANCIES: AN UPDATE OF THE UTAH EXPERIENCE	*Robert M. Silver, D.W. Branch, D.J. Dudley, J.R. Scott* University of Utah Medical Center Salt Lake City, UT
2:45-3:00pm	14	ACETYLSALICYLIC ACID INHIBITS ANTICARDIOLIPIN ANTIBODY-INDUCED PLATELET-ACTIVATING FACTOR SYNTHESIS	*Richard K. Silver, P.D. O'Connell, M.S. Caplan* Northwestern University Medical School Evanston, IL
3:00-3:15pm	15	A RANDOMIZED PROSPECTIVE COMPARISON OF NIFEDIPINE AND BED REST VERSUS BED REST ALONE IN THE MANAGEMENT OF PREECLAMPSIA REMOTE FROM TERM	*Baha M. Sibai, J.R. Barton, S. Aki, C. Sarinoglu, B.M. Mercer* University of Tennessee Memphis, TN
3:15-3:30pm	16	MAGNESIUM SULFATE INJECTIONS BLOCK NMDA-INDUCED HIPPOCAMPAL SEIZURES	*David B. Cotton, R.F. Berman, S. Irtenkauf* Wayne State University/Hutzel Hospital Detroit, MI

3:30-3:45pm	17	MAGNESIUM PIDOLATE INFUSION REDUCES ANGIOTENSIN II PRESSOR RESPONSE IN PREGNANT WOMEN	*Andrea L. Tranquilli, M.L. Mariani, C.G. Garzetti, H. Valensie, C. Romanini* University of Ancona Ancona, Italy
3:45-4:00pm	18	A PROSPECTIVE STUDY OF BIOIMPEDANCE ANALYSIS IN NORMAL AND HYPERTENSIVE PREGNANCIES	*Thomas Murphy Goodwin, S. Estrada, K.A. Smith, L. Bernstein, R. Artal* University of Southern California Los Angeles, CA

Friday, February 7, 1992

8:00am-10:00am		**Oral Session III: Genetics & Teratology; Fetal Therapy; Placental Physiology** **Moderator:** ***Garland Anderson, M.D.*** ***President Elect, SPO***	**Grand Salons V-VIII**
8:00-8:15am	19	A PROSPECTIVE EVALUATION OF TRIPLE MARKER MATERNAL SERUM SCREENING FOR TRISOMY-21	*E.Y. Cheng, D.A. Luthy, D.E. Hickok, R. Lieppman, R.G. Resta, M. Williams, A. Zebelman, F. Luthardt* Swedish Hospital Medical Center Seattle, WA
8:15-8:30am	20	MID-TRIMESTER ECHOGENIC BOWEL AND CHROMOSOMAL ABNORMALITIES	*Angela Scioscia, D. Pretorius, N. Budorick, T. Cahill, F. Axelrod, G. Leopold* University of California, San Diego San Diego, CA
8:30-8:45am	21	PREGNANCY LOSS AFTER FIRST TRIMESTER ULTRASONOGRAPHIC DOCUMENTATION OF EMBRYONIC/FETAL CARDIAC ACTIVITY	*Jeffrey M. Barrett, Jennifer Brinson* Watson Clinic Lakeland, FL
8:45-9:00am	22	EVALUATION OF FETAL BLOOD CONTENT IN TRANSABDOMINAL AND TRANSCERVICAL CHORIONIC VILLUS SAMPLES	*Karin Blakemore, I. Baser, N. Callan, R.S. Shirey, T. Kickler, M. Blitzer* The Johns Hopkins University and University of Maryland Baltimore, MD
9:00-9:15am	23	DIAGNOSIS AND TREATMENT OF TWIN TO TWIN TRANSFUSION SYNDROME (TTTS)	*Carl Weiner, A. Ludomirski* University of Iowa Hospital, Iowa City, IA and Pennsylvania Hospital, Philadelphia, PA
9:15-9:30am	24	LYMPHOCYTE SUBSETS IN PRENATALLY OBTAINED FETAL BLOOD	*Stanley M. Berry, J. Kaplan, N.L. Fine, J.A. Bichalski, M.P. Dombrowski, N.B. Isada, M.I. Evans, D.B. Cotton* Wayne State/Hutzel Hospital and Children's Hospital of Michigan Detroit, MI

9:30-9:45am	25	PRODUCTION OF ENDOTHELIN-1 BY HUMAN TROPHOBLASTS	*Philip Samuels, J.D. Steinfeld, M. Rhoa, S. Murray, J. Amico, D.B. Cines, K.R. McCrae* University of Pennsylvania Philadelphia, PA and University of Pittsburgh Pittsburgh, PA
9:45-10:00am	26	THE EFFECTS OF LOW-DOSE ASPIRIN ON PROSTACYCLIN AND THROMBOXANE PRODUCTION BY THE PERFUSED HUMAN PLACENTA	*Robert L. Jacobson, Anthony Brewer, Tariq A. Siddiqi, Leslie Myatt* University of Cincinnati Cincinnati, OH

Friday, February 7, 1992

2:00pm-4:00pm	**Oral Session IV: Clinical/Operative Obstetrics; Ultrasound; Infectious Disease** **Moderator:** ***Sze-ya Yeh, M.D.*** ***Secretary-Treasurer, SPO***	**Grand Salons V-VIII**

2:00-2:15pm	27	A SIGNIFICANT REDUCTION IN CESAREAN DELIVERIES: EFFECT ON PERINATAL OUTCOME	*Luis Sanchez-Ramos, Mark T. Cullen, Carol Walker* University of Florida Jacksonville, FL
2:15-2:30pm	28	VAGINAL DELIVERY OF THE NON-VERTEX SECOND TWIN	*Alan Fishman, Debra Grubb, Bruce Kovacs* University of Southern California Los Angeles, CA

1 ONCOFETAL FIBRONECTIN IN PATIENTS AT INCREASED RISK FOR PRETERM DELIVERY

Nageotte MP, Hollenbach KA, Vanderwahl BA, Hutch KM
Long Beach Memorial Womens Hospital
University of California, Irvine

In an effort to evaluate oncofetal fibronectin (fFN) as a screening test for premature birth, asymptomatic high risk patients were identified and followed prospectively. Risk factors included multiple gestation, previous preterm labor, previous preterm birth, congenital uterine anomaly and incompetent cervix with cerclage. Beginning at 20 weeks of gestation and repeated weeky until delivery or 37 weeks, a home visiting nurse obtained specimens of cervicovaginal fluid from the posterior fornix. A total of 1144 specimens were obtained (mean 11.2/patient). Specimens were batched and an ELISA immunoassay for fFN was performed following delivery. A specimen was defined as positive when greater than 50 ng fFN/ml was present. Sixty-four patients delivered at or beyond 37 weeks of gestation while 38 patients delivered before 37 completed weeks. However, 6 of these preterm deliveries were induced with a resultant spontaneous preterm birth rate of 33.3% (32/96). By 34 weeks of gestation 16 patients had delivered, only 1 of whom was induced (14.9%, 15/101). As a marker for delivery prior to 37 weeks, fFN had a sensitivity of 90.6%, a specificity of 44.3%, a positive predictive value of 42.6% and a negative predictive value of 91.2% (OR-6.2; 95% CI 1.6-22.4; p = 0.005; RR-4.0; 95% CI 1.5-9.5). For delivery prior to 34 weeks, sensitivity was 93.8%, specificity 58.8%, positive predictive value 30.0% and negative predictive value 98.0% (OR 21.4; 95% CI 2.7-114.4; p = 0.0003; RR-15.3; 95% CI 3.4-68.2).

Conclusion: Oncofetal fibronectin is an excellent marker for preterm delivery in asymptomatic high risk patients.

2 NATURAL INTERLEUKIN-1 RECEPTOR ANTAGONIST BLOCKS INTERLEUKIN-1-INDUCED PROSTAGLANDIN PRODUCTION BY HUMAN INTRAUTERINE TISSUES: THE BASIS FOR A NOVEL APPROACH TO THE TREATMENT OF PRETERM LABOR IN THE SETTING OF INFECTION.

R.Romero, W.Sepulveda,* M.Mazor, C.Dinarello, M Mitchell, Depts. of Ob-Gyn, Yale Univ. Sch. of Med., New Haven, CT; Wayne State Univ., Detroit, MI; The Univ. of Utah, Salt Lake City, UT and Dept. of Geographic Med., Tufts Univ., Boston, MA

Interleukin-1 (IL-1) has been implicated in the mechanisms responsible for preterm labor (PTL) in the setting of infection. Recently, a natural IL-1 receptor antagonist protein (IRAP) has been identified. This new member of the IL-1 gene family seems to have evolved to regulate the biological effects of IL-1α and IL-1β (Proc Natl Acad Sci 1991;88:5232). Inhibition of IL-1-induced prostaglandin (PG) production by intrauterine tissues may have potential value in the treatment of PTL associated with infection. The purpose of these studies was 1) to determine whether IRAP is present in the amniotic fluid (AF) of women with term labor (TL) and PTL (with and without infection) and 2) to study the effects of IRAP on IL-1-induced PG biosynthesis by human amnion and chorion. Materials and Methods: AF was obtained from women with TL and PTL (n = 98). Fluid was cultured for aerobic and anaerobic bacteria and Mycoplasmas. IL-1α, IL-1β and IRAP AF concentrations were measured by immunoassays previously validated for human AF. The effect of IRAP on IL-1-induced PG production by amnion and chorion was studied using primary cultures. Cells were incubated with IRAP and IL-1β for 16 hrs. PGE_2 released into the media was assayed by immunoassay. Results: 1) IRAP was present in all AF samples. 2) AF contains the highest IRAP concentrations detected in any biological fluid to date. 3) AF IRAP concentrations were not increased in women with preterm labor and intraamniotic infection despite dramatically elevated concentrations of IL-1α and IL-1β in the same fluid (PTL with negative AF culture: median=22 ng/ml, range=1.6-70 vs. PTL with positive AF culture: median=38 ng/ml, range=6-70; p >0.05). 4) IRAP blocked IL-1β-induced PGE_2 production by amnion and chorion in a dose-dependent manner. 5) IRAP, by itself, did not stimulate PGE_2 release by amnion and chorion when used in concentrations ranging from 0.1 mg/ml to 1000 ng/ml. Conclusion: 1) IRAP is a physiologic component of AF; 2) The release of IL-1α and IL-1β into the AF in women with premature labor is not associated with changes in IRAP bioavailability in AF; 3) IRAP blocks IL-1-induced FG production by amnion and chorion; 4) Anti-cytokine agents may be of value in the treatment of PTL.

3 KETOROLAC BLOCKS RITODRINE-STIMULATED PRODUCTION OF $PGF_{2\alpha}$ IN PREGNANT SHEEP.

Phillip N. Rauk, Steven A. Laifer, University of Pittsburgh School of Medicine, Magee-Womens Hospital, Pittsburgh, PA

We have previously demonstrated that ritodrine infusion to pregnant sheep increases uteroplacental production of prostaglandin (PG)$F_{2\alpha}$. We have speculated that the increase in uterotonic $PGF_{2\alpha}$ may contribute to the tachyphylaxis that occurs with ritodrine. We performed the following study to determine if infusion of the prostaglandin synthesis inhibitor, ketorolac, would block ritodrine-induced production of $PGF_{2\alpha}$, when the 2 agents are administered in combination to pregnant sheep. In 5 pregnant sheep (gestational ages 110-120/147), we placed catheters in the aorta, vena cava and in the uterine vein from the pregnant uterine horn. In random order on different days we infused saline, ritodrine (4 μg/kg/min), ketorolac (1.2 μg/kg/min), or a combination of ritodrine and ketorolac, into the venous catheter at a rate of 10 cc/min over a 4h period. Uterine venous and maternal arterial blood was sampled 60 min before and immediately before the infusion, and then at 60, 120, 180, 240 min during the infusion and assayed for $PGF_{2\alpha}$. Ritodrine significantly increased uterine venous $PGF_{2\alpha}$ during the 4h infusion (mean increase at 4h 1.16 ng/ml, $p<0.05$). When ritodrine and ketorolac were administered in combination, there was no change in uterine venous $PGF_{2\alpha}$ throughout the 4h infusion. Ketorolac completely blocked the ritodrine-induced production of $PGF_{2\alpha}$. This is the first study to show that a prostaglandin synthesis inhibitor can effectively block uteroplacental prostaglandin production stimulated by ritodrine in vivo. Based on these results, there appears to be definite physiologic advantage for tocolytic regimens that include a combination of ritodrine and a prostaglandin synthesis inhibitor.

4 CESAREAN SECTION FOR FETAL INDICATIONS AT THE LIMITS OF FETAL VIABILITY (1986 TO 1991).

Erol Amon,MD, Sam Moyn* St. Louis University, St. Mary's Health Center, Department of OB-GYN.

We repeated a similar survey of the SPO membership to assess changes in management regarding cesarean delivery at the limits of viability. Data on 560, 1991 members, were compared to 404, 1986 members. 85% of respondents are attendings in MFM. 30% are strongly influenced by legal concerns. 70% rely more on GA than EFW for accuracy in deciding for C/S. 60% are Univ. based; 24% Univ. affil.; and 16% non-Univ. The lower limit for initiation of cesarean delivery for fetal indications are summarized in the table.

	% Response (cumulative %)			
Lowest GA to	C/S-fetal distress		C/S-breech	
initiate mgmt	1986	1991	1986	1991
22(weeks)	0	0.5	0	0.2
23	0.4	3.4(4)	0	2.7(3)
24	18(18)	33(37)	14	24(27)
25	25(43)	35(72)	22(36)	29(56)
26	47(90)	27(99)	46(82)	27(83)
27	8(98)	1(100)	7(89)	4(87)
28	2(100)	0.4	4(93)	2(89)
>28	-	-	2(95)	1(90)
Do not usually C/S for breech			5%	10%

Although individualization of care prevails, the cumulative percentage of members willing to perform C/S at 24 weeks gestation for fetal indications has doubled during the last five years.

5 NEONATAL INTRAVENTRICULAR HEMORRHAGE (IVH) FOLLOWING MATERNAL BETA-SYMPATHOMIMETIC TOCOLYSIS.

LJ Groome, RL Goldenberg, SP Cliver,* RO Davis, RL Copper,*
University of Alabama Hospitals, Birmingham, Alabama

There has not been a reduction in neonatal morbidity or mortality associated with the widespread use of ß-mimetic agents (BMA) to delay delivery. An increase in the incidence of IVH following ß-mimetic tocolysis may be partly responsible for this lack of improvement even if delivery is delayed. This study was designed to determine if the incidence of IVH is increased in the offspring of women who received a BMA for preterm labor tocolysis. The population consisted of women who delivered singleton liveborn infants free of neurological anomalies at 25-36 weeks during a multicenter preterm birth prevention trial (1982-86). Based on factors such as gestational age and cervical dilatation, women in preterm labor were either not treated, given magnesium sulfate ($MgSO_4$) or received a BMA. IVH was diagnosed by ultrasound, routinely performed on infants <1500 gms and as indicated at higher weights. Of the 1978 infants with either spontaneous preterm labor or PROM who delivered preterm, 105 (5.3%) had IVH and 32 (1.6%) had grade III or IV IVH. Use of a BMA was associated with a 4-fold increase in the incidence of IVH compared to the use of either $MgSO_4$ or no tocolytic agent ($p<0.001$). In virtually all preterm gestational age groups, there was a 2-fold and generally significant increase in the incidence of IVH following BMA tocolysis. A logistic regression analysis was performed adjusting for the type of tocolytic agent, gestational age at delivery, birthweight, medical center, route of delivery, indication for delivery, race, infant sex, and respiratory distress syndrome. The use of a BMA was found to be significantly associated with IVH [Odds Ratio (OR) of 2.3 (1.23-4.29)]. In addition, BMA tocolysis was associated with a significant increase in the incidence of grades III and IV IVH when compared to no treatment [OR of 2.91 (1.06-7.97)]. This retrospective study suggests that BMA tocolytic therapy may be associated with at least a 2-fold increase in the incidence of IVH even when other risk factors are taken into account.

6 THE CANADIAN MULTICENTRE RCT OF EARLY AMNIOTOMY.

WD Fraser[X], S Marcoux[X], JM Moutquin, A Christen[X], BA Armson, JP Verreault[X], N Okun[X], C Nimrod, AK Joshi[X], H Cohen, L Bayer, T Doran[X], P Bernstein, J Carroll[X], S Bottoms, F Galerneau[X], Laval University, Quebec, Canada.

The goal of the study was to determine if a policy of early amniotomy for nulliparae in term spontaneous labour is an effective means to prevent dystocia. In 11 centres, 925 women were randomly allocated to either early amniotomy (ARM) or to conservation of the membranes (COM). For the purpose of the study, dystocia was defined as a period of at least 4 hours, after 3 centimeters dilatation had been achieved, during which the mean rate of cervical dilatation was < 0.5 cm/hr. Treatment groups were similar with respect to age, GA, years of education, weight, cervical status, and baby's birthweight. The median interval from randomization to membrane rupture was 20 min. in the ARM group and 230 min. in the COM group. Epidural anesthesia and electronic fetal monitoring were used with similar frequency in the two groups. Oxytocin was used prior to a diagnosis of dystocia in a similar proportion of women in the two groups (ARM - 13.2%; COM - 11.4%). Dystocia was less frequent in the ARM group than in the COM group (33.6% vs 44.6%; p = 0.001). The mean interval from randomization to delivery for women delivering vaginally was approximately 1.5 hours shorter in the ARM than in the COM group ($p < 0.0001$). The distribution of modes of delivery was similar in the two groups. Groups were also comparable with respect to indicators of neonatal status (APGAR 5 < 7, arterial cord pH < 7.20, admission to ICU, cephalohematoma). Thus, a policy of early amniotomy was found to be protective for dystocia by the study definition (RR = 0.75).

7 EXPRESSION OF PARATHYROID HORMONE-RELATED PEPTIDE (PTHrP) mRNA IN PLACENTAL MEMBRANES AND AMNIOTIC FLUID (AF).

Ferguson II JE, Gorman J[X], Bruns DE[X], Pandian MR[X,+], Bruns MEH[X]. Departments of Obstetrics and Gynecology and Pathology, University of Virginia School of Medicine, Charlottesville, VA, and +Nichols Institute, San Juan Capistrano, CA.

PTHrP was originally discovered in human tumors that produce hypercalcemia of malignancy. The hormone increases cyclic AMP and prostaglandin E_2 in target tissues, but its physiological functions are unknown. We previously reported that PTHrP mRNA is expressed in laboring human uterus. We here report the unexpected finding that PTHrP is abundantly expressed in human amnion and reaches high concentrations in amniotic fluid. PTHrP mRNA was measured by computer-aided densitometry of Northern blot autoradiographs. The hormone was measured by use of a sandwich immunoassay. PTHrP mRNA abundance was 5-15 times that found in myometrium and exceeded that found even in lactating mouse mammary gland, the richest source previously identified. PTHrP mRNA abundance was decreased by 60% ($p<0.025$) in amnion from laboring (n=16) vs. non-laboring (n=16) women. The concentration of PTHrP in AF equaled or exceeded those found in serum of patients with hypercalcemia of malignancy. The mean concentrations of hormone in AF at 16 and 39 weeks were 21 ± 6 and 38 ± 11 pmol/L, respectively. These data suggest that the amnion sustains regulated abundant expression of PTHrP; the high concentrations of PTHrP in AF suggest an important role of PTHrP in normal pregnancy.

8 COMPARISON OF INDUCTION METHODS FOR PREMATURE RUPTURE OF MEMBRANES AT TERM.

J.F. McCaul, L.M. Williams,[X] R.W. Martin, E.F. Magann,[X] L. Gallagher,[X] J.C. Morrison, Dept. Ob/Gyn, Univ. Mississippi Med. Ctr., Jackson, MS

Objective: Determine which method of induction is most beneficial for women at term with premature rupture of the membranes (ROM). Patient Population: Women (n = 96) 36-42 weeks' gestation with documented ROM (< 6 hours, without labor or infection) were given informed consent and randomized to one of three groups. Interventions: Expectant management (E) patients were observed for labor. Oxytocin (O) induction was used in the second group while PGE_2 gel (PG) was given (4-mg dose every 6 hours) to patients in the third group. PG was repeated only in women who were not in active labor. Main Outcome Measures: Rupture to delivery interval, length of labor, maternal infectious complications, incidence of cesarean section, hospital stay, and neonatal outcome parameters. Results: There were no significant differences in cervical exam on admission, length of labor, number of vaginal exams, infectious morbidity (maternal/neonatal), or Apgar scores between the three groups.

Group	N	Duration ROM (d)	Fetal Bradycardia	Maternal Hospital Stay
E	31	1.45	4	3.6 ± 1.4
O	25	.76	0	2.6 ± 0.7
PG	35	.89	1	2.5 ± 1.0

The length of hospital stay was significantly longer in E versus O and PG (P = .02) as was duration of ROM for E patients when compared to the other two groups (P = .01). There were no significant differences in the rate of cesarean birth and while neonatal morbidity was not different between the two groups, there was a significant increase in the number of patients with fetal bradycardia in E versus the other two groups (P = .04). Conclusion: E management of ROM at or near term significantly prolongs hospital stay without the benefit of decreasing abdominal delivery rates and with an increased risk of fetal bradycardia.

9 **DOES ANTENATAL MATERNAL BETAMETHASONE ADMINISTRATION REDUCE NEONATAL MORBIDITY FOLLOWING IMMEDIATE SURFACTANT THERAPY AT DELIVERY?**

Andrew M. Davey*, David M. Sherer, Jacques S. Abramowicz, Christopher Cox*, James W. Kendig*.
University of Rochester, Rochester, New York

Retrospective analysis was performed on the neonatal outcome of 190 premature infants delivered between 24-29 weeks gestation (inclusive) who received prophylactic calf-lung surfactant extract (CLSE), (90 mg intratracheally) to examine the possible effect of antenatal steroid administration on subsequent neonatal morbidity. All deliveries occurred at two level III referral centers. Two groups of infants were compiled and compared. The mothers of one group (n=66) received antenatal betamethasone, and those of the second group (n=124) did not. Statistical analysis was performed with one-sided Mann-Witney and Chi- Square tests and Kaplan-Maier survival curves. **Results**: Both groups were similar for maternal age, gravidity, parity, gestational age at delivery, incidence and duration of ruptured membranes, incidence of chorioamnionitis, fetal presentation, mode of delivery, and 1 and 5 minute Apgar scores.
Neonatal morbidity was as follows:

Neonatal Morbidity	CLSE	Betamethasone + CLSE	p value
Intraventricular Hemorrhage (Grade 3,4)	38.1%	22.6%	0.02
Alive & Free of O_2 Requirements at 28 days	49 5%	64.5%	0.03
Patent Ductus Arteriosus	44.1%	30.9%	0.09
Days on Ventilator Median ±SD	20±4.4	6±4.7	0.04
Days in Level III NICU Median±SD	33±4.4	12±6.7	0.05
Days to Discharge Home Mecian±SD	7E±3.8	71±3.5	0.09

The incidence of survival, pulmonary interstitial emphysema and pneumothorax was not statistically different between the two groups. **Conclusion**: The above results suggest a beneficial effect of antenatal maternal betamethasone administration on subsequent prophylactic CLSE in reducing neonatal morbidity in premature infants delivered ≤ 29 weeks gestation.

10 UMBILICAL ARTERY CREATINE KINASE BRAIN BAND % PREDICTS MAJOR INTRAVENTRICULAR HEMORRHAGE.

R. Figueroa[x], L. Gonzalez[x], U. Verma, R. Carter[x], I. Argani[x], N. Tejani. NY Med. Coll., Valhalla, NY.

Objective Creatine Kinase brain band (CKBB) would be elevated in the umbilical artery (UA) of newborns (NB) who develop major intraventricular hemorrhage (IVH) & periventricular leucomalacia (PVL). **Study design** 46 NB with birth wt (BW) ≤ 1750g were studied. UA blood was analyzed for acid base & CKBB%. Results of fontanelle scans done on days 1&3 divided the NB into groups: normal (N), minor (G_1+G_2), major (G_3+G_4), & PVL. T-test, Anova, Fisher's test, & regression analysis were used. **Results** UA CKBB% was higher in NB with major IVH (34.2±7.6) compared to N (8.9±2.4), minor (11±2.8), & PVL (14.7±8.5) ($p < .001$). A CKB% of >15 (mean of N ±2 SE) was used to reexamine the study group.

BB%	#	GA	BW(g)	Ap1	Ap5	UApH	Major	PVL
≤15	(33)	29±3	1177±356	5±3	7±3	7.25±.1	2	3
>15	(13)	28±3	1050±358	3±3	5±2	7.23±.1	6	1
		ns	ns	ns	$p<.01$	ns	$p<.001$	ns

Analysis of Ap5 subsets showed that NB with Ap5<7 did not have a higher risk of major IVH inspite of a high CKBB%. **Conclusions** 1) Prevalence of a major IVH: total 19.2%, low Ap5 36%, CKBB% ≤ 15 7%, CKBB% >15 53%. 2) Depression in NB with elevated UA CKBB% in the absence of acidosis may be due to an "insult" which later results in major IVH. 3) PVL seen within 3 days of birth may not be predicted by UA CKBB% because it evolves over 7-14 days.

Oral Session II

Medical Complications of Pregnancy; Hypertensive Disease of Pregnancy

Thursday, February 6, 1992
2:00-4:00 p.m.

Moderator: *Julian T. Parer, M.D., Ph.D.*

11 THRESHOLD VALUES FOR GLUCOSE TOLERANCE TEST (GTT) IN PREGNANCY NEED TO BE MODIFIED. N. Boe,[X] J. Dacus, B. Mercer,[X] K. Schulz, B. Sibai. University of Tennessee, Memphis.

Considerable controversy exists regarding plasma glucose values considered abnormal on glucose tolerance tests (O'Sullivan et al. Sacks et al). We hypothesized that pregnant women with a positive glucola screen and two or more abnormal values (as defined by Sacks et al) on the GTT would have a higher incidence of macrosomia and neonatal complications than women with a negative glucola screen. Materials & Methods: The study group included 123 women with a positive glucola screen who subsequently had a normal GTT by O'Sullivan's criteria (Fasting, 105 mg/dl; 1 hour 190 mg/dl; 2 hours, 165 mg/dl; 3 hours, 145 mg/dl), but who had two or more abnormal values using Sacks' threshold values for the GTT (Fasting, 96 mg/dl; 1 hour, 172 mg/dl; 2 hours 152 mg/dl; and 3 hours, 131 mg/dl). The control group included 102 women who had a negative glucola screen. Results: Maternal and perinatal outcome variables analyzed are summarized below. Although the birthweights in the two groups were not significantly different grossly (3350 vs 3240 grams), a statistically significant increase of 158 grams in the study group birthweights was found after correcting for maternal weight at delivery and gestational age ($p<0.01$). Conclusions: Patients with a positive glucola screen and normal GTT by O'Sullivan's criteria, but abnormal GTT by Sacks' criteria are at increased risk for cesarean section and neonatal morbidity as compared to patients with a negative glucola screen. These findings suggest that the GTT criteria of O'Sullivan should be modified.

Variable	Study Group n=123	Control Group n=102	P value
Maternal weight, at delivery	190±41	177±48	0.03
Delivery by C/S (%)	22.0	9.9	<0.02
LGA (%)	21.1	13.7	0.16
Percent macrosomia (>4000 g)	15	7	0.13
Neonatal hypoglycemia (%)	8	1	<0.02

LGA=large for gestational age, C/S=cesarean section

12 NEONATAL OUTCOME IN PREGNANCIES COMPLICATED BY HYPERTHYROIDISM L. Millar, MD[X], D. Wing, MD[X], P. Koonings, MD[X], M. Montoro, MD[X], J. Mestman, MD[X]
University of Southern California, Los Angeles

A review of 205 patients (1974-1990) was performed to analyze efficacy of treatment and effect of TSH receptor antibody on neonatal outcome. Hyperthyroid patients at delivery had the highest percentage of LBW infants and a 3-fold increase in perinatal mortality and morbidity when compared to euthyroid patients. Euthyroid patients at delivery had an increased incidence of LBW infants if they were hyperthyroid at initial presentation when compared with euthyroid patients at presentation.

STATE AT PRESENTATION	STATE AT DELIVERY	# PATIENTS	# LBW INFANTS	%
Euthyroid	Euthyroid	52	5	10
Hyperthyroid	Euthyroid	81	16	20
Hyperthyroid	Hyperthyroid	44	16	36
	Noncompliant	28	9	32

TSH receptor antibody (TBII and TSI) was evaluated in 95 patients and 38 had positive tests (40%). TBII and TSI levels < 50% regardless of thyroid state were not associated with LBW. Nine patients (8%) had a TBII or TSI >50%. Five of nine had LBW infants (55%) despite medical treatment with a decreasing FT4I and TBII level at delivery. **Thus, a TBII or TSI >50% at presentation is associated with an increased incidence of LBW, even with treatment and decreasing antibody levels. In patients with negative or low levels of TSH receptor antibody, control of hyperthyroidism decreases the incidence of LBW. Preconception control of hyperthyroidism further decreases the incidence of LBW.**

13 **ANTIPHOSPHOLIPID SYNDROME. OUTCOME OF TREATED PREGNANCIES: AN UPDATE OF THE UTAH EXPERIENCE.** **Silver RM,[X] Branch DW, Dudley DJ, Scott JR,[X] Dept. Ob/Gyn, Univ. Utah Med. Ctr., Salt Lake City, UT 84132**

We report 80 consecutive pregnancies in 53 women with antiphospholipid antibodies; 96% had lupus anticoagulant and 98% had IgG anticardiolipin. These patients had 182 previous, untreated pregnancies resulting in 162 losses [80 spontaneous abortions (SAB), 69 fetal deaths (FD), 3 neonatal deaths (ND)] and 22 surviving children (13)%. Fifty met the rigid criteria for antiphospholipid syndrome, and 27 had other autoimmune diseases. In 21 patients with 37 thrombotic events (including 7 strokes) 84% were associated with pregnancy or oral contraceptives. Primary treatments included prednisone (PRED), heparin (HEP), and low-dose aspirin (LDA). Results:

			Surviving Children Delivery		Losses		
Treatment	N	Total	< 32 w	> 32 w	SAB	FD	ND
PRED/LDA	39	21 (54%)	10	11	8*	8	2
HEP/LDA	18	13 (72%)	2	11	1	2	2
PRED/HEP/LDA	12	10 (83%)	3	7	0	1	1
Other	11	7 (64%)	2	5	2	2	0

*** Live embryo not confirmed in all cases.**

Excluding SABs from the analysis yields: 21 (68%) living children in the PRED/LDA group and 13 (76%) in the HEP/LDA group (p=NS). Fifty-four percent of mothers reaching the second trimester developed preclampsia. Fetal distress developed in 51% of cases, and 29% of live borns were SGA. Three patients also had 4 pregnancies complicated by postpartum thrombosis during treatment. Conclusions: (1) There were no significant differences in perinatal outcomes or maternal complications between groups and (2) the high rate of thromboembolic episodes suggests the need for anticoagulation in this population.

14 ACETYLSALICYLIC ACID INHIBITS ANTICARDIOLIPIN ANTIBODY-INDUCED PLATELET-ACTIVATING FACTOR SYNTHESIS. RK Silver, M.D., PD O'Connell,[X] MS Caplan,[X] Departments of OB/GYN and Pediatrics, Northwestern University Medical School, Evanston Hospital, Evanston, Illinois

Anticardiolipin antibodies (ACA) are thought to cause recurrent pregnancy loss by promoting placental and decidual thrombosis. We have shown that endothelial cell platelet-activating factor (PAF) synthesis is enhanced by ACA, and speculate that increased levels of this autacoid in ACA-positive patients, might promote thrombosis via platelet aggregation and fibrin deposition. As acetylsalicylic acid (ASA) has been utilized in these women with the intention of inhibiting platelet aggregation directly (through a reduction in thromboxane A_2 production), we wished to determine if ASA might in addition, influence ACA-mediated endothelial cell PAF synthesis. Endothelial cells were harvested from human umbilical veins, grown to confluence in culture, then incubated for 48 hours with [20%] ACA+, heat-inactivated human serum, plus ASA in a dosage of 1.0 mM/L. After incubation, culture wells were stimulated with 10uM/ml A23187 (a potent PAF agonist). Intracellular PAF was recovered by radiolabeling each monolayer with ^{3}H-acetate, followed by phospholipid extraction and thin-layer chromatography. PAF levels were quantified by averaging triplicate measures for each condition. Results from separate experiments (using a singe ACA+ serum source) are shown below (PAF is expressed as dpm x 10^3):

	Exp 1	Exp 2	Exp 3	Mean (SE)
No ASA	10.6	9.4	8.7	9.6 ± 4.5
ASA	5.9	5.7	2.8	4.8 ± 0.8

A 54% reduction in PAF synthesis was observed in ASA-treated cultures (range of 41-68%; $p=0.016$, two-tailed T-test). In an additional experiment, inhibition of PAF appeared to be dose-dependent, with ASA concentrations of 0, 0.1, 1, 10 and 100mMol/L resulting in PAF levels of 8.7, 3.6, 2.8, 0.5 and 0.1 dpm x 10^3, respectively ($r^2=0.87$; $p=0.022$). As expected, prostacyclin synthesis (measured by its metabolite, 6-keto-F1-alpha) was greatly attenuated in ASA-exposed cultures. These observations suggest that in ACA-positive women, the antithrombotic effects of ASA may relate in part, to reduced endothelial cell PAF synthesis. (Supported by a Dee & Moody Grant, Evanston Hospital)

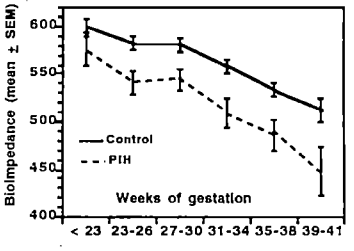
15 A RANDOMIZED PROSPECTIVE COMPARISON OF NIFEDIPINE AND BED REST VERSUS BED REST ALONE IN THE MANAGEMENT OF PREECLAMPSIA REMOTE FROM TERM, BM Sibai, JR Barton[X], S Akl[X], C Sarinoglu[X], BM Mercer[X], University of Tennessee, Memphis.

Two hundred primigravidas with preeclampsia (hypertension plus proteinuria) at 26-36 weeks' gestation were randomly allocated to be managed with bedrest alone or bedrest plus oral nifedipine 40-120 mg/day. All women had baseline and serial evaluations of maternal and fetal well being. Following hospitalization, patients with adequate blood pressure response and absent proteinuria (<300 mg/24 hr) were subsequently managed on an outpatient basis. There were no differences between the two groups in mean systolic and diastolic blood pressures at time of randomization, however, the nifedipine group had significantly lower systolic ($p<0.0001$) and diastolic ($p< 0.0001$) blood pressures during therapy. There were no differences in number of days of antepartum maternal hospitalization (12.6 ± 7.9 v 12.3 ± 10.3). Table compares the clinical findings in 197 patients (3 were lost to follow-up). The two groups had similar incidences of abruptio placentae (2% v 3%) and HELLP syndrome (2% v 4%). There were no perinatal deaths in either group and no differences in cord gasses between groups. **Conclusions:** Nifedipine therapy for preeclampsia significantly reduces maternal blood pressure but does not shorten maternal hospitalization or improve perinatal outcome.

Mean ± SD	Control (n = 99)	Nifedipine (n = 98)
Admission gest age (wks)	33.5 ± 2.3	32.9 ± 2.6
Pregnancy prolongation (days)	22.3 ± 13.5	22.5 ± 15.7
Delivery for severe HTN # (%)	*18 (18)	9 (9)
Delivered ≥ 37 wk # (%)	60 (60)	50 (51)
Birth weight (grams)	2509 ± 723	2403 ± 769
IUGR # (%)	13 (13)	15 (15)
Cord pH < 7.20	11(13)	9 (10)
Admitted to SCN # (%)	21 (21)	30 (30)

SCN = Special Care Nursery, HTN = hypertension, *P < 0.05

16 MAGNESIUM SULFATE INJECTIONS BLOCK NMDA-INDUCED HIPPOCAMPAL SEIZURES. D.B. Cotton, R.F. Berman,[x] S. Irtenkauf,[x] Dept. Ob/Gyn. Wayne State Univ./Hutzel Hosp., Detroit, MI



The use of magnesium sulfate in the treatment of seizures and convulsions associated with preeclampsia-eclampsia is well established. However, the mechanism by which magnesium blocks seizures is unknown. Recent evidence has suggested that activation of excitatory amino acid receptors, such as the N-methyl-D-aspartate (NMDA) receptor, can result in seizures and that these receptors are blocked in a voltage dependent manner by magnesium. Thus magnesium sulfate injections may inhibit seizures directly via a magnesium-induced block of NMDA receptors. As a test of this hypothesis, we examined the ability of intraperitoneal injections of magnesium sulfate to block seizures produced by direct injections of 20 μg of NMDA into the dorsal hippocampus of rats, a region enriched in NMDA receptors. NMDA injections into the hippocampus resulted in almost immediate epileptiform activity, with an average onset latency of 40.7 ± 11 sec. and an average initial seizure duration of 19.5 ± 5 sec. These seizures gradually increased in severity and frequency, evolving into status-type seizures after approximately 10-15 min. Animals pretreated with 270 mg/kg magnesium sulfate either failed to seize or showed seizures of greatly reduced severity and duration. Of those magnesium treated animals which did seize, average seizure onset following NMDA was increased to 96 ± 13 sec. and the average duration was reduced to 8.7 ± 4 sec. These data indicate that magnesium can exert marked anticonvulsant effects against NMDA-induced seizures and suggest a possible link between excitatory amino acid transmitters (e.g., NMDA) in the nervous system and seizures associated with preeclampsia-eclampsia.

17 **MAGNESIUM PIDOLATE INFUSION REDUCES ANGIOTENSIN II PRESSOR RESPONSE IN PREGNANT WOMEN.** Tranquilli AL,[X] Mariani ML,[X] Garzetti CG,[X] Valensie H,[X] Romanini C.[X] University of Ancona, Italy

Circulating eicosanoids and intracellular free calcium (Cai) may contribute in the systemic pressor response to infused angiotensin II (AII) in pregnancy. Since magnesium (Mg) may interfere with both those factors, we studied Cai and the pressor response to AII in 10 primigravid women (28-32 weeks' gestation) before and after the infusion of 1 gt Mg pidolate. After the effective pressore dose (EPD) (i.e. the AII infusion rate at which the diastolic blood pressure increased 20 mmHg) was achieved, or a maximum of 64 ng/kg/min rate was reached, we infused 1 gr Mg pidolate and repeated the test. Cai was measured by means of fluorescent probes at the beginning and the end of both tests. Six women were classified as refractory to AII and 4 as sensitive (EPD<10 ng/kg/min). After Mg pidolate infusion, the 4 sensitive women became refractory, and EPD was significantly enhanced in 3 out of the 6 refractory. Cai increased significantly during AII infusion, whereas, after Mg pidolate administration, it did not change. From these results, Mg pidolate may therefore enhance the vascular refractoriness, and Cai mediate the pressor response to AII, in pregnancy.

18 **A PROSPECTIVE STUDY OF BIOIMPEDANCE ANALYSIS IN NORMAL AND HYPERTENSIVE PREGNANCIES.** TM Goodwin, S Estrada[x], KA Smith[x], L Bernstein[x], R Artal. University of Southern. California, Los Angeles, CA

Bioelectrical impedance analysis (BIA) has been proposed as a safe and inexpensive method of estimating total body water in normal and pathologic states. The formula for the volume of a conductor, $V=L^2/Z$, describes the relationship between bioimpedance (Z), total body water (V) and height (L). A prospective study was undertaken to test the hypothesis that lower bioimpedance (indicative of increased body water) is detectable prior to the time of diagnosis in women destined to develop pregnancy induced hypertension (PIH). Six hundred determinations were made on 161 healthy nulliparae from 18 to 41 weeks gestation. Thirty-six subjects (22%) developed PIH, but only 3 were diagnosed before 36 weeks gestation. Bioimpedance correlated negatively with gestational age among normals($r=.4, p<.001$) and patients who developed PIH ($r=.5, p<.001$). The data are displayed above as means for arbitrarily defined gestational age intervals.

Mean bioimpedance differed significantly between normal and PIH subjects beginning as early as 23 weeks gestation. BIA may be useful in studying the natural history of PIH.

19 **A PROSPECTIVE EVALUATION OF TRIPLE MARKER MATERNAL SERUM SCREENING FOR TRISOMY-21.** EY Cheng,[X] DA Luthy, DE Hickok, R Lieppman, RG Resta,[X] M Williams, [X] A Zebelman,[X] F Luthardt,[X] Swedish Hosp. Med. Ctr., Seattle WA

Early data suggest the use of triple marker analysis from maternal serum may be an effective screening tool for the prenatal diagnosis of Trisomy-21. From 1/1/90 to 8/15/91 we evaluated the triple marker screen obtained at 16-18 weeks gestation in singleton, non-diabetic pregnancies, using MSAFP (HYBERTECH), unconjugated estriol, and total HCG (AMERSHAM) as the analytes measured. We defined a midtrimester risk for Trisomy-21 of ≤1:195 as a positive screen. Pilot studies indicated that 7% of pregnancies would be screen-positive and approximately 2/3 of all cases of Trisomy-21 could be detected. During the 20-month study period 7785 pregnancies were tested with a mean maternal age of 29.3±4.8. 572 pregnancies (7.5%) were screen-positive. 298 of the 7785 pregnancies screened (3.8%) eventually underwent amniocentesis, yielding 21 cases of Trisomy-21. Twenty-one of 298 of amniocenteses (PVP=7%) resulted in a diagnosis of Trisomy-21, comparing favorably to amniocenteses for advanced maternal age, in which 1-2% of procedures yield Trisomy-21. The use of 3 markers (MSAFP, HCG, estriol) improved screening performance, compared to MSAFP and HCG without estriol. The data suggest triple marker analysis is an effective prenatal screen for Trisomy-21.

20 MID-TRIMESTER ECHOGENIC BOWEL AND CHROMOSOMAL ABNORMALITIES. AL Scioscia, D Pretorius[X], N Budorick[X], T Cahill[X], F Axelrod[X], G Leopold[X]. University of California, San Diego, La Jolla, CA.

Sonographic detection of echogenic bowel (EB) in the midtrimester fetus has been associated with cystic fibrosis (CF) and aneuploidy, as well as being a normal variant. From 8/1/90-7/31/91, 22 cases of EB were prospectively detected. Sonograms were performed for the following indications: advanced maternal age(8),↑MSAFP(6),↓MSAFP(4), anatomic survey(2), and outside studies revealing EB (1) and polyhydramnios and EB (1). Gestational age ranged from 15-26 wks, mean 18 wks. Families were counselled regarding the association of EB with CF and aneuploidy and offered testing; 19 amniocenteses were performed, and 17 chose DNA-based CF risk assessment. Six trisomic fetuses were detected (Trisomy 21 (5) Trisomy 18 (1)). No fetus with CF was detected. The diagnosis of EB can be subjective due to technical variability. Equipment, settings and maternal habitus all affect bowel appearance. To determine reliability and interobserver variability, the 22 cases and 10 randomly selected controls were reviewed by 4 authors and graded as: normal-0, mild-1, or bright-2. All agreed on grade (Gr) in 15 cases, 3 of 4 agreed in 14, and in 3 cases the assessment was split. In only one case was the disagreement greater than 1 Gr. To further analyze the 22 cases of EB, Gr was assigned by consensus, 10 cases were Gr 2 and 10 cases Gr 1. Two cases were split between mild and bright and arbitrarily assigned Gr 2, both had normal studies. Of the 12 cases with Gr 2 EB - 5 trisomic fetuses were detected; 1 trisomic fetus was detected in the 10 with Gr 1 EB. Other abnormalities detected prenatally in the trisomic fetuses included - Trisomy 18 -VSD, absent stomach, club feet, clenched hands and renal abnormalities; Trisomy 21-nuchal thickening (NT) of 5.7 mm (1), NT 5.1 mm and short femur (1), bilateral choroid plexus cysts and NT 4 mm (1); no abnormalities detected (2). In 3 trisomic fetuses, pathologic examination of the bowel revealed no gross or microscopic abnormalities. CF studies revealed no parent or fetus with the delta F508 mutation and the haplotype distribution was unremarkable. A larger series is necessary to determine whether CF testing is efficacious. Conclusion:(1) It appears that interobserver error is sufficiently small to allow detection of EB. (2) Six of 22 fetuses with EB proved to be trisomic; those with brightly EB were at greatest risk.

21 PREGNANCY LOSS AFTER FIRST TRIMESTER ULTRASONOGRAPHIC DOCUMENTATION OF EMBRYONIC/FETAL CARDIAC ACTIVITY. Jeffrey M. Barrett, M.D., Jennifer Brinson, R.N.C.[X], Watson Clinic, Lakeland, Florida.

A prospective study was performed to evaluate the characteristics of pregnancy loss before 26 weeks when there is first trimester documentation of embryonic/fetal cardiac activity. Pregnancy dating and documentation of cardiac activity was performed with real time ultrasonography. Pregnancy losses were evaluated and dated with ultrasonography and/or pathologic macroscopic evaluation of most cases. A total of 897 consecutive patients were evaluated with pregnancy outcome known in 99.8%. The overall loss rate after documentation of embryonic/fetal cardiac activity, corrected for elective first trimester termination, was 4.6%, increasing from 10.5% <7 weeks to 2.2% >/10 weeks and 1.6% >/15 weeks. Over half of the losses occurred before 10 weeks, with there being no relationship between maternal age and frequency of loss in this group. However, with gestational age >/10 weeks, maternal age was a factor in the frequency of pregnancy loss with the total loss rate 1.6% <age 35 and 5.4% >/age 35. The age related increase in pregnancy loss continued to be present when corrected for pregnancies terminated due to chromosomal or severe structural abnormalities. These findings have important implications regarding the safety of invasive fetal testing and the evaluation of exogenous factors which may cause fetal loss.

22 EVALUATION OF FETAL BLOOD CONTENT IN TRANSABDOMINAL AND TRANSCERVICAL CHORIONIC VILLUS SAMPLES. K. Blakemore, I. Baser[X], N. Callan, R.S. Shirey[X], T. Kickler[X], M. Blitzer[X]. The Johns Hopkins Univ. Sch. of Med. and Univ. of Maryland, Balto., MD.

The risk of fetal blood loss with first trimester chorionic villus sampling (CVS) has attained renewed importance. Fetal limb reduction abnormalities that appear consistent with a vascular disruptive etiology have raised questions as to whether or not CVS is potentially teratogenic, or whether the technique employed, transcervical (TC) or transabdominal (TA), matters. To determine how often fetal blood is actually retrieved with CVS, we examined 70 first trimester CVS aspirates, i.e. the blood surrounding the villus tissue, by acid-elution staining for fetal hemoglobin (HbF). Forty aspirates were obtained by TC catheter aspiration, and 30 by TA aspiration using a 20 gauge spinal needle. In 23 cases, pre- and post-procedure maternal serum alpha fetoprotein (MSAFP) levels were obtained (16 TC and 7 TA). The percentage of HbF positive cells was ≥10% in 45/70 aspirates (64%), ≥30% in 25/70 aspirates (36%), and ≥80% in 8 cases (11%). All 8 aspirates ≥80% HbF were obtained transabdominally. Chi square analysis of TA vs TC aspirates revealed TA aspirates to have a consistently higher %HbF ($p<.02$,.005, and .001 respectively). Mean %HbF, TA=43% vs TC=16%; was also statistically different ($p<.001$). The mean sample size (mg of villi) differed between the two groups (TA=16 mg vs TC=29 mg; $p<.001$) with TC aspirates appearing more bloody on a scale of 0-4. The TA group had a greater proportion of patients whose MSAFP values increased by >50%, but this did not reach statistical significance with these small patient numbers. These data suggest that TA CVS may be associated with greater fetal blood spillage; however, the acid elution technique cannot directly quantify fetal blood amount, as it varies with the amount of maternal blood present. Our data do provide direct evidence that the integrity of the placenta's fetal vasculature is disrupted to at least some degree in the majority of CVS procedures, both TA and TC. A larger study including AFP measurement on CVS aspirates is underway.

23 DIAGNOSIS AND TREATMENT OF TWIN TO TWIN TRANSFUSION SYNDROME (TTTS). C. Weiner and A. Ludomirsky, Univ Ia Hosp and Penn Hosp, Iowa City, Ia 52242

Authors investigating the "stuck" twin have applied such therapies as laser ablation, therapeutic amniocenteses, and digoxin. In each, TTTs was assumed but not objectively documented We report 20 pregnancies with acute hydramnios and a "stuck" twin at 23.8±2w (range 21-27w) where TTTs was ***documented antenatally***. This represents < ½ of all "stuck" twins evaluated Cordocenteses demonstrated anemia in each "stuck" twin and polycythemia in each larger twin. In 6, adult RBCs were infused to the donor and later identified in the recipient. 15/20 presented <25 w. All patients had serial, therapeutic amniocenteses (>1000 ml per episode), one a pregnancy termination, three a selective fetocide (donor twin), and 3 partial exchange transfusions (PET) for either anemia or polycythemia. Despite aggressive therapy, the delivery GA was 28.6 ±4w and only 17/40 (43%) fetuses survived (<25w at presentation, 10/30; ≥25w 7/10). ***Anemia/polycythemia persisted when therapeutic amniocentesis was the sole treatment.***

	Hct	TotPro	Alb	Hydrops	Survived
Recipients	49±5	5.5±1	3.0±.3	6/20	7/20
Donors	27±5	2.7±.6	1.3±.2	0/20	10/20

Hyperviscosity resulted from both polycythemia and hyperproteinemia. All recipients had Tot Pro and Alb above the 97.5 centile. Hydrops was observed only <25w. Hydropic fetuses treated by PET had a high preload (elevated umbilical venous pressure, UVP) which was acutely lowered. In the two instances where 0.9NS was used for the PET, the UVP declined but the hydrops worsened. Plasmanate maintained the COP in one fetus and the hydrops resolved. **CONCLUSIONS:** ***1) a minority of "stuck" twins result from TTTs; 2) the earlier in GA TTTs manifests, the worse the prognosis; 3) serial therapeutic amniocentesis prolongs gestation, but there is no evidence it alters the dynamics of TTTs; 4) hyperviscosity results from polycythemia and hyperproteinemia; 6) PET may reverse hydrops if the COP is unaltered.***

24 LYMPHOCYTE SUBSETS IN PRENATALLY OBTAINED FETAL BLOOD. SM Berry, J Kaplan[X], NL Fine[X], JA Bichalski[X], MP Dombrowski, NB Isada, MI Evans, DB Cotton. Departments of Ob/Gyn & Pediatrics Wayne State University/Hutzel Hospital & Children's Hospital of Michigan, Detroit, MI.

The diagnosis of fetal viral or protozoal infection is complicated by the inability of the fetus to produce IgM antibody until the late second trimester, and the difficulty of culturing the organisms. "Nonspecific" markers of infection such as thrombocytopenia, eosinophilia, anemia, and elevations in liver function tests have been used to diagnose fetal infection in the absence of traditional serologic markers. Because infection is known to induce changes in lymphocyte subsets, we began using flow cytometry on fetal blood to establish baseline values for the proportions of peripheral blood lymphocytes expressing a variety of cell surface markers. The specimens were obtained by cordocentesis at different gestational ages (GA) for a variety of indications. Two-color flow cytometric analysis was performed on cells from 42 cordocentesis specimens, (GA=19-39), 16 umbilical cord specimens obtained at delivery, and 30 normal adult controls. None of the specimens showed specific or nonspecific evidence of infection. The cell surface markers examined included CD3, CD4, CD5, CD20, CD38, CD56, and CD57. No significant differences between the three groups were found for CD4, CD8, or CD20. Compared to adult lymphocytes, fetal and umbilical cord lymphocytes showed slight reductions in %CD5 ($p < 0.05$), marked reductions in %CD57 ($p < 0.05$), and consistent increases in %CD5+CD20+ ($p < 0.05$). The most striking differences observed were marked increases in CD38+ ($p < 0.05$) cells in fetal and cord blood. This was primarily due to increases in the proportion of CD3+CD38+ cells which probably represent proliferating T cells. Umbilical cord lymphocytes had higher proportions of CD3-CD38+ cells than either fetal or adult specimens which may, therefore, reflect a change induced by the "stress of delivery". These results should form the basis for future assessment of the value of lymphocyte marker analysis for detection of fetal infection.

25 PRODUCTION OF ENDOTHELIN-1 BY HUMAN TROPHOBLASTS P Samuels, J D Steinfeld[X], M Rhoa[X], S Murray[X], J Amico[X], D B Cines[X], K R McCrae[X]. Depts of Obstetrics & Gynecology, Medicine and Laboratory Medicine, University of Pennsylvania, Philadelphia, PA and University of Pittsburgh, Pittsburgh, PA

Endothelin-1 (ET-1) is a 21 amino acid peptide with potent vasoactive properties produced by endothelial cells, macrophages, and other cell types. Increased plasma concentrations of ET-1 have been detected in some gravidas with preeclampsia and intrauterine growth retardation. However, the plasma concentrations of ET-1 are only modestly elevated in these conditions, and it is likely that ET-1 acts as an autocrine or paracrine mediator of vasospasm. Moreover, increased vascular resistance may begin within the placenta. Since trophoblasts are the most prevalent cell type in the placenta, we investigated whether they produce ET-1. Trophoblasts were digested from normal term placentae using trypsin and DNAse, isolated using a Percoll gradient, and allowed to adhere to fibronectin-coated plastic wells. Cytotrophoblasts comprise >95% of the cell population isolated. Trophoblasts were cultured in Dulbeco's Modified Eagle Medium using 2% Ultroser as a serum substitute, and the concentration of ET-1 in conditioned media was measured using a radioimmunoassay. We measured the production of ET-1 24 (n=27), 48 (n=16), and 72 (n=8) hours after isolation. During the first 24 hours, trophoblasts produced 28 ± 11.5 fmol of ET-1 per 10^6 cells. Trophoblasts continued to synthesize ET-1 over the next two days (20.3 ±10.2 fmol/10^6 cells and 22.8 ± 15.8 fmol/10^6 cells produced between days 1-2 and days 2-3, respectively). Synthesis was confirmed by Northern blot analysis of trophoblast mRNA using endothelin-specific cDNA. Human umbilical vein endothelial cells, used as a positive control, produced 102.5 ± 30.8 fmol/10^6 cells during the first 24 hours in culture. **Conclusion:** Cultured term trophoblasts synthesize endothelin-1. The amount of ET-1 produced by these cells is approximately 25% of that produced by endothelial cells. Since the number of trophoblasts exceeds that of any other cell type in the placenta, production of ET-1 by trophoblasts may contribute to the regulation of vascular tone and participate in the pathogenesis of preeclampsia and related disorders.

26 THE EFFECTS OF LOW-DOSE ASPIRIN ON PROSTACYCLIN AND THROMBOXANE PRODUCTION BY THE PERFUSED HUMAN PLACENTA: Robert L. Jacobson, M.D.[X], Anthony Brewer, B.S.[X], Tariq A. Siddiqi, M.D. and Leslie Myatt, Ph.D.[X], University of Cincinnati Medical Center, Cincinnati, OH USA.

There is evidence for altered fetal-placental blood flow in idiopathic intrauterine growth retardation (IUGR) which is manifested by an abnormal umbilical systolic/diastolic (S/D) blood flow velocity ratio. Both preeclampsia and IUGR are asscociated with reduced prostacyclin (PGI_2) production by both maternal and fetal tissues resulting in a relative dominance of thromboxane A_2 (TXA_2) over PGI_2. Low-dose aspirin, acetyl salicylic acid (ASA) selectively inhibits TXA_2 synthesis and may alter feto-placental blood flow. The purpose of this study was to determine the effect of infusion of low-dose ASA into the maternal circulation of the dually perfused isolated human placental cotyledon on fetal and maternal PGI_2 and TXA_2 production. Human placental cotyledons were perfused with tissue culture medium 199 plus 5% polyvinyl-pyrrolidone gassed with 95% O_2, 5% CO_2 at flow rates of 10 ml/min (maternal) and 4 ml/min (fetal). ASA (10^{-5} mol/L) was added to the maternal circuit and cotyledons were perfused for one hour with aliquots taken from the closed fetal circuit every five minutes. Thromboxane B_2 (TXB_2) and 6-keto prostaglandin $F_{1\alpha}$ (metabolites of TXA_2 and PGI_2 respectively) were assayed by radioimmunoassay. Our data indicate a significant fall in maternal production of 6-keto-$PGF_{1\alpha}$ and maternal TXB_2 which then increased to pre-ASA infusion levels. There was a decrease in fetal 6-keto-$PGF_{1\alpha}$ which returned to pre-ASA infusion levels. Fetal TXB_2 production, however, significantly decreased and remained inhibited during the one-hour perfusion period. Maternal and fetal 6-keto-$PGF_{1\alpha}$/TXB_2 ratios remained unchanged. As TXA_2 has a vasoconstrictive effect on arteriolar smooth muscle, the significant and sustained inhibition of its production in the fetal-placental circulation may be responsible in vivo for the lowering of placental vascular resistance as manifested in vivo by the improved S/D ratio seen on Doppler velocimetry and the improved fetal weight, head circumference and placental weight noted by other authors.

27 A SIGNIFICANT REDUCTION IN CESAREAN DELIVERIES: EFFECT ON PERINATAL OUTCOME

Luis Sanchez-Ramos, M.D., Mark T. Cullen, M.D., Carol Walker, R.N.[X] Division of Maternal-Fetal Medicine, University of Florida, Jacksonville, FL.

In the United States the rate of cesarean sections has quintupled from 5% of obstetric deliveries in 1964 to approximately 25% in 1988.The increase in cesarean deliveries occurred against a background of better survival rates and lower morbidity rates for babies. Some have assumed that these changes were linked. From 1986 to 1990 we have reduced the cesarean section rate from 27% to 8%. A key question is whether this has been accomplished safely, both for the mother and for her infant. In search for this answer we evaluated perinatal outcome in 25,356 deliveries occurring during this five year period. Perinatal outcome was evaluated by analysis of Apgar scores, cord gases, NICU admissions. perinatal mortality, meconium aspiration, seizures, NICU length of stay, birth asphyxia, and birth trauma. In evaluating neonatal outcome the distribution of birthweights and gestational ages, and the degree of prenatal care were addressed. No differences in perinatal outcome was noted, and in many instances improvement occurred. Our experience suggests that cesarean section rates can be substantially reduced without compromising the newborn.

28 VAGINAL DELIVERY OF THE NON-VERTEX SECOND TWIN

Alan Fishman[X] MD, Debra Grubb[X] MD, Bruce Kovacs[X] MD
University of Southern California, Los Angeles, California

In order to test the hypothesis, that there is no difference in morbidity or mortality between vertex (vtx) and non-vertex (non/vtx) vaginal delivery of second twins, we reviewed 781 consecutive twin deliveries achieving greater than 20 weeks of gestation occurring at our hospital between January 1, 1985 and December 31,1988. Outcome measures evaluated include: 5 minute Apgars, length of hospital stay, NICU admissions, and neonatal deaths. The medical records were retrospectively reviewed for all live born, vaginally delivered second twins with respect to presentation (vtx-non/vtx) and the above mentioned outcome variables. Statistical analysis was performed using χ^2 and Mann-Whitney U tests. During the period of time encompassed by this study there were 407 vaginally born second twins, 17 of which were stillborn (42/1000). Of the remaining 390, 207 (53.1%) were delivered as vtx, and 183 (46.9%) were non/vtx vaginal deliveries. The vast majority (>95%) of these non/vtx vaginal deliveries were total breech extractions. Results for live born second twins were:

	VTX N=207	NON/VTX N=183
5 minute Apgars<7	11 (5.4%)	13 (7.1%)
NICU admissions	38 (184/1000)	37 (202/1000)
Neonatal deaths	14 (68/1000)	9 (49/1000)
Hospital days-median	3	3
Hospital days-mode	2	2

There were no statistically significant differences for any of the neonatal outcome variables, even when stratified by birthweight. These results support the null hypothesis to a confidence limit of 95%, and substantiate non/vtx vaginal delivery of the second twin as a safe intrapartum management option.

29 PRENATAL CARE: DIFFERENTIAL EFFECTS ON MATERNAL AND NEONATAL OUTCOMES.

J.W. Sparks[x], J. McGregor, M.G. Leff[x], D.C. Lezotte[x], M. Orleans[x].
Departments of Ob/Gyn, Pediatrics, Preventive Medicine, UCHSC, Denver, CO.

Prenatal care is of great medical and public concern. Despite this, basic attributes of prenatal care remain poorly understood. We evaluated effects of quantified amounts of prenatal care on maternal and neonatal outcomes. All liveborn, singleton births at University Hospital from 7/81 - 6/85 (n=10,359) were studied. Preliminary analyses showed that an increasing number of prenatal visits showed linear increases in mean birthweight, gestational age, and appropriateness of gestational age. Further analyses were performed taking into account pregnancy duration and amount of prenatal care. The percent of prenatal visits (% PNV) was calculated using the actual number of prenatal visits divided by the number of visits recommended by the Institute of Medicine, adjusted for pregnancy duration. Logistic regression and chi-square analyses of relative risks (RR) for adverse outcomes by % PNV were performed. Increasing % PNV had no effect on maternal outcomes. Survival analyses showed that increasing % PNV correlated with increased birthweight, gestational age, and decreased nursery stay (each $p<0.001$, log rank). The 0% PNV (i.e. no care) neonates had significantly ($\alpha = 0.02$) increased risks of prematurity (RR = 4.0), birthweight <1500 g (RR = 5.6), NICU admission (RR = 2.2) and ventilator use (RR = 3.8). Relative risks decreased in a step-wise fashion as % PNV approached $\geq$ 100%. Direct costs of neonatal care were markedly increased with reduced antenatal care. Prenatal care was strongly associated with improved neonatal outcomes and decreased costs in a graded, step-wise fashion.

30 INTRAUTERINE GROWTH RETARDATION: A COMPARISON OF THE 3RD VERSUS 10TH PERCENTILE.

SL Baker[X], JC Hauth, RL Goldenberg, SP Cliver[X], RL Copper[X].
University of Alabama Hospitals, Birmingham.

Fetal growth retardation, defined as a birthweight at or below the 10th percentile for gestational age, is associated with increased perinatal morbidity and mortality. However, it is unclear whether the most severely affected infants ($\leq$ 3rd percentile) are more frequently associated with identifiable maternal medical or obstetric conditions or have a worse neonatal outcome than those at the 4th-10th percentile. Using the multicenter March of Dimes data base, a growth curve was constructed from 31,890 liveborn, singleton pregnancies after excluding chromosomal or major structural anomalies. Gestational age was based on a composite of the best available criteria for each patient (clinical, ultrasound, Dubowitz). We compared demographic variables, maternal medical or obstetric complications, and neonatal outcome among infants at $\leq$ 3rd percentile (n=963) or the 4th-10th percentiles (n=2268) and compared these groups to infants at the 25th-75th percentile (n=16,012). For each group, the mean gestational age was 39 weeks and the percent of infants $\leq$ 34 weeks was similar. When compared to those at the 4th-10th or 25th-75th percentiles infants at $\leq$ 3rd percentile were more frequently associated with maternal nulliparity, preeclampsia, and smoking, but not with maternal diabetes, hemoglobinopathies, or placenta previa. These infants also had significantly more low Apgar scores ($\leq$ 7 at 1 and 5 minutes), fetal distress in labor, intraventricular hemorrhage, hyperbilirubinemia, hypoglycemia, a higher cesarean section rate, and increased mortality ($p \leq .05$). Infants at the 4th-10th percentile were similar to those at the 25th-75th percentile in neonatal morbidity, but had a significantly higher mortality rate and a stronger association with certain maternal risk factors such as smoking, preeclampsia, and placental abruption. In summary, newborns at the $\leq$ 3rd percentile were more frequently associated with a maternal medical or obstetric complications, and had an increased morbidity and mortality when compared to those at the 4th-10th or the 25th-75th percentile. Interventional studies designed to reduce the adverse effects of low birthweight should focus on this subset of patients.

31 **EVALUATION OF DIFFERENT MODES OF DELIVERY IN TWIN PREGNANCIES WITH DIFFERENT PRESENTATIONS.**
Phillip Greig,* Jean-Claude Veille,* Linda Henderson,* Department of Ob/Gyn, Bowman Gray School of Medicine, Winston-Salem, North Carolina.

Four hundred and fifty-two twin deliveries occurred at Forsyth Memorial Hospital between January of 1985 and December of 1990. Thirty-two sets were excluded from analysis because of elective repeat cesarean section, extreme prematurity and prenatal fetal demise. We evaluated twins from 25 weeks to term. All deliveries had Apgar scores recorded and 214 sets had umbilical cord gases available for evaluation. The overall cesarean section rate was 45.2%. There were 225 sets of vertex/vertex twins, 68% delivered vaginally. There were 99 sets of vertex/breech presentations, 44% delivered vaginally. We analyzed the individual and joint effects of gestational age and mode of delivery in the different twin presentations using analysis of covariance. There were no statistically significant differences in fetal outcome when Apgar scores and umbilical cord gases were compared in the different age groups between those delivered vaginally and those by cesarean section for any given twin presentation. There were 16 sets of twins with a vertex presentation/transverse lie. In 6, vaginal delivery was attempted. Three required emergent cesarean section for twin B because of cord prolapse or persistent malpresentation. None of these fetuses showed lower Apgar scores or significantly different umbilical cord gases when compared to the first twin or twins undergoing elective cesarean delivery at the same gestational age and position.

Conclusion: Our data does not support routine abdominal delivery in vertex/non-vertex twin pregnancies for any gestational age.

32 **THE EFFECT OF OPERATIVE VAGINAL DELIVERY ON COGNITIVE DEVELOPMENT**
B. Wesley, B. Van den Berg, E. A. Reece, Temple Sch. of Medicine, Phila., Pa. and Sch. of Public Health, Univ. of Calif. at Berkeley

Forceps deliveries have been implicated in the causation of birth trauma resulting in long term adverse outcomes. Although many of these studies were relatively small containing many confounding variables including lack of control for socioeconomic status (SES) or non-ideal comparison groups, e.g Cesarean sections, such data have led to a decline in forceps use. Despite the resultant change in obstetrical practice, there is no decrease in the prevalence of neurologic sequelae in school age children. The present project was a collaborative and retrospective study between the University of California at Berkeley (Kaiser Foundation Health Plan, San Francisco) and Temple University School of Medicine in Philadelphia. From a database of 20,000 working women who received obstetrical care, 3,590 children were randomly selected for evaluation at age 5 by the Peabody Picture Vocabulary Test and the Raven Standard Progressive Matrices. Children were stratified according to mode of delivery and the data of each subset were further divided into lengths of hours in active labor. The data were controlled for SES status. Children weighing less than 2500 grams or less than 37 weeks gestation, or those with congenital anomalies were excluded. Of the 3590 children, 93% were tested: 1746 delivered vaginally, 1351 delivered by forceps (low and mid) and the remainder (breech and C-section delivery) were excluded from analysis. Standardized IQ scores of children taking these tests were 50 ± 10 (mean ± standard deviation). There was no significant difference in IQ scores between children delivered spontaneously or by forceps. CONCLUSION: These data demonstrate in a relatively large study of school age children, that the method of delivery is not associated with significant alteration of intelligence quotient. In this light, the general association of forceps delivery with adverse neonatal outcomes cannot be supported.

Mean Test Scores: Peabody and Raven
(Maternal Education ≥ High School)

	Spontaneous		Low-Mid Forceps		Mid Forceps	
	N	X̄	N	X̄	N	X̄
PARITY 0	132	52.18	24	52.21	59	51.87
PARITY 1+	807	51.05	17	52.27	29	51.09

33 PERINATAL TRANSMISSION OF HEPATITIS C VIRUS
E.Leikin, J.Reinus, H. Alter, S.Piazza, J.Shih, B Jett
Depts. Ob/Gyn and Peds, NY Med Coll, Valhalla, NY
Div. GI, Albert Einstein Coll of Med, Bronx, NY
Dept. Transfusion Med, NIH, Bethesda, Md

Hepatitis C virus (HCV) infection is asymptomatic in over 75% of cases, particularly in infants and young children. In about 40% of affected individuals the source of HCV infection is unknown; vertical transmission may be responsible for some of these cases. From 7/1/89 to 7/31/91 we prospectively studied vertical transmission of HCV, using an immunoassay (Ortho Diagnostics, Raritan, NJ) to test 743 mothers and their babies for anti-HCV antibody. Serum from anti-HCV+ mothers and cord blood from their babies also was tested for HCV nucleic acid sequences by nested polymerase chain reaction (PCR). Anti-HCV antibody was detected in serum from 30 mothers (4%) and cord blood of all but 1 of their 31 babies. 11 of 18 mothers tested to date and none of their babies were PCR+. 21 of 22 infants evaluated after discharge from the hospital became anti-HCV- by 33 wks; the remaining child was anti-HCV+ when lost to followup at 11 wks. None of the babies with long-term followup (mean 49 wks) has had reappearance of anti-HCV antibody, and PCR remains negative. Although anti-HCV antibody appears to be transferred passively, vertical transmission of HCV is uncommon if it occurs.

34 **SECOND TRIMESTER OBSTETRICAL ULTRASOUND IN THE PRENATAL DETECTION OF CONGENITAL HEART DISEASE.**
Janet N. Scheel,* Nancy A. Callan, Gail D. Pearson,* Jean S. Kan,* Catherine A. Neill.*
The Divisions of Maternal Fetal Medicine and Pediatric Cardiology. The Johns Hopkins Medical School, Baltimore, MD.

To determine the effectiveness of second trimester obstetrical ultrasound (STUS) in the prenatal diagnosis of congenital cardiac malformations (CCM), we reviewed referrals for fetal echocardiography (FE) after STUS using maternally reported data from a population based study of all infants with CCM born in our geographic area (The Baltimore-Washington Infant Study). During 1987-89, 1063 infants were born with CCM. Of these 602 (56.7%) had STUS. A total of 69 of 1063 (6.5%) had FE, 47 after STUS and 22 without STUS. Of those with CCM, 52.2% (555 of 1,063) had STUS but not FE. The sensitivity of STUS in detecting critical CCM (CCM readily detectable by 4-chamber view) was 12.7%. The number of pregnancies with STUS and FE by critical lesion are shown:

Critical CCM	n	STUS (%)	FE (% STUS)
Endocardial Cushion	87	35 (40.2)	4 (11.4)
Hypoplastic Left Heart	30	17 (56.7)	2 (11.8)
Ebstein's Anomaly	14	8 (57.1)	2 (25.0)
Single Ventricle	10	5 (50.0)	0 (0.0)
Tricuspid Atresia	9	6 (66.7)	1 (16.7)

This suggests, that STUS as practiced during the study period when visualization of the four chamber view was recommended, detected only a small percentage of those with critical CCM. STUS with four chamber view has not been optimally practiced as a screening tool for CCM. Further education of those performing STUS is required to improve prenatal cardiac diagnosis.

Oral Session V

Infectious Disease; Maternal/Fetal Physiology

Saturday, February 8, 1992
8:00-10:30 a.m.

Society of Perinatal Obstetricians

Grand Salons V-VIII

35 IS BACTERIAL ENDOTOXIN A CAUSE OF MECONIUM PASSAGE IN UTERO?
R. Romero, M. Mazor, W. Sepulveda,[x] F. Brandt,[x] R. Gonzalez,[x] M. Ramirez,[x] E. Behnke,[x] Depts. of Ob/Gyn, Yale Univ. Sch. of Med., New Haven, CT; Wayne State Univ., Detroit, MI; Soroka Med. Center, Ben Gurion Univ., Israel; Sotero del Rio Hosp., Santiago, Chile

The causes of meconium passage during labor are largely unknown. Although hypoxia and acidosis are frequently considered as causes of meconium-stained amniotic fluid (MS-AF), fetal pH and blood gases are within normal range in most cases. Intraamniotic infection has been recently implicated as a cause of MS-AF in preterm labor (AJOG 1991;164:859). No information is available regarding the relationship between the presence of microorganisms and/or their products in AF and meconium passage during term labor. Bacterial endotoxin, a component of the cell wall of Gram-negative bacteria, is a potent bioactive agent that can stimulate gastrointestinal peristalsis and lead to meconium passage in utero. Materials and Methods: A case-control study was designed to compare the detection rate of bacterial endotoxin in clear (n = 88) and MS-AF (n = 88). Endotoxin was assayed with the gel clot limulus amebocyte lysate assay (LAL) using a method previously described (sensitivity = 100 pg/ml) (AJOG 1987;157:815). Results: 1) The rate of positive LAL was greater in MS-AF than in clear AF (44.3% [39/88] vs. 4.5% [4/88]; p <0.001). 2) After heat treatment at 100°C for 4 minutes (a method to inactivate non-endotoxin-cross-reacting substances), 43.5% (17/39) of MS-AF had a repeat positive LAL assay, while only one of four clear AF remained positive. 3) Endotoxin was present more commonly in MS-AF than in clear AF (19.3% [17/88] vs. 3.4% [3/88]; p <0.001). 4) Microorganisms were identified by Gram stain in 12.7% (11/86) of MS-AF and in only 3.5% (3/84) of clear AF (p <0.05). Conclusions: 1) Bacterial endotoxin is frequently present in patients with MS-AF. 2) MS-AF contains a heat-labile substance that cross-reacts with endotoxin in the LAL assay. 3) Intraamniotic infection may be an important and previously unrecognized cause of MS-AF. These findings are novel and have important clinical implications for intrapartum and neonatal management.

36 PLACENTA NATURAL KILLER CELL CYTOTOXICITY (NKC) IN HUMAN IMMUNODEFICIENCY VIRUS (HIV) INFECTED PARTURIENTS.
B. Gonik, L. Loc,[x] J. Reuben,[x] T. Cowles, A. Helfgott, A. Harris,[x] M. Doyle,[x] Depts. Ob/Gyn/Repro Sci, Peds., and Immunol. Univ. of Texas Med School and MD Anderson Cancer Ctr., Houston, TX

HIV disease is characterized by host immune dysfunction and opportunistic infection. Infants born of HIV-infected mothers are at-risk for transplacental acquisition of HIV infection, along with the passage of other potential pathogens into the fetal compartment. To better assess the functional capabilities of the placenta as an immune barrier, we examined placental NKC in 7 HIV-infected and 7 control parturients. Following removal of the maternal decidua, cotyledon-derived tissues were minced and the cells dispersed with Dispase. A Ficoll-paque gradient was used to isolate placental mononuclear cells. In a subset of experiments using a DNA hybridization probe for the Y chromosome, the separated cells were determined to be >75% fetal in origin. NKC was measured using a 4 hour chromium-release assay with labelled K562 target cells at an effector to target cell ratio of 100:1. Clinically, the majority of the HIV-infected subjects were classified as group II by CDC criteria, delivered at or near term (37.6 ± 2.8 weeks), and had infants who weighed significantly less (p<0.04) than the control group (2795 ± 346 gms vs 3302 ± 442 gms). At delivery, all infants were clinically well. Thus far, one infant has died of AIDS, one is culture positive, and the remainder are clinically well. NKC was profoundly depressed in all HIV-associated placentas compared to controls (0.2 ± 0.4% vs 19.3 ± 9.6%, p<0.001). Both adherent and nonadherent cell populations contributed to the measurable NKC-like activity. These are the first data examining the immune capabilities of the placenta in relation to HIV disease. These results demonstrate severely attenuated placental NKC and suggest a loss of placental immune response in otherwise asymptomatic HIV-infected parturients.

37 AMNIOTIC FLUID INFECTION (AFI) AND PRETERM LABOR IN RHESUS MACAQUES.
MG Gravett, GJ Haluska[x], JL Edwards[x], MJ Cook[x], S Baggia[x], SS Witkin[x], MJ Novy. Depts Ob/Gyn OHSU and Cornell, and Oregon Reg Primate Res Ctr, Portland, OR.

To study the relationship between AFI, cytokines, prostaglandins (PG), and preterm labor, experimental AFI was established by intra-amniotic inoculation of 10^6 cfu Group B streptococci in 4 chronically instrumented Rhesus monkeys at 130 days gestation (term is 167 days). Amniotic fluid (AF) was sampled sequentially for bacteria, TNF-α (bioassay), IL-1B (ELISA), and PG (specific RIA). Uterine contractility was recorded as the hourly area under the contraction curve and expressed as HCA in mmHg·sec/hr. Increases in the HCA occurred at 28 hrs (14-36) after inoculation in all 4 monkeys and led to progressive cervical dilatation in 3 of 4. These contractions were of high-amplitude, low-frequency, and long-duration. AF TNF rose from 48 pg/ml before inoc. to 20,000 pg/ml 9 hrs (6-14) after inoc. and 20 hrs (8-34) before increases in the HCA. Parallel increases in IL-1B (from 10 pg/ml to 1,142 pg/ml), PGE_2, and $PGF_{2\alpha}$ occurred 18 hrs (12-24) after inoc. and 10 hrs (2-18) prior to increases in the HCA. In contrast, spontaneous term labor in 4 control monkeys was not associated with increases in AF TNF or IL-1B and contractions were of high-amplitude, high-frequency, and short-duration. We conclude: 1) AFI with GBS leads to a predictable increase in uterine contractility which is different than spontaneous labor; and 2) in AFI, increases in AF cytokines and PG occur prior to increases in uterine contractility.

38 DOES THE RISK OF PERINATAL TRANSMISSION OF HIV-1 INCREASE WITH SUBSEQUENT PREGNANCIES? RR Viscarello, NJ DeGennaro*, YG Gollin*, WA Andiman*, JC Hobbins, Yale University School of Medicine, New Haven, CT.

Early reports of the rate of vertical transmission of HIV-1 in mothers who had delivered an index child with AIDS or ARC were as high as 65 to 80%. Recent, prospective studies have estimated the rate to be 7 to 33%. No study to date has examined the transmission rate in successive pregnancies. We studied 62 infants born to 27 HIV-positive women to determine if the risk of perinatal transmission of HIV-1 increases with subsequent pregnancies. There were 23 Blacks, three Hispanics, and one Caucasian. Eighteen of the women were current or previous IVDAs and 9 were infected heterosexually. Nineteen women had two pregnancies while infected and 8 had three. There are 14 infants currently CDC Stage P0 who were excluded from the analysis. The remaining 48 infants were classified according to CDC criteria into three groups: Seroreverted, P1, and P2, and stratified according to birth order. No statistically significant difference was found between infant disease status and birth order using Chi-square analysis. Mean gestational age at time of delivery and mean birth weight were inversely-related to birth order as follows: Pregnancy # 1: 37.3 wks ± 3 and 2814g ± 532; Pregnancy # 2: 36.6 wks ± 3 and 2768g ± 427; Pregnancy # 3: 35.3 wks ± 2 and 2226g ± 795. Maternal factors, including low CD4 cell count, positive HIV p24 antigen status, and maternal CDC Group IV disease (AIDS), were positively correlated with the presence of disease in the infant, but not with birth order. Our data does not support an increased risk of vertical transmission of HIV-1 with successive pregnancies. Markers of maternal viremia or immunodeficiency may be more accurate predictors of transmission of HIV-1. (This research was partially supported by a grant from the American Foundation for AIDS Research and the Pediatric AIDS Foundation AmFAR/PAF #S0034-7).

39 HYPOXIC ACIDEMIA DECREASES LEFT VENTRICULAR END-SYSTOLIC ELASTANCE IN FETAL SHEEP. R.M. Lewinsky[X], R.S. Szwarc[X], L.N. Benson[X], J.W.K. Ritchie. University of Toronto, Toronto, Ontario, Canada

End-systolic elastance, the slope of the end-systolic pressure volume relationship, is a relatively load and heart rate insensitive measure of the intrinsic contractile properties of the myocardium. Using the conductance catheter technique, we measured the effects of hypoxic acidemia on left ventricular (LV) end-systolic elastance in anaesthetized, 133 day gestation, *in utero* fetal sheep (n=7). Conductance and Millar catheters were introduced into the LV through a carotid artery cutdown. Fetuses were rendered progressively hypoxic and acidemic by embolization of the fetal placenta with repeated injections of $5{\cdot}10^5$ 50μM plastic spheres. We recorded pressure-volume data and arterial pH at 15 minute intervals. End systolic elastance was computed using a single beat method of extrapolating maximum isovolumic pressure. A gradual drop in fetal pH from 7.32 ± 0.06 (mean ± SD) to 6.95 ± 0.04 caused a significant decrease in LV elastance. A linear relationship was found to exist between elastance and pH, correlation coefficients ranging from 0.85 to 0.98, with a mean decrease of 4.42 mmHg/ml per 0.1 unit drop in pH. This decrease in elastance was gradual and extended over the entire clinically important range of pH, rather than being a terminal event. This study which, to our knowledge, is the first to use the conductance catheter to measure fetal LV function, shows that hypoxia acidemia adversely affects myocardial contractility, and suggests that indices of myocardial function should be explored as a means of improving upon the diagnostic accuracy provided by current monitoring methods.

40 DO ABNORMAL STARLING'S FORCES CAUSE FETAL HYDROPS IN RED CELL ALLOIMMUNIZATION?

Kenneth J. Moise, Jr., M.D., Robert J. Carpenter, Jr., M.D., Diane Hesketh, R.N.[X]; Department of Obstetrics and Gynecology; Division of Maternal-Fetal Medicine, Baylor College of Medicine; Houston, Texas.

The etiology of fetal hydrops in anemic fetuses secondary to maternal red cell alloimmunization remains undefined. To investigate this problem, we studied 30 fetuses undergoing 56 intravascular transfusions (IVT). At 41 procedures, no ultrasound evidence of hydrops was noted (gestational age: mean +/- SD: 28.5 +/- 3.8 wks), while hydrops was present at 15 IVT's (25.9 +/- 4.1 wks). **Methods:** At IVT, umbilical venous (UVP) and amniotic fluid pressures (AP) were measured using a neonatal blood pressure monitor. Corrected UVP was determined by subtracting the AP from the absolute UVP. An aliquot of fetal blood was obtained and serum colloid osmotic pressure (COP) determined. Unpaired t tests were used for comparison; $p < 0.05$ was considered significant. **Results:** Hydropic fetuses had lower hematocrits than non-hydropic fetuses (17.7 +/- 7.3% vs 29.4 +/- 6.8%; $p < 0.001$). The COP-UVP gradient was lower in hydropic fetuses (0.9 +/- 4.1 vs 3.5 +/- 3.8 mm HG; $p = 0.03$). When the components were analyzed separately, UVP was not different between the two groups (8.0 +/- 3.8 vs 7.5 +/- 4.0 mm HG; p = NS); however COP was significantly lower in fetuses with hydrops (8.9 +/- 2.8 vs 11.0 +/- 2.1 mm HG; $p < 0.01$). **Conclusions:** Portal hypertension as reflected by UVP is unaltered in the anemic fetus with hydrops. Hypoproteinemia as reflected by COP may contribute to the pathophysiology of immune hydrops.

41 LONGITUDINAL CHANGES IN BASAL HEPATIC GLUCOSE PRODUCTION AND SUPPRESSION DURING INSULIN INFUSION IN NORMAL PREGNANT WOMEN

PM. Catalano, RR Wolfe[X], ED Tyzbir[X], N Roman[X], S. Amini[X], EAH Sims[X]. Dept. of OB/GYN, Univ. of VT, Coll. of Medicine, Burlington, VT, Dept. of Repro. Bio., MetroHealth Med. Ctr., Case Western Reserve Univ., Cleveland, OH, Shriners Burn Inst., Univ. of TX, Galveston, TX.

The purpose of this study was to prospectively evaluate basal hepatic glucose production and suppression during insulin infusion longitudinally in pregnancy. Six multigravid, non-obese women were studied (mean±SD) 2.2±.3 months prior to conception (P) and again at 12-14 (E) and 34-36 (L) weeks gestation. Body composition was estimated by underwater weighing with correction for residual lung volume. Basal hepatic glucose production was estimated using a prime/constant infusion of 6-6 dideuterated (D2) glucose for 3 hours. Suppression of hepatic glucose production was estimated during insulin infusion with the hyperinsulinemic-euglycemic clamp at an insulin infusion of 40 mU/m2. There was a significant ($p=.005$) 30% increase in hepatic glucose production with advancing gestation (P-127.3±23.8, E-122.9±28.2, L-166.2±20.2 mg/min). This increase in hepatic glucose production remained significant ($p=0.05$) when corrected for fat free mass (P-2.74±0.23, E-2.62±0.35, L-3.14±0.36) and despite a significant ($p=0.02$) increase in fasting insulin (P-6.3±3.2, E-5.0±2.0, L-10.4±3.8 uU/ml). However, during insulin infusion hepatic glucose production was almost completely suppressed i.e. >90% throughout gestation. In summary, basal hepatic glucose production significantly increases to meet fetal/placental carbohydrate needs by late gestation but remains sensitive to infusion of insulin throughout gestation. Supported by NIH22965-01.

42 ENDOTHELIUM-DERIVED RELAXING FACTOR MEDIATES ESTROGEN-INDUCED INCREASES IN UTERINE BLOOD FLOW.

G.A. Van Buren[X], D-S. Yang[X], T. Siddiqi, K.E. Clark[X], Department of Ob/Gyn, University of Cincinnati, College of Medicine, Cincinnati, Ohio.

Administration of estrogen results in significant increases in uterine blood flow (UBF) which may be mediated by endothelium-derived relaxing factor (EDRF). Eleven nonpregnant oophorectomized ewes were given 1 μg/kg of estradiol-17β and at the peak of the estrogen response received bolus injections of the EDRF inhibitor L-nitroarginine methyl ester (L-NAME). Estradiol-17β administration increased UBF from 19 ± 7 to 153 ± 35 ml/min. Local uterine artery administration of L-NAME (1-30 mg) led to dose-related decreases in UBF (26-63%) without any change in blood pressure (BP), heart rate (HR), or cardiac output (CO). In a second study, systemic administration of L-NAME (1 to 30 mg/kg) led to significant dose-related increases in BP (26% max), and decreases in HR (34% max), and CO (42% max). UBF in this group increased from a baseline of 4±3 ml/min to a maximum of 126±19 ml/min. Systemic administration of L-NAME decreased UBF in a dose-dependent fashion reaching a maximum at 30 mg/kg of 81±4%. Subsequent administration of the EDRF precursor, L-arginine (100 mg/kg), partially reversed the inhibition of L-NAME on BP, HR, CO and increased UBF from 25±4 to 65±16 ml/min. Conclusion: Estrogen produces uterine vasodilation which is antagonized by L-NAME, an EDRF inhibitor, and reversed by L-arginine, an EDRF precursor.

43 **TUMOR NECROSIS FACTOR ALPHA (TNF-α) IN SECOND-TRIMESTER AMNIOTIC FLUID IS ASSOCIATED WITH IMPAIRED INTRAUTERINE FETAL GROWTH.** K. Heyborne[1], J. McGregor[1], S. Witkin[2x], G. Henry[3x], Departments of Ob/Gyn, University of Colorado[1] and Cornell Medical Center[2] and Reproductive Genetics[3], Denver, CO

Inadequate intrauterine fetal growth is a common cause of low birth weight and perinatal morbidity. To investigate whether abnormal immune system activation is involved in the pathogenesis of some instances of intrauterine growth retardation, TNF-α/cachexin, a cytokine linked to impaired cell growth, was measured in amniotic fluid. Bioactive TNF-α was measured using a sensitive and specific WEHI cell assay. Amniotic fluid samples were obtained by genetic amniocentesis at 14 - 20 weeks gestation. In a case-control study, samples obtained from 25 gestations that resulted in small for gestational age infants (SGA, birth weight less than 10%) were compared with 35 samples obtained from gestations resulting in the birth of a term AGA infant. The two groups were not significantly different with regard to maternal age, race, socioeconomic status, or gestational age at amniocentesis. All infants had normal karyotypes, and gestational ages were confirmed by ultrasound at the time of amniocentesis. Groups were compared using the Wilcoxon rank sum test. Elevated amniotic fluid TNF-α was associated with SGA birth, $P = 0.014$. Using a threshold of 11 pg/ml, the assay had a sensitivity of 48% for the detection of SGA birth, with a specificity of 83%. TNF-α noted in amniotic fluid at second trimester amniocentesis is associated with impaired intrauterine growth. Abnormal immune system activation as manifest by increased TNF-α may mediate impaired fetal growth in some cases.

44 **COCAINE DIRECTLY AFFECTS SIGNAL TRANSDUCTION IN HUMAN MYOMETRIAL CELLS.** F. Hertelendy[X], M. Molnár[X], Dept. Ob/Gyn, St. Louis University Med. Ctr., St. Louis, MO

Cocaine has been reported to stimulate myometrial activity both in vivo and in vitro. The aim of this study was to test the hypothesis that cocaine directly interferes with adenylate cyclase-mediated signal transduction, thereby attenuating responses to agonists that raise intracellular cAMP, known to promote uterine relaxation. Exposure of human myometrial cells (HMC) to cocaine for up to 4 days dose-dependently inhibited (max. 70%) isoproterenol (ISO)-, $PGF_{2\alpha}$- and forskolin (FSK)-stimulated cAMP production. Similarly, in HMC permeabilized with α-toxin, cocaine (0.01-10μM) attenuated ISO-, FSK- and GTPγS-promoted cAMP synthesis. However, whereas in intact cells the inhibitory effect was correlated with the duration of cocaine exposure (1-4 days), in the permeabilized system it was immediate. Pretreatment of HMC with pertussis toxin prevented the inhibitory action of cocaine, suggesting a postreceptor site at which cocaine interferes with signal transduction. It is concluded that at least one of the mechanisms by which cocaine promotes uterine contractility is the attenuation of cAMP generation by uterine relaxants.

Poster Session I

46 **MID-GESTATIONAL HYPERINSULINEMIA AND DEVELOPMENT OF PREECLAMPSIA.** JR Sowers[x], AA Saleh T Niyogi[x], P Standley[x], SF Bottoms, GS Norman[x], MB Zemel[x], PC Zemel[x], BE Johnson[x], RJ Sokol, Department of Medicine, Ob/Gyn, Wayne State University School of Medicine, Detroit, MI and Department of Nutrition, University of Tennessee, Knoxville, TN

There is evidence that hyperinsulinemia/insulin resistance play a role in development of hypertension. Accordingly, in our ongoing longitudinal study of pregnancy-induced hypertension we have measured fasting levels of insulin and glucose at 20 to 21 weeks of gestation in 140 nulliparous black women followed prospectively to delivery and with complete data. To test the hypothesis that hyperinsulinemia may be related to development of preeclampsia discriminant analysis of mean arterial pressure (MAP), fasting plasma insulin levels and left lateral forearm vascular resistance were examined as predictors of preeclampsia with control of two factors known to be related to insulin levels, gestational age and pre-gestational body mass index. Characteristics of eleven gestational hypertensives were not different from that of normals and thus they were placed in the control group. Women who developed preeclampsia had fasting plasma insulin levels at 21 weeks of 51.2 ± 47(S.D.) and controls at 20 weeks had values of 29.2 ± 31.5 μU/ml. Only MAP ($F(4,135)=8.8$, $p<0.01$) and insulin ($F1,135)=6.5$, $p<0.05$) were related to development of preeclampsia ($F(4,135)=4.39$, $R^2=11.5\%$). The finding that mid-gestational insulin levels characterize the subsequent development of preeclampsia with control for increased MAP supports the hypothesis that hyperinsulinemia/insulin resistance may contribute to the pathogenesis of preeclampsia.

47 **EFFECT OF PROGESTERONE RECEPTOR BLOCKADE ON RENIN SYNTHESIS AND SECRETION FROM ENDOMETRIAL STROMAL CELLS: PULSE EXPERIMENT.** D. Shah, R. Riehl,[x] Dept. of OB/GYN, The University of Texas Health Science Center, San Antonio, TX.

The etiology of preeclampsia is largely unknown, but a decrease of uteroplacental blood flow is an important aspect of pathophysiology. Uterine renin may have a role in regulation of uterine blood flow. We have recently shown, by RIA for angiotensin I, that the endometrial stromal cell is the specific cell responsible for uterine renin secretion. Furthermore, progesterone increases this renin secretion. We examined new renin synthesis and secretion by pulse experiment to study the effect of progesterone receptor blockade. Endometrial specimens were obtained from benign uteri removed at hysterectomy for clinical indications. Isolation and culture of a highly purified population of stromal cells were established by a previously described method. After initial 2-day incubation in serum-containing media, the cells were maintained in culture up to 9 days in serum-free DME/F-12 nutrient mixture with ITS supplement. Four experimental groups [1. No steroid control (C), 2. Progesterone alone (P), 3. RU-486 alone (R), and 4. progesterone + RU 486 (PR)] were established from day 3 onwards. Culture media were changed at 2-day intervals. On the day of the experiment, after 6 hours of treatment with fresh culture fluid, all culture fluids were removed and replaced by methionine-free DME/F-12 + ITS mixture containing ^{35}S-labeled methionine. After 16 hours of endogenous radiolabeling, culture fluids were collected the next day and proteins were TCA precipitated. SDS-polyacrylamide gel electrophoresis was carried out on secretory proteins. Results: Secretory proteins show a 55 KD band representing prorenin and a 44KD band representing renin. The renin band was faint in the control group. The progesterone treatment group primarily showed renin and the prorenin band was essentially absent. Treatment with receptor blockade alone or with progesterone had a pattern similar to that of the control group. This suggests that progesterone treatment of stromal cells (*in-vitro* decidualization) induces secretion of renin in preference to prorenin and that receptor blockade effectively blocks the preferential renin secretion.

48 SEVERE FETAL IUGR MAY ANTEDATE CLINICAL EVIDENCE OF PREECLAMPSIA BY SEVERAL WEEKS. A. Nova,[x] B. Sibai, J. Barton,[x] A. Khoury,[x] N. Meyer,[x] B. Mercer.[x] University of Tennessee, Memphis.

The association of preeclampsia with fetal intrauterine growth retardation (IUGR) is well known. We hypothesized that severe fetal IUGR may be an early finding for impending preeclampsia. The purpose of this study is to report the clinical, laboratory findings, and perinatal outcome in 43 normotensive women with well-established IUGR who ultimately developed preeclampsia. Materials and Methods: Inclusion criteria were: good dating criteria by dates, first visit and/or early USG, absence of chronic hypertension, documented IUGR by USG, singleton pregnancy, no hypertension and/or proteinuria at initial diagnosis of IUGR. Results: All 43 patients developed preeclampsia: 20 mild and 23 severe (5 with HELLP syndrome). The mean uric acid in these women was 6.6±1.4 mg/dl, and 40 (93%) had significant proteinuria. The mean interval from diagnosis of IUGR to onset of preeclampsia was 2.1 weeks (range, 0.43 to 6). Table summarizes clinical findings in these patients. Twenty-seven (63%) of the infants were <5th percentile and 16 (37%) were <10th percentile. There were 3 stillbirths and 11 neonatal deaths for a perinatal death rate of 32.6%. Thirty-one infants required admission to special care nursery for an average stay of 39 days (range, 4-203 days). Conclusions: IUGR may antedate impending preeclampsia. Thus, preeclampsia should be considered in differential diagnosis of normotensive patients presenting with severe IUGR. Such pregnancies are at high risk for severe preeclampsia, HELLP syndrome, preterm delivery, and poor perinatal outcome.

	Means±SD	Range
SBP at diagnosis of IUGR (mmHg)	120±9.8	102-138
DBP at diagnosis of IUGR (mmHg)	75±9.5	60-86
GA at diagnosis of IUGR (wk)	29.4±4.2	22-37
GA at diagnosis of preeclampsia (wk)	31.3±3.9	25-39
Delivery ga (wk)	31.7±3.8	25.6-39
SBP at onset of preeclampsia (mmHg)	156±21	130-220
DBP at onset of preeclampsia (mmHg)	101±10	86-110

SBP=systolic blood pressure, DBP=diastolic blood pressure

49 UMBILICAL VENOUS PLASMA ENDOTHELIN IS NOT INCREASED IN PREECLAMPSIA. A.Nova,[X] J. Barton,[X] M.D. Mitchell, B.M. Mercer, [X]B.M. Sibai, University of Tennessee, Memphis, and University of Utah, Salt Lake City.

Plasma endothelin (ET) levels are usually increased in conditions characterized by endothelial damage and local tissue hypoxia. We previously reported that women with preeclampsia, particularly those with HELLP syndrome, have significantly higher endothelin levels than women with normotensive pregnancies. The purpose of this investigation is to compare umbilical vein plasma ET levels in preeclampsia and normotensive pregnancies. Methods: The study population included 7 women with preeclampsia and 12 with normotensive pregnancies. All but one woman delivered vaginally at term. Samples were collected immediately after cord clamping using cold vacutainer tubes containing EDTA and aprotinin. The blood was immediately cold centrifuged and plasma fraction was then stored at -70°c. Plasma was analyzed for endothelin using an RIA technique (Amersham Corp.). Results: As expected, preeclamptic women had significantly higher systolic blood pressures (152 ± 13 v 118 ± 10 mmHg, $p < 0.0001$) and higher diastolic pressures (97 ± 9.4 v 69 ± 9.2, $p < 0.0001$). There were no differences between the two groups regarding either gestational age at time of delivery or cord vein ET levels (Table). However, cord blood ET levels are significantly higher than previous reported maternal levels (preeclamptics 12.87 ± 3.6 v 5.5 ± 0.3, $p < 0.001$ and normotensive 12.2 ± 2.7 v 3.8 ± 0.3, $p < 0.0001$). Conclusions: Fetal secretion of ET is not increased in preeclampsia. The increase in umbilical ET at delivery suggests a role for ET in perinatal circulatory adaptation.

	Preeclampsia n = 7	Normotensive n = 12
Gestational age (wk)	37.7 2.6	39.0 1.5
Umbilical vein ET (fmole/ml)	12.87 3.62	12.21 2.69

50 **LOW-DOSE ASPIRIN (ASA) INHIBITS LIPID PEROXIDES (LPO) AND THROMBOXANE (TX), BUT NOT PROSTACYCLIN (PGI), IN PREGNANT WOMEN.** SW Walsh,[X] Y Wang,[X] HH Kay, MC McCoy.[X] Depts OB/GYN, Medical College of Virginia, Richmond, VA and Duke Univ., Durham, NC

Preeclampsia is associated with an imbalance of increased TX and decreased PGI, and recently reported an abnormal increase of LPO (AJOG, Dec., 1991). LPO are toxic compounds that damage cells and inhibit PGI synthesis. Low-dose ASA therapy reduces the incidence of preeclampsia, presumably by selective inhibition of TX to restore a balance between TX and PGI. However, the effectiveness of low-dose ASA might also relate to inhibition of LPO. To test this, 10 women at risk of preeclampsia were placed on low-dose ASA therapy (81 mg/day) between 19-33 wks of gestation. Plasma samples were collected before ASA and after 3-4 days and 3-4 wks of ASA. Samples were analyzed for TX and PGI by RIA of their stable metabolites, TXB_2 and 6-keto PGF_{1a}, and for LPO by H_2O_2 equivalents. Low-dose ASA significantly decreased ($P<0.05$) both LPO (130 ± 18 vs 92 ± 11 and 68 ± 9 nmol/ml, mean ± SE) and TX (502 ± 67 vs. 138 ± 67 and 8 ± 5 pg/ml), but it did not affect PGI (55 ± 10 vs 41 ± 8 and 40 ± 11 pg/ml). Conclusion: Low-dose ASA selectively inhibits both LPO and TX without affecting PGI. Speculation: This selective inhibitory action of low-dose ASA may account for its effectiveness in the prevention of preeclampsia. HD 20973.

51 INSULIN CONCENTRATIONS IN CHRONIC HYPERTENSIVE PREGNANT WOMEN. E. Rey,[X] A. Bonin,[X] Dept. Ob/Gyn, Sainte-Justine Hospital, Montreal (Quebec), Canada.

In order to investigate the state of insulin resistance of chronic hypertensive pregnant women, we studied glucose and insulin responses to oral glucose loads in these patients. Chronic hypertension was defined as essential hypertension known before pregnancy. Gestational diabetic and treated chronic hypertensive women were excluded. Serum capillary glucose was determined by the glucose oxidase method and insulin levels by radio-immunoassay. One hundred and forty-seven (147) euglycemic lean normotensive pregnant women (Body mass index (BMI) = 21.8 ± 0.2), 30 euglycemic obese normotensive pregnant women (BMI = 32.5 ± 1.0) and 25 euglycemic lean chronic hypertensive pregnant women (BMI = 23.7 ± 0.6) received a 50 gm oral glucose load. Insulin levels and insulin to glucose ratio at one hour were significantly higher in normotensive obese and hypertensive women than in normotensive lean women ($p < 0.001$ and $p < 0.01$). Following a 100 gm glucose load, glucose and insulin concentrations were measured for a three-hour period in 26 euglycemic lean normotensive women (BMI = 21.9 ± 0.5), 27 euglycemic lean hypertensive women (BMI = 23.5 ± 0.6) and 57 lean gestational diabetic women (BMI = 23.2 ± 0.5). Hypertensive and gestational diabetic women disclosed significantly higher insulin concentration and insulin to glucose ratio than normotensive women at 2 and 3 hours ($p < 0.05$). These data suggest that mild hypertensive pregnant women, as obese and gestational diabetic patients, display a state of insulin resistance.

52 DOPPLER EVIDENCE OF RENAL HYPERPERFUSION IN PREECLAMPSIA. JF Smith, GJ Gilson, GO Del Valle, G Joffe, LA Izquierdo, M Chatterjee, LB Curet. University of New Mexico, Albuquerque, NM

To further clarify the renal hemodynamic changes associated with preeclampsia, we initiated a prospective study of maternal renal arcuate artery Doppler velocimetry changes associated with that disease. Twelve preeclamptics were compared to 21 normotensive patients. All preeclamptics had blood pressures of at least 140/90, and proteinuria of at least 300 mgs/24 hours. Renal arcuate arteries were identified at the bases of the renal pyramids in a subcostal, transverse view; for consistency, the right kidney was chosen for insonation. A sample volume of 3-5 mm and wall filter setting of 50 Hz was used. FINDINGS: Compared to the normotensive patients, the preeclamptics had a significantly lower mean pulsatility index (0.89 vs 1.18, P=0.01) of the maternal renal arcuate artery. We have found that the increase in pulsatility index in the late third trimester that occurs in normotensive pregnancies may not occur in preeclamptics; confirmatory longitudinal studies are necessary. The data presented here suggests increased renal blood flow in preeclampsia and is consistent with the renal hyperperfusion model for this disease.

53 ERYTHROCYTE MEMBRANE FLUIDITY IN PATIENTS WITH PREECLAMPSIA.

L. Sanchez-Ramos MD, M. Jordan MD[X], D L Mollitt MD[X], D Adair MD[X], M. T. Cullen, M.D., Divisions of Maternal-Fetal Medicine and Pediatric Surgery, University of Florida, Jacksonville, FL.

Recent information indicates that membrane lipids and other cell components are disrupted in patients with preeclampsia. Under physiologic conditions, the lipids of biologic membranes are in liquid-crystalline state. Although the hydrophobic interactions and the hydrogen bonding that occur between lipids maintain the integrity of the lipid bilayer, they also permit appreciable amounts of molecular motion within that bilayer. The process of molecular motion within the membrane is referred to as fluidity. Fluorescence studies of membrane fluidity were conducted using washed erythrocytes prepared from 9 patients with severe preeclampsia, including 4 with the HELLP syndrome, and an equal number of normotensive controls. The fluidity of the hydrocarbon and liquid-aqueous interface regions of cell membranes was determined at 37°C by fluorescence spectroscopy using the lipid probe 1-[4-(trimethylamino)phenyl]-6-phenyl-1,3,5-hexatriene (TMA-DPH). The rotation rate of TMA-DPH in labeled red cell membranes did not differ between preeclamptics and normotensive controls (0.286±.02 and 0.280±.02). However, the rotation rate in patients with HELLP was less than normotensive controls (0.307±.01 and 0.280±.02; p<.001) suggesting decreased membrane fluidity. Such changes may be associated with alterations of the red cell membrane leading to hemolysis.

54 THE EFFECT OF MAGNESIUM SULFATE ON MATERNAL BRAIN BLOOD FLOW IN MILD PREECLAMPSIA: A RANDOMIZED PLACEBO-CONTROLLED STUDY

Michael A. Belfort,[X] Kenneth J. Moise, Jr., George Saade.[X] Dept. Ob/Gyn, Baylor College of Medicine, Houston, Texas.

INTRODUCTION: The effects of magnesium sulfate on maternal cerebral blood flow (CBF) in PIH are not well described. We therefore studied the acute effect of a 6 gram dose of magnesium sulfate on CBF in mild PIH. METHODS AND MATERIALS: Twelve patients were randomized to 2 groups and studied with Doppler ultrasound before and after infusion of either a 6 gram intravenous loading dose of magnesium sulfate, or placebo. The change in the pulsatility index (Delta-PI) in the middle cerebral (MCA), common carotid (CCA), and internal carotid (ICA) arteries was compared (unpaired student t-test). RESULTS: All data* is presented as the change in the pulsatility index (Delta-PI).

	Placebo Group (n=6)	Magnesium Sulfate Group (n=6)	p
MCA	-0.02 +/- 0.06	-0.16 +/- 0.09	0.01
CCA	-0.05 +/- 0.27	-0.28 +/- 0.35	NS
ICA	-0.01 +/- 0.29	-0.14 +/- 0.24	NS

* = Mean +/- SD

Magnesium sulfate significantly reduced the pulsatility index in the MCA, without significantly changing the indices of the carotid vessels. CONCLUSIONS: Magnesium sulfate vasodilates the small intracranial vessels distal to the MCA, and may help to prevent seizures by relieving cerebral ischemia rather than by suppressing neuronal activity.

55 THE EFFECT OF MAGNESIUM SULFATE ON MATERNAL AND FETAL BLOOD FLOW IN PREGNANCY-INDUCED HYPERTENSION (PIH).

Michael A. Belfort,[X] Kenneth J. Moise, Jr., George Saade.[X] Dept. Ob/Gyn, Baylor College of Medicine, Houston, Texas.

The acute effects of magnesium sulfate (MgSO4) on maternal and fetal cerebral blood flow are not well described in PIH. MATERIALS AND METHODS: Twelve patients with PIH were prospectively studied with transcranial and transabdominal color Doppler, before and after infusion of a 6 gram IV dose of MgSO4. The maternal vessels studied included the middle cerebral (MCA), common carotid (CCA), and internal carotid (ICA) arteries. The fetal vessels included the middle cerebral, renal, and umbilical arteries. The maternal circulation in the placental base plate was also imaged. RESULTS: Doppler data (mean +/- SD; all values are pulsatility index unless otherwise indicated. * = S/D ratio.

MATERNAL VESSELS	n	Baseline	After MgSO4	p
MCA	12	0.77 +/- 0.07	0.69 +/- 0.1	>0.02
CCA	12	2.34 +/- 1.0	1.98 +/- 0.5	NS
ICA	12	1.23 +/- 0.6	1.11 +/- 0.3	NS
FETAL VESSELS				
MCA	9	1.53 +/- 0.2	1.61 +/- 0.3	NS
Renal Artery	7	2.17 +/- 0.3	2.23 +/- 0.4	NS
Umbilical Artery*	10	2.86 +/- 0.9	2.40 +/- 0.4	NS
PLACENTAL VESSELS				
Maternal Placental*	8	1.72 +/- 0.2	1.70 +/- 0.3	NS

CONCLUSIONS: A 6 gram bolus dose of MgSO4 significantly vasodilated vessels distal to the maternal MCA, without significantly affecting the other maternal or fetal vessels studied.

56 THE EFFECT OF MAGNESIUM SULFATE ON BLOOD FLOW IN THE MATERNAL RETINA IN MILD PREGNANCY-INDUCED HYPERTENSION (PIH): A PRELIMINARY STUDY.

Michael Belfort.[X] Dept. Ob/Gyn, Baylor College of Medicine, Houston, Texas.

There are few data on retinal blood flow (RBF) in patients with PIH. The central retinal artery (CRA) is an end branch of the internal carotid artery (ICA) and may reflect changes in cerebral blood flow (CBF). This prospective study was designed to assess the effects of a bolus infusion of 6 grams of MgSO4 on the CRA in patients with PIH. MATERIALS AND METHODS: Five women with PIH undergoing induction of labor underwent color flow Doppler ultrasound examination of the CRA before and after IV MgSO4 (6 grams in 100 ml 5% dextrose water over 20 minutes). BP, HR, Pulsatility Index (PI), Resistance Index (RI), angle-corrected flow-velocity were recorded. RESULTS: The central retinal artery was easily and reliably visualized. Six grams of MgSO4 significantly reduced (p<0.03) the PI from 0.93 (SD 0.16) to 0.76 (SD 0.19) and RI from 0.57 (SD 0.05) to 0.47 (SD 0.08). Flow-velocity increased post MgSO4. CONCLUSIONS: MgSO4 acutely vasodilates small arteries in the retina, increasing blood velocity: similar changes may occur in other branches of the ICA supplying the brain. This technique may allow better monitoring of the effects of therapeutic interventions on CBF in patients with PIH.

57 **EUTHYROID SICK SYNDROME IN PRE-ECLAMPSIA.** T. T. LAO[X], R. K. H. CHIN[X], N. S. PANESAR[X], R. SWAMINATHAN[X]. Depts Ob/Gyn and Chemical Pathology, The Chinese University of Hong Kong, Prince of Wales Hospital, Shatin, Hong Kong.

The Euthyroid Sick Syndrome (low plasma levels of thyroid hormones in euthyroid patients) is often found in severely ill non-pregnant patients. To examine the occurrence of this Syndrome in pre-eclampsia, 53 consecutively admitted proteinuric pre-eclamptic patients (ACOG criteria), who had no history of thyroid disease and not requiring urgent delivery for maternal/fetal reasons, were studied together with 30 normotensive third trimester controls. Blood was collected in a heparinized tube and the plasma separated by centrifuge at 4°C and stored until assayed with Syva EMIT for total thyroxine (TT4) and RIA (Diagnostic Products Corporation) for free thyroxine (FT4), total and free tri-iodothyronine (TT3 and FT3), and thyrotropin (TSH). All the pre-eclamptic patients had thyroid hormone levels within the normal non-pregnant range. Compared to controls, 24 (45.3%) pre-eclamptic patients had decreased levels in one or more thyroid hormones in the form of (1)low TT4 and TT3 ± low FT4 and/or FT3, n=7; (2)low TT4 ± low FT4 and/or FT3, n=10; (3)low TT3 ± low FT4 and/or FT3, n=2; (4)low FT4 and/or FT3 only, n=5. Elevated TSH was found in 8 (33.3%) of these patients and 6 (20.7%) of the other pre-eclamptic patients. There was no consistent trend in the pattern of abnormal thyroid hormone levels. There was no difference in the incidence of intrauterine growth retardation in pre-eclamptic patients with abnormal (45.8%) and normal (34.5%) thyroid hormone levels. In conclusion, the Euthyroid Sick Syndrome is a frequent occurrence and probably a reflection of the severity of the maternal condition in pre-eclampsia.

58 **MAGNESIUM SULPHATE (MGSO4) THERAPY IN PREECLAMPSIA IS ASSOCIATED WITH INCREASED URINARY CYCLIC GUANOSINE MONOPHOSPHATE (CGMP) EXCRETION.** JR Barton[X], BM Sibai, R. Ahokas[X], WD Whybrew[X], BM Mercer[X]. University of TN, Memphis.

Endothelium-derived relaxing factor (EDRF) is a mediator of vascular smooth muscle relaxation. Assays for EDRF are difficult due to its short half life. However, it has been found to stimulate the formation of cGMP which is more stable. Since both normotensive and hypertensive pregnancies are associated with significant changes in vascular smooth muscle tone, we investigated maternal urinary cGMP levels as a potential indicator of EDRF activity. **Methods:** 57 women with preeclampsia (38 prior to and 19 during $MgSO_4$ infusion) and 14 normotensives were studied. 24hr urine samples were collected in the third trimester and an aliquot was stored at -70°C. Urinary cGMP was analyzed using a RIA technique (Amersham Corp.) and expressed as pmole per mg of urinary creatinine to standardize for renal function. **Results:** There was no difference in gestational age at time of urine collection between the two groups. Urinary cGMP levels expressed as mean ± SD were similar between the two groups (table). Although not statistically different, preeclamptic women not receiving $MgSO_4$ had lower cGMP levels than normotensives. There was no correlation between cGMP levels and severity of hypertension. Preeclamptic women receiving $MgSO_4$ had significantly higher levels of cGMP ($p=0.02$) than those not receiving $MgSO_4$. **Conclusions:** These preliminary results indicate that cGMP excretion increases in patients with preeclampsia during $MgSO_4$ infusion. This may indicate that the vascular smooth muscle relaxation effects of $MgSO_4$ are mediated by EDRF as determined by increased cGMP production.

		GA (wks)	cGMP (pmole/mg cr)	
Normotensive	(n=14)[+]	32.9±3.3	751±498	
Preeclampsia	(n=57)	34.1±3.8	632±363	[+]p=0.12
without MgSO4	(n=38)[*+]	34.6±3.5	555±344	[*]p=0.02
with MgSO4	(n=19)[*]	33.4±4.0	786±360	

59 **URINARY ENDOTHELIN-1: NOT A USEFUL MARKER FOR PREECLAMPSIA.** JR Barton,[X] BM Sibai, WD Whybrew[X], BM Mercer[X]. University of Tennessee, Memphis.

Endothelin-1 (ET-1), a 21-residue peptide produced by endothelial cells, is one of the most potent vasoconstrictors identified in humans. ET-1 serum levels are reportedly increased in situations of endothelial damage, including preeclampsia. We investigated maternal urinary ET-1 levels to determine if a similar increase could be detected and used as a marker for preeclampsia. **Methods:** 50 women with preeclampsia (36 prior to and 14 during $MgSO_4$ infusion) and 11 normotensive gravidas were studied. 24 hour urine samples were collected in the third trimester and an aliquot was stored at -70°C. Urinary ET-1 was analyzed using an RIA technique (Amersham Corp.) and expressed as femtomoles ET-1 per mg of urinary creatinine to standardize for renal function. **Results:** There was no difference in gestational age at time of urine collection between the two groups. Urinary ET-1 levels expressed as mean ± SEM were similar between the two groups (table). There was no correlation between ET-1 levels and severity of hypertension. Preeclamptic women receiving $MgSO_4$ had similar levels of urinary ET-1 to those not receiving $MgSO_4$.

		GA (wks)	ET-1 (fmole/mg cr)
Normotensive	(n=11)	32.4 ± 0.7	62.7 ± 7.5
Preeclampsia	(n=50)	33.4 ± 0.6	79.8 ± 9.3
without MgSO4	(n=36)	34.1 ± 0.7	78.7 ± 9.3
with MgSO4	(n=14)	32.2 ± 0.9	82.7 ± 23.9

Conclusions: These results indicate that ET-1 excretion is not significantly increased in patients with preeclampsia. Thus, urinary ET-1 excretion is not a good marker for preeclampsia.

60 **IS ACCELERATED FETAL LUNG MATURITY EQUATED WITH HYPERTENSIVE DISORDERS?** O. Langer, J. Piper,[X] A. Samueloff,[X] L. Ridgway, M. Berkus, E. Xenakis.[X] Department of OB/GYN, University of Texas Health Science Center at San Antonio, TX.

Increased fetal lung maturity for a given gestational age (GA) has consistently been associated with hypertensive disorders However, the definitive role of hypertensive disorders in pregnancy has not been established. In order to investigate this relationship, 6019 consecutive women with hypertensive disorders and 6358 non hypertensive consecutive preterm deliveries serving as controls were studied. Women with diabetes and twin gestations were. For purpose of analysis, patients were stratified by gestational week. The incidence of hyaline membrane disease in each group was:

GA	*CHTN (N=1807)*	*PET (N=4212)*	*CONTROL (N=6358)*
26 29	13.0*	29.4	29.6
30 32	9.8	17.4	14.4
33-35	8.6	4.0	4.6
36 37	1.2	1.0	1.6
38-HI	0.3	0.1	

*Significant difference $p < .01$ CHTN vs PET and CONTROL

The study further revealed: 1) comparison between and within each group revealed similarity in maternal age, infant gender, race and method of delivery; 2) at 30 weeks gestation, PET and control groups are at greater risk for developing RDS (RR 2.77, 95% CI 1.07-7.2) in comparison to the CHTN infants; 3) overall, a 2-fold higher risk for SGA was found in hypertensive disorders compared to controls. There was no significant difference in incidence of SGA between PET and CHTN subjects; and 4) CHTN subjects had significantly higher rates of stillbirth at each gestational age category in comparison to PET and control groups (overall odds ratio 3.9, 95% CI 2.8 5 4), respectively In conclusion, for the same gestational age group, PET and non hypertensive infants are at comparable risk for developing lung complications Conversely, the CHTN infant at 26 29 weeks gestation has a lower incidence of lung disease. This information will enhance the decision-making process when early delivery is considered in these high-risk fetuses.

61 **COCAINE: POSTPARTUM HYPERTENSION NOT A RISK WITH BROMOCRIPTINE USE.** YR Renfroe[X], RK Bhatia, SF Bottoms, DL Watson, and RJ Sokol. Wayne State Univ., Hutzel Hospital, Detroit, MI.

On the basis of two case reports of severe postpartum hypertension (PPH) and secondary cortical blindness, seizures, or pulmonary edema, it has been recommended that bromocriptine should not be used for lactation suppression in cocaine abusers. A postulated mechanism for cocaine to potentiate the dopaminergic effects of bromocriptine could be reuptake inhibition of both dopamine and norepinephrine at the presynaptic receptors. However, severe hypertension and its sequelae have also been reported with bromocriptine alone, especially in patients with preeclampsia. To investigate the relationship, if any, between bromocriptine, cocaine abuse, and postpartum hypertension, we studied 1065 patients, excluding those with antepartum hypertension. All patients had blood pressure determinations during 2 home visits by a nurse within 3 weeks postpartum. PPH (n = 178) was defined as persistent elevation $\geq$ 140/90 at either visit. Stepwise discriminant analysis with PPH as the dependent variable revealed that a history of preeclampsia ($p < 0.001$), obesity ($p < 0.01$), and parity ($p < 0.05$) were significant risk factors for PPH. Neither bromocriptine use (n = 773), cocaine abuse (n = 52), or their combination (n = 46) was significantly associated with PPH. None of the studied patients developed serious sequelae of PPH. We conclude that cocaine abuse is not a contraindication for the use of bromocriptine to suppress lactation.

62 TRANSCRANIAL ASSESSMENT OF MATERNAL CEREBRAL BLOOD FLOW VELOCITY IN NORMAL VS PREECLAMPTIC WOMEN; VARIATION WITH MATERNAL POSTURE

K. Williams[X], C. McLean[X], University of British Columbia, Vancouver B.C. Canada.

Cerebral blood flow velocity (CBFV) can be extensively evaluated in adults using a 2 mHz transcranial doppler ultrasound. Middle Cerebral Artery (MCA) blood flow velocity is lower with the patient in the upright then in the supine position (Ultrashall Med 1986; 7: 248-52). We assessed MCA blood flow using a pulsed wave doppler with a 2 mHz. probe in five normotensive and five preeclamptic (PET) pregnant patients in both supine and standing positions to evaluate the effect of change in maternal position on CBFV. The MCA was insonated through a temporal ultrasound window at a depth of 5.2 cm. We assessed maximum systolic, minimum diastolic and mean MCA flow velocity. We found (1) PET women showed higher MCA velocity than normotensive women, (2) Normotensive women showed a fall in all aspects of MCA velocity, from supine to standing (5-12%), (3) PET women showed a significant rise ($P<.05$) (average 20% increase) in all aspects of MCA velocity from supine to standing.

		Max. Systolic (mm/sec)	Max. Diastolic (mm/sec)	Mean
Normo-	supine	87 +/- 15	31 +/- 6	50 +/- 8
tensive	standing	80 +/- 17	28 +/- 6	47 +/- 10
PET:	supine	80 +/- 17	39 +/- 12	55 +/- 15
	standing	94 +/- 14*	48 +/- 11**	66 +/- 13*

* P <.04, ** P <.01

Conclusions: These data show that maternal cerebral blood vessels react differently in pregnant PET women. The pathophysiology of this finding and whether clinically it can be used in a predictive fashion requires further investigation.

63 **ECLAMPSIA--TYPICAL FINDINGS WITH MRI.**

MA Dahmus[X]--JRBarton[X], BM Sibai, University of TN, Memphis.

Purpose: To study the MRI findings in patients with eclampsia, and to determine the clinical utility of this imaging modality. **Methods:** 25 patients with a diagnosis of eclampsia received cerebral magnetic resonance imaging. The scans were obtained from 0 to 18 days after the first seizure (median 6.6 days). The scan at 18 days was a rescheduled exam secondary to claustrophobia during the first study one week earlier. **Results:** Fourteen scans were normal (median of 5.5 days after the first seizure). One additional scan could not be completed due to claustrophobia, and was not rescheduled. The T2-weighted images were the most useful. Only 2 of the patients had abnormalities on the T1 weighted scans. No cerebral hemorrhage or atrophy was noted. Cortical edema in the posterior hemispheres (posterior parietal and occipital lobes) was the single most common finding--seen in all 11 abnormal scans. Infratentorial abnormalities were noted in two cases--edema in the midbrain and brain stem in 1 case, and cerebellar edema in the other case. Five patients had edema of the cortex and white matter. Three of the patients had focal neurologic deficits at admission, but one patient recovered before the time of scanning. The patient with normalization of neurologic function had only cortical edema on her scan (obtained at 18 days secondary to claustrophobia). The other 2 patients, who also had residual focal neurologic deficits at discharge, had both white matter edema and cortical edema, and one also had changes consistent with infarction. Three of the 7 patients who had scans more than one week after the first seizure activity had abnormal studies. These 3 patients had the most abnormal neurologic exams of all 26 patients. Patient management was not changed by MRI results, but the studies helped to exclude certain pathology (tumor, aneurysm, stroke) for which specific intervention might be useful. **Conclusion:** Cortical edema is the most common abnormality in eclamptic patients receiving cerebral MRI studies. We recommend limiting the use of MRI to patients with focal neurologic deficits, prolonged coma, or intractable seizures in order to exclude serious pathology for which specific therapy might be indicated.

64 **PROSTAGLANDIN PRODUCTION BY TROPHOBLAST OF NORMOTENSIVE AND PREECLAMPTIC PREGNANCIES**

M. Morgan, S. Silavin[X], D. Rice[X], Dept Ob/Gyn, Univ. of California Irvine, Orange, CA and Dept Ob/Gyn, Univ. of Oklahoma Health Sciences Center, Oklahoma City, OK

Preeclampsia, is hypothesized to have an alteration in placental production of thromboxane and prostacyclin. The purpose of this study was to determine if trophoblasts from preeclamptic (PIH) patients produce differential amounts of thromboxane and prostacyclin compared to normotensives (NORM). Placentae from PIH (n=7) and NORM(n=9) pregnancies were utilized to isolate cytotrophoblasts via the method of Kliman et. al. (Endocrinol 118:1567;1986). These cells were incubated for 24 hours in culture media with (S) or without (NS) 10% calf serum. Media were assayed for the stable metabolites of thromboxane (TBX_2) and prostacyclin (6-ketoPGF_{1a}) via specific RIA. Separate cultures were incubated with indomethacin 50μM (IND) or arachidonic acid 100μM (AA) to confirm trophoblast prostanoid production. Both TBX_2 and 6-ketoPGF_{1a} concentrations were reduced with IND added and increased with AA added. The prostanoid concentrations are in pg/mg protein. Results: The mean ±SEM concentration of TBX_2 and 6-ketoPGF_{1a} of trophoblasts from PIH patients was less than NORM women.

	TBX_2		PGF_{1a}		ratio	
	S	NS	S	NS*	S	NS
PIH	847±301	875±264	17±5	20±2	55±12	41±12
NORM	1204±164	1299±167	28±5	37±5	42±4	39±7

*p<0.005

Based on these data, cultured cytotrophoblasts in media with or without 10% calf serum from PIH patients have slightly elevated prostanoid ratios (TBX_2 to 6-ketoPGF_{1a}) compared to NORM patients.

65 A COMPARISON OF THE EFFECT OF PHENYTOIN & MGSO4 ON FETAL HEART RATE TRACINGS USING COMPUTER ANALYSIS. E Guzman, M Conley*, R Stewart*, K Kappy, J Ivan*, P Kharabe*, Dept. Obs/Gyn, Newark Beth Israel Medical Center, Newark, New Jersey.

One of the proposed advantages in using phenytoin over MGSO4 for the prevention of eclampsia is its lack of effect on the fetal heart rate tracing. However, this has not been substantiated in the literature. Because of the documented inter- and intra-observer variation in visual interpretation of fetal heart rate tracings (FHRT), we used computer analysis (SYSTEM 8000) to compare the effects of these two medications on the FHRT's of 30 preeclamptic women. Treatment groups were non-randomized and equal in number. FHRT's of 1 hour duration obtained before and after treatment were analyzed in regard to the following parameters: heart rate accelerations of 10 and 15 beats per minute (BPM), episodes of high and low variation, and long and short term variability. No other medications were given during the study period. Using biophysical profile testing along with FHRT, all fetuses were considered well during the control period. Statistical analysis of FHRT parameters before and after treatment were analyzed with paired T-Test and statistical significance was reached at $p<.05$. There was no difference in gestational age, birthweight, APGAR scores, and computer scoring of FHRT's between the control periods of both treatment groups. Phenytoin had no effect on any of the computer measured FHRT parameters. On the other hand, MGSO4 significantly decreased the frequency of accelerations of 10 and 15 BPM, as well as short and long term variability. Though not significant, MGSO4 doubled the amount of time the fetus spent in periods of low variation. Therefore, the use of phenytoin for eclampsia prophylaxis seems preferable to MGSO4 in cases where fetal well-being is in question or FHRT interpretation is difficult, as in prematurity.

66 AN EASILY ADMINISTERED PHENYTOIN REGIMEN FOR THE MANAGEMENT OF PREECLAMPSIA. Michael Lucas, Ralph DePalma, Mark Peters, Kenneth Leveno, David Persons,* F. Gary Cunningham. Dept. Ob/Gyn, Univ. of Texas Southwestern Med. Center, Dallas, Tx.

Current phenytoin regimens for seizure prophylaxis during labor typically involve relatively complicated dosing schemes with varying rates of infusion or multiple intravenous dosages. Moreover, dosage adjustments are recommended based upon body weight. We sought to develop a single regimen that could be used regardless of body weight and that minimized side effects by prolonging the initial infusion. 1 gram of phenytoin was infused over one hour and plasma levels measured in 28 term pregnancies complicated by preeclampsia. In 14 of these pregnancies, phenytoin, 500 mg, was administered orally 10 hours post infusion. The results are summarized below:

Plasma Phenytoin µg/ml Mean (SD) — Elapsed Time (hours) Post Initiation of Phenytoin Infusion

	1	2	8	16	24	32
IV Regimen (N=14)	18(5)	15(5)	11(4)	8(3)	6(2)	5(2)
IV & PO Regimen (N=14)	22(6)	17(6)	13(5)	12(4)	12(4)	11(4)

Side effects were minor and included transient burning at the IV site, mild euphoria, dizziness and nystagmus. A mild and asymptomatic decrease in BP was observed in most women. Comment: Assuming that the therapeutic plasma levels for phenytoin in non-pregnant women (10-20 µg/ml) apply during pregnancy, our regimen of a 1 gram phenytoin infusion followed 10 hours later by 500 mg orally resulted in therapeutic levels for up to 32 hours in all but one woman. This patient weighed 265 lbs. suggesting that only very large women (in excess of 250 lbs.) require dosage adjustment. Moreover, a constant infusion spanning one hour avoids the complexities of adjusting infusion rates or giving multiple intravenous dosages.

67 EFFECT OF LOW DOSE ASPIRIN THERAPY ON POLYUNSATURATED FATTY ACIDS IN PREGNANCY. M.C. McCoy,* H.H.Kay, Y.Wang,* A.P.Killam, Dept. Ob/Gyn, Duke Univ., Durham, NC

Preeclampsia is reported to be due to an imbalance between thromboxane and prostacyclin. Many investigators have found low dose aspirin (ASA) therapy effective in reducing the incidence and/or severity of preeclampsia because it inhibits cyclooxygenase and decreases thromboxane production. We recently reported that plasma levels of polyunsaturated fatty acids in the n-3 and n-6 classes, which are precursors for prostanoids such as thromboxane and prostacyclin, are decreased in preeclamptic patients. The purpose of this study was to determine if low dose ASA therapy affects the plasma levels of these fatty acid precursors, specifically whether these levels would increase with inhibition of cyclooxygenase. We assayed linoleic, linolenic, arachidonic, eicosapentaenoic and docosahexaenoic acids using HPLC as previously reported (AJOG 164:812,1991). Eleven pregnant patients at risk for preeclampsia or growth retardation were placed on ASA therapy (81 mg/d) at varying gestational ages. Blood was drawn before starting, after 3-4 days and after 3-4 weeks of ASA therapy. Results were analyzed using the two-tailed paired t-test and sign rank test. We found no significant change in the levels of fatty acids either at 3-4 days or 3-4 weeks compared to baseline. Conclusion: low dose ASA does not appear to change the levels of fatty acid precursors of the prostanoids.

68 CIRCULATING ENDOTHELIN-1 IS NOT INCREASED IN PREECLAMPSIA. D. Shah, M. Frazer,* K. Badr.* Dept. of OB/GYN, The University of Texas Health Science Center, San Antonio, TX and Dept. of Internal Medicine, Vanderbilt University School of Medicine, Nashville, TN.

Endothelin-1 is a novel, potent vasoconstrictor peptide released by vascular endothelial cells. Preeclampsia is a unique hypertensive disorder of pregnancy. Endothelial cell injury has been implicated in the pathophysiology of this disorder. Endothelial cell injury has been shown *in vitro* to cause release of endothelin-1. Therefore, we conducted a prospective study of patients with hypertensive disorders of pregnancy and a control population to examine if circulating levels of endothelin-1 are elevated in these disorders. We studied 21 patients with the following diagnoses: severe preeclampsia ($n=9$); chronic hypertension ($n=6$), of whom two had severe preeclampsia; and control patients ($n=6$). The mean maternal age and gestational ages were similar in these three groups. More importantly, severe preeclampsia patients were selected by very strict criteria and most had evidence of thrombocytopenia. Blood samples were collected in cold EDTA tubes containing aprotinin. Endothelin was extracted immediately after collection of blood and measured by a standard radioimmunoassay. There was no difference between the endothelin-1 levels (mean$\pm$SEM) in the patients with severe preeclampsia (2.1 ± 0.6), chronic hypertensives without superimposed preeclampsia (1.9 ± 0.8), and the control population (1.7 ± 0.6). Our results are consistent with the current concept that endothelin-1 does not function as a circulating hormone. However, because of its prolonged duration of action and function as a locally acting hormone, demonstration of elevated circulating levels of ET-1 is not necessary to support its participation in the vasospasm of preeclampsia.

69 THE EFFECT OF ROUTE OF DELIVERY ON THE IMMEDIATE AND LONG-TERM OUTCOME OF THE VERY LOW BIRTH WEIGHT INFANT IN THE SETTING OF PREECLAMPSIA.

AC Regenstein, RK Laros, A Wakeley[X], JA Kitterman[X], WH Tooley[X], University of California, San Francisco, CA

The role of vaginal delivery of the very low birth weight (VLBW) infant in the setting of preeclampsia is controversial. At our institution, vaginal delivery has been attempted when maternal and fetal factors did not preclude it. An analysis of all singleton liveborn infants weighing 1500g or less and delivered to women with preeclampsia or eclampsia from 1975 to 1990 was undertaken. Of the 116 infants who qualified for the study 54.3% underwent a cesarean section (C/S) without labor. The indications for these C/S were non-reassuring fetal assessment (57.1%), preeclampsia (20.6%) and obstetric contraindications to labor (22.2%). Of the patients allowed to labor 47.2% had a C/S for fetal intolerance of labor and 32.1% delivered vaginally. 73.3% of the patients who delivered vaginally had an unfavorable Bishop score (≤ 5) at the outset of their induction. To investigate the effect of labor on neonatal outcome, the infants who underwent a C/S without labor and with a reassuring fetal assessment were compared to the infants who experienced labor. There were no significant differences between the two groups in gestational age, birthweight, year of delivery, incidence of intrauterine growth retardation (approximately 6.5%), neonatal mortality, incidence of intraventricular hemorrhage, patent ductus arteriosus, or necrotizing enterocolitis. Neurological assessment at follow-up (mean length 4.5 years) and Bayley's score at one year of age were also not statistically different. The incidence of respiratory distress syndrome (RDS) was less in the labor group (50.9% vs. 74.1%, Pearson chi square $p = 0.047$). The incidence of RDS among the infants delivered vaginally was 35.3%. The finding of a lower incidence of RDS in the group that experienced labor and in the vaginally delivered group remained even when controlling for the use of antenatal corticosteriods using logistic regression ($p \leq 0.05$) Based on these limited data a trial of labor is appropriate in carefully selected preeclamptic women who have VLBW infants.

70 PREDICTION OF PREECLAMPSIA BY DOPPLER UTERINE FLOW WAVEFORMS. A. Caruso [X], S. Ferrazzani [X], S. De Carolis [X], G. Rizzo [X], D. Arduini [X] AC. Testa [X], A. Pometti. [X]. Dept. Ob/Gyn, Catholic University, Rome, Italy.

We studied 90 high-risk pregnant inpatients by Doppler ultrasound performed in two periods of gestation: group A (52 pregnancies, 18-24 wks), group B (55 pregnancies, 25-28 wks). 17 patients were studied in both groups. Recordings were obtained using a pulsed color Doppler system at the level of uterine arteries and the higher uterine resistance index (RI) was considered for the analysis. The prevalence of non proteinuric gestational hypertension (NPGH), proteinuric gestational hypertension (PGH), birth weight <2500 g, birth percentile <10th and week of delivery <36 was: 15%, 12%, 35%, 17%, 29% respectively in group A and 24%, 11%, 51%, 18%, 47% respectively in group B. ROC curves indicated that values of RI > 2SD over the mean as cut-off provided the best predictivity. The NPGH plus PGH and birth percentile <10th end-points revealed a low predictivity of the test in both groups. On the other side, the PGH endpoint suggested a good predictive performance: (group A: sensitivity=100%, specificity=78%, positive predictive value [PPV]= 38%, negative predictive value [NPV]=100% and group B: sensitivity=100%, specificity=76%, PPV=33%, NPV= 100%). We emphasize the early onset of PGH (week of delivery 29±3 [mean ±SD]). The birth weight <2500 g and the week of delivery <36 end-points revealed high PPV: 69% and 69% respectively in group A, 95% and 95% respectively in group B. We conclude that color Doppler ultrasound applied to uterine arteries can be a reliable and useful tool in the prediction of both preeclampsia of early onset and poor fetal outcome of high-risk pregnancies. Partially supported by grant 91.00110.PF41 from Progetto Finalizzato FATMA, CNR.

71 CEREBRAL BLOOD FLOW IN PREGNANCY AND PREECLAMPSIA. W Hansen[X], Dept. Ob/Gyn, UNC School of Medicine, Chapel Hill, NC.

Preeclampsia is a hypertensive disorder of pregnancy, associated with a myriad of symptoms and signs, involving numerous organ systems including the central nervous system. Preeclampsia can progress rapidly into a convulsive state termed eclampsia. It is hypothesized that the accompanying neurologic symptoms and subsequent seizures are a result of cerebral vasospasm. The purpose of this study is to determine whether cerebral vasospasm is a concomitant of preeclampsia. Transcranial doppler sonography (TCD), makes it possible to selectively measure the hemodynamic effects of arterial vasospasm, namely increased blood flow velocity. First, cross-sectional groups of healthy pregnant women are enrolled at 6-12 weeks (n=15), 24-40 weeks (n=25), and postpartum (n=15). In each subject, blood flow velocity was measured in the middle cerebral and basilar artery. Normal values are established in each group, and the effect of pregnancy on cerebral blood flow is described. Patients admitted to UNC Hospitals with the diagnosis of preeclampsia (n=18) were enrolled into the study. Serial examinations using TCD sonography of the middle cerebral and basilar arteries were completed from admission through postpartum. Healthy pregnant patients are compared with preeclamptic patients. The relationship between the severity of preeclampsia and vasospasm is examined. Preeclamptic subjects had statistically significant increased cerebral artery blood flow velocities. We conclude that cerebral vasospasm is a concomitant of preeclampsia.

72 ELEVATED ENDOTHELIN IN THE SECOND TRIMESTER IS ASSOCIATED WITH THE RISK OF PREGNANCY INDUCED HYPERTENSION. P. Ogburn, Jr, R. Thompson,[X] A. Lerman,[X] J. Burnett, Jr,[X] M. Cullen, L. Sanchez-Ramos, Mayo Clinic, Rochester, MN & University of FL, Jacksonville, FL.

Endothelin (ET) is a vasoconstrictor peptide which has been shown to be elevated in hypertensive conditions including preeclampsia (PE). In order to determine whether ET elevation may precede clinical evidence of PE, second trimester primigravidas were divided as to positive (+) (n=10) or negative (-) (n=7) roll over tests (ROT). Each of these patients then had angiotensin II infusion tests (AII) with ET measured at baseline and at maximal AII. ET analyses were done using radioimmunoassay. The group with + ROT had 4 of 10 with + AII and 3 of 10 with PIH. The group with - ROT had no + AII and no PIH. ET was 8.87 $\pm$ 0.56 pg/mL in the - ROT and 16.96 $\pm$ 2.59 in the + ROT ($p<.02$). One patient with a + ROT but a - AII developed PIH and had a quite elevated ET of 34.3 pg/mL. AII infusion did not increase the ET levels in any group. Our results suggest that elevated ET is present as early as the second trimester in pregnancies at risk for developing PE.

73 ENDOTHELIN IN ARTERIAL AND VENOUS BLOOD IN SEVERE PREECLAMPSIA.
Arjan A. Kraayenbrink MD*, Gustaaf A. Dekker MD PhD*, and Herman P. van Geijn MD PhD*, Dept. of Obstetrics, Free University Hospital, Amsterdam, The Netherlands.

The endothelial cell is known to release the vasodilators prostacyclin and Endothelium Derived Relaxing Factor, and Endothelin (ET), a potent vasoconstrictor. ET acts mainly as a local hormone. In preeclampsia venous plasma levels of ET are significantly elevated, suggesting that ET acts as an indicator for the severity of the disease. The human lungs are known to remove ± 30% of the circulating amount of ET in one pass. It would be interesting to know if arterial levels of ET are different from venous levels and could act as a better indicator for the severity of preeclampsia. We investigated 6 patients with severe preeclampsia (third trimester) from which both arterial and venous blood was obtained. Six normotensive pregnant women acted as controls for arterial ET levels and 17 other women for venous ET levels. In severe preeclampsia arterial ET levels were higher (mean 11.62, sd 5.52,) compared with venous plasma levels (mean 7.62, sd 1.85). The same result is seen in normotensive pregnancy (arterial: mean 4.82, sd 0.66, n=6; venous: mean 2.28, sd 0.75, n=17). These results show that although ET is substantially removed in the pulmonary circulation, peripheral arterial levels are still higher than venous levels. This suggests continuous arterial production and receptor binding of ET in the peripheral arterial circulation. These findings emphasize the potential role of ET in the pathophysiology of preeclampsia. Urinary ET levels, currently being collected, will provide further insight into the role of ET in preeclampsia.

74 NIFEDIPINE TREATMENT IN PRE-ECLAMPSIA REVERTS THE INCREASED ERYTHROCYTE AGGREGATION TO NORMAL
Tranquilli AL*, Garzetti GG*, De Tommaso G*, Boemi M*, Fumelli P*, Romanini C*. Dept. Obstet/Gynecol, University of Ancona and INRCA, Ancona, Italy

Erythrocyte aggregation was studied by means of an automatic microviscosimeter in 20 normotensive pregnant women, 7 chronic hypertensive, 10 chronic hypertensive with superimposed pre-eclampsia, and 20 women with proteinuric pregnancy-induced hypertension (pre-eclampsia). Erythrocyte aggregation was increased in all the hypertensive pregnant patients, compared to the normotensive pregnant controls, regardless of both the duration (chronic or pregnancy-induced) of hypertension and the status of plasma macromolecules, that did not differ in the groups. Although the antihypertensive treatment with labetalol significantly reduced erythrocyte aggregation, the treatment with nifedipine reverted it to normal. The increased erythrocyte aggregation may be either due to conformational changes of the membrane occurring during hypertension, or to a redistribution of the ionic charges on the two surfaces of the membrane. The specific effect of nifedipine treatment, restoring the ionic charges, may likely be due to this latter event.

75 PLACENTAL LIPID PEROXIDES (LPO) AND THROMBOXANE (TX) ARE BOTH INCREASED AND PROSTACYCLIN (PGI) DECREASED IN WOMEN WITH PREECLAMPSIA.
Y. Wang,* SW Walsh,* HH Kay. Depts OB/GYN, Medical College of Virginia, Richmond, VA and Duke Univ., Durham, NC

There is an imbalance of 1 TX/1 PGI in placentas of women with preeclampsia, but this may not be the only imbalance. Recently reported is an abnormal increase in serum LPO in preeclamptic women (AJOG, Dec., 1991). LPO are toxic compounds that damage cells and inhibit PGI synthesis. The following study examined if LPO were also increased in placentas of preeclamptic women. Placental tissues from 9 normal and 8 preeclamptic women were immediately frozen in liquid N_2 after delivery. Tissue samples (1 gm) were homogenized and analyzed for LPO by MDA and H_2O_2 equivalents, and for TX and PGI by RIA of their stable metabolites, TXB_2 and 6-keto $PGF_{1\alpha}$. LPO were significantly higher in preeclamptic than normal placentas by both analytical methods (MDA: 49 ± 5 vs 31 ± 1 nmol/gm, H_2O_2 equiv: 5.3 ± 0.3 vs 3.2 ± 0.3 µmol/gm, mean ± SE, $P < 0.01$, respectively). TX was significantly higher and PGI significantly lower in preeclamptic than normal placentas (TX: 213 ± 23 vs 158 ± 14 ng/gm, PGI: 24 ± 3 vs 53 ± 7 ng/gm, $P < 0.05$). The ratios of TX/PGI and LPO/PGI were 3-fold higher in preeclamptic than normal placentas. Conclusion: Placental levels of both LPO and TX are increased and PGI decreased in preeclampsia. Speculation: Abnormally increased LPO may be the cause of decreased PGI. HD 20973.

76 MILD PREECLAMPSIA: RARELY A RECURRENT CONDITION.
RK Bhatia, and SF Bottoms. Wayne State Univ., Hutzel Hospital, Detroit, MI.

Chesley reported that 36% of eclamptics develop hypertensive disorders in subsequent pregnancies and speculated that preeclampsia would have a similar recurrence rate. Sibai reported that among women with severe second trimester preeclampsia, 65% develop hypertensive disorders in subsequent pregnancies. Data regarding the recurrence of mild preeclampsia is lacking. This investigation tests the hypothesis that mild preeclampsia is similar in recurrence to more severe disease. We studied 6090 nulliparas who were normotensive prior to pregnancy, received prenatal care, and delivered at our hospital from 1984-1990. A total of 843 (13.8%) had a subsequent delivery at our hospital, with a mean interval between deliveries of 24.2 months. 487 (8%) developed preeclampsia during the first pregnancy, of which 75 (15.4%) had a second delivery. Of the latter, 61 had mild and 14 had severe preeclampsia. Of the 14 severe preeclamptics, 2 (14.3%) had a recurrent hypertensive disorder (severe preeclampsia). Of the 61 mild preeclamptics, 3 (5%) had recurrence (1 each mild, severe, and chronic hypertension). Of 5503 non-preeclamptics, 768 (14.0%) returned for delivery, of which 7 (0.9%) developed a hypertensive disorder in the second pregnancy (6 mild, 1 chronic hypertension). The recurrence risk for mild preeclampsia in this study was significantly lower than rates reported for eclampsia or severe midtrimester preeclampsia (χ^2 goodness of fit, $p < 0.001$ in each case). There was no evidence of followup bias, and diagnostic frequencies are consistent with other large series. The relatively lower recurrence risk associated with mild preeclampsia suggests a lower frequency of preexisting renal/vascular disease and/or less chance of permanent damage secondary to hypertension.

77 RANDOMIZED STUDY OF GENERAL ANESTHESIA VERSUS EPIDURAL OR SPINAL-EPIDURAL ANALGESIA FOR CESAREAN SECTION IN PREGNANCIES COMPLICATED BY SEVERE PREECLAMPSIA. D.H. Wallace,* K.J. Leveno, F.G. Cunningham, V. Shearer,* S. Black,* J. Holloway,* Dept. Anes/Ob-Gyn, Univ. Texas Southwestern Med. Ctr., Dallas, Texas

The choice of anesthesia for cesarean section in pregnancies complicated by severe preeclampsia is controversial. Many clinicians fear the fetal effects resulting from sympathetic blockade secondary to regional analgesia in women with preeclampsia. In this on-going study that was begun in 1989, 66 pregnancies complicated by severe preeclampsia have been randomized to receive either general anesthesia, epidural or spinal-epidural analgesia for cesarean section. Cesarean sections for fetal distress were excluded. Shown below are selected outcomes:

OUTCOME	General	Epidural	Spinal-Epidural	P
Pregnancies	23	20	23	—
Birthweight, g Mean (SE)	1990 (209)	2016 (132)	2621 (185)	.02
Maternal hypotension, ephedrine used (%)	0	6 (30)	5 (22)	.01
Umbilical artery blood pH: ≤ 7.20 (%) ≤ 7.00	1 (4: 0	3 (12) 0	2 (9) 0	NS —
5-Minute Apgar, 3 or less (%)	0	0	0	—

Conclusions: 1) Maternal hypotension is a frequent complication of regional analgesia in pregnancies comp.icated by severe preeclampsia. 2) However, the fetal effects were minimal. 3) Alternatively, general anesthesia was not associated with apparent disadvantages.

78 MATERNAL CHARACTERISTICS FOR EARLY VS. LATE DIAGNOSIS OF GESTATIONAL DIABETES. G.S. Berkowitz[x], R.H. Lapinski[x], S.H. Roman[x], M. Alvarez, C.J. Lockwood. Mount Sinai School of Medicine, New York, NY

A 50 gram glucola test is routinely administered to the patients on our clinic service at the time of their first prenatal visit. If the inital plasma glucose value is < 135 mg/dl, the patien: is rescreened after 24 weeks of gestation. Out of 2776 patients who were screened before 24 weeks between 1986-1990, an abnormal glucose tolerance test was documented in 102 patients before 24 weeks (Early Dx Group) and in 252 patients at 24 weeks or later (Late Dx Group). This study was undertaken to evaluate characteristics associated with early vs. late diagnosis of gestational diabetes (GDM). Univariate comparisons identified the following differences between the Early and Late Dx groups.

Characteristic	Early Dx	Late Dx	P-value
Maternal Age > 30	63.7%	45.2%	<0.01
Preeclampsia	14.7%	7.5%	0.06
Chronic hypertension	11.8%	4.4%	0.02
Body Mass Index ≥ 32.3	28.6%	16.9%	0.02
Weekly Weight Gain < 0.27 kg	45.8%	30.5%	0.01
Prior history of GDM	25.5%	15.1%	0.03
Insulin Use	55.9%	29.8%	<0.01

Logistic regression analysis confirmed that the Early Dx group was significantly older, heavier, more likely to have hypertensive disorders, low maternal weight gain, and a prior history of GDM compared to the Late Dx group. Insulin use during the index pregnancy was also significantly higher in the Early Dx than in the Late Dx group. SUMMARY: These data indicate that a sizeable proportion of GDM patients can be diagnosed early in pregnancy and that differences in maternal characteristics and insulin requirements between the early and late GDM diagnosed groups suggest that the former group may have had preexisting impaired glucose tolerance or diabetes.

79 THE PERINATAL SIGNIFICANCE OF ONE ABNORMAL GLUCOSE TOLERANCE TEST VALUE. R Rait[x], G Berkowitz, M Alvarez, R Lapinski, RL Berkowitz and CJ Lockwood. Mt Sinai School of Medicine, New York, NY.

Gestational diabetes mellitus (GDM) is currently diagnosed by the presence of 2 abnormal values of a 3 hour Glucose Tolerance Test (GTT). However, there have been conflicting reports of the clinical significance of only one abnormal GTT value. We conducted a retrospective study of 5397 clinic patients followed between 1986-89 who were divided into 3 groups: controls with a normal glucose screen (Nls) (n=4868); patients with one abnormal GTT value (Abn-1) (n=176); and those with two abnormal values (GDM) (n=353). The criteria of Carpenter & Coustan were employed (Am J Obstet Gynecol 1982; 144:768-73). Differences in demographic and obstetric outcomes are presented as percents or mean (±SD) and assessed by either chi-square or t-test:

Variable	Nls	Abn-1'	*p+	GDM	*p++
Age > 35 yrs	6.7%	17.6%	0.0001	22.3%	0.02
Nulliparity	45.0%	32.4%	0.0001	28.8%	NS
Hypertension	3.7%	7.4%	0.01	6.5%	NS
Birth Wt ≥90%	10.2%	17.2%	0.003	15.1%	NS
Birth Wt %ile	.52 (.28)	.62 (.26)	0.0001	.56 (.28)	0.04
C-section	16.4%	23.9%	0.008	29.5%	NS

* = comparison of Nls and Abn-1 (p+) or Abn-1 and GDM (p++)

There were no differences in neonatal morbidity including hypoglycemia between the groups. To determine whether the presence of one abnormal value was an independent contributor to the occurrence of macrosomia, a multiple logistic regression was performed. When maternal weight gain, parity, age, smoking and prepregnancy weight were employed as independent variables, no significant association was found between one abnormal value and birth weight ≥ 90th percentile for gestational age.

SUMMARY: Employing a larger number of patients and stricter GTT criteria than previous studies, we note that when potential confounders are controlled for, the presence of one abnormal GTT value is not signficantly associated with macrosomia.

80 RELATIONSHIP OF MATERNAL AND NEONATAL PLATELET COUNT AT DELIVERY. R.F. Burrows, J.G. Kelton[x], McMaster University, Hamilton, Ontario, Canada.

Maternal thrombocytopenia creates anxiety for the obstetrician because of its association with severe neonatal thrombocytopenia. But what is the relationship of these two events? To determine this we prospectively collected maternal platelet counts at delivery and neonatal cord counts over a 63-month interval, recording 11,813 maternal and 12,150 neonatal outcomes. Only 11 of 12,150 infants (0.09%) had severe thrombocytopenia as defined by a cord platelet count $\leq 50x10^9/L$. In contrast, maternal thrombocytopenia ($\leq 150x10^9/L$) was a relatively common event occurring in 789 mothers (6.7%). The maternal platelet count did not predict neonatal thrombocytopenia, with only 4 of the 11 thrombocytopenic infants being born to thrombocytopenic mothers (positive predictive value 0.5%). There were 12 alloimmunized pregnancies resulting in one stillbirth and 6 infants with cord platelet counts $\leq 50x10^9/L$ (6,8,9,11,13,30). Three intrauterine bleeding events were associated with alloimmunization. Thirty mothers who had immune thrombocytopenic purpura (19 with thrombocytopenia) had 3 infants with cord platelet counts $\leq 50x10^9/L$ (21,36,49). There were 1040 hypertensive patients (162 with thrombocytopenia) and 2 of their infants had cord platelet counts $\leq 50x10^9/L$. None of the 590 mothers with thrombocytopenia not in these 3 groups had infants with cord platelet counts $\leq 50x10^9/L$. This study indicates: (a) maternal thrombocytopenia at delivery is not a predictor of neonatal thrombocytopenia; (b) neonatal cord platelet counts $\leq 50x10^9/L$ are rare; and (c) counts $< 20x10^9/L$ and intrauterine bleeding are only associated with alloimmunized pregnancies.

81 **THE SIGNIFICANCE OF ANTICARDIOLIPIN ANTIBODIES IN DIABETIC PREGNANCIES.** *S Rotmensch, EA Reece, M Liberati,* J Peipert,* J Garofalo,* M Breitenstein,* JC Hobbins. Depts OB/GYN and Rheumatology, Yale University*

Anticardiolipin antibody (ACA) is characteristically found in patients with autoimmune diseases and the primary "antiphospholipid antibody syndrome". Gestational and pregestational diabetes are also associated with increases in a variety of autoantibodies. We determined IgG and IgM ACA concentrations in 41 consecutive pregnant diabetics (Classes A, n=21; B, n=13,; C, n=7) using solid phase ELISA (>2SD above mean = positive). Elevated ACA concentrations were found in 32% (13/41; IgM = 2/13; IgG =11/13). No differences were found between ACA positive and negative patients in mean birthweight (3455±573 vs 3369 ± 772gm), gestational age at delivery 39.1 vs 38 wks), mean arterial pressure in all three trimesters (92.6 vs 90.3; 93.3 vs 93.0; 93.0 vs 95.9 mmHg), and platelet count (292,000 vs 287,000 per mm^3). No cases of deep vein thrombosis occurred. One patient in each group was delivered preterm due to early onset severe preeclampsia. Statistical power calculations confirmed adequacy of sample sizes for the detection of clinically meaningful differences. Two intrauterine demises occurred in the ACA negative group. **Conclusions:** Elevated ACA concentrations are frequent in diabetic pregnancies, with an incidence approaching that of patients with systemic lupus erythematosus. However, they are not associated with adverse maternal or fetal outcome.

82 INCREASED PLASMA LEVELS OF ENDOTHELIN-1 IN GRAVIDAS ABUSING COCAINE

J.D. Steinfeld[X], P. Samuels, M. Rhoa[X], D.B. Cines[X], and K.R. McCrae[X]
Depts. of Obstetrics & Gynecology, Medicine, and Laboratory Medicine, University of Pennsylvania, Philadelphia, PA

Cocaine abuse during pregnancy is often associated with maternal vascular complications including hypertension and abruption. We investigated the possibility that these complications may be mediated by the vasoactive peptide, endothelin-1 (ET-1). We measured the plasma concentration of ET-1 in 20 patients with acute cocaine intoxication, 20 normal gravidas, and 10 nonpregnant individuals. There were no significant differences in age ($p = 0.64$), gravidity ($p = 0.08$) or diastolic blood pressures ($p = 0.13$) between women using cocaine and healthy, pregnant controls. There were, however, significant differences in the systolic blood pressures (126 ± 18 vs 108 ± 9 mm Hg, $p < 0.01$), gestational age (31.6 ± 3.4 vs 37.5 ± 2.2 weeks, $p < 0.01$), and number of women presenting with evidence of abruption (11 vs 0, $p < 0.01$). No patient met clinical or laboratory criteria for preeclampsia. Plasma concentrations of ET-1 were determined in early labor (cervix dilated ≤ 3 cm) in both pregnant groups using a commercially available radioimmunoassay kit (Amersham). The mean (± SD) concentration of ET-1 in the gravidas with a positive screening assay for cocaine was 12.8 ± 6.2 fmol/ml compared with 5.8 ± 2.7 fmol/ml in the pregnant control group ($p < 0.01$) and 3:5 ± 2.2 fmol/ml in nonpregnant women ($p < 0.01$) The plasma concentration of ET-1 continued to rise in the 5 gravidas with cocaine abuse in whom additional samples were obtained, from a mean of 13.7 ± 6.9 fmol/ml in early labor to 16.2 ± 7.7 fmol/ml at 24 hours after delivery, and remained elevated 48 hours after delivery (13.7 ± 6.6 fmol/ml). In contrast, the concentration of ET-1 in 5 normal gravidas did not change significantly after delivery (5.8 ± 2.5 fmol/ml before delivery, 4.3 ± 0.57 fmol/ml and 3.9 ± 1.1 fmol/ml 24 and 48 hours after delivery, respectively). **Conclusion:** Thirteen of 20 (65%) women who presented with cocaine abuse and pregnancy complications had endothelin-1 levels > 2 SD above the mean for normal pregnant controls. The source(s) of this vasoactive peptide and its role in the pathogenesis of the vascular complications of cocaine abuse remain to be identified.

83 **IS FETAL PULMONARY MATURITY RELATED TO SIZE FOR GESTATIONAL AGE IN PREGNANCIES COMPLICATED BY DIABETES OR HYPERTENSION?** J. Piper,[X] O. Langer, Dept. Ob/Gyn, UTHSC, San Antonio, TX.

Fetal size for gestational age is influenced by maternal diabetes and hypertensive disorders. Alterations in fetal pulmonary maturity have also been attributed to these conditions. Thus, maternal hypertension of sufficient severity to cause fetal growth retardation should also cause the greatest acceleration of pulmonary maturity while the macrosomic infants of diabetic mothers should have the most marked delay of pulmonary maturation when compared to a control population. This hypothesis was tested on all patients undergoing an amniocentesis for maturity studies at this institution since 1986. More than 730 women have been entered thus far in this ongoing study. The associations between birth percentiles, gestational age and lung maturity are summarized below.

PERCENT WITH AN IMMATURE AMNIOCENTESIS

	Preterm (<37 weeks)			Term (≥ 37weeks		
	DM	Htn	Controls	DM	Htn	Controls
SGA	100%	38%	35%	39%	33%	17%
AGA	69%	34%	49%	17%	25%	3%
LGA	42%	–	62%	19%	–	25%
	n=82	*n=43*	*n=331*	*n=147*	*n=7*	*n=126*

This study reveals 1) infants of hypertensive mothers showed no significant acceleration of maturity when compared to controls, 2) preterm AGA infants of diabetic mothers had a significantly higher risk of pulmonary immaturity when compared to hypertensive mothers ($p < .003$) and control mothers ($p < .01$), 3) term AGA infants of diabetic mothers were significantly less mature than controls ($p < .004$) and 4) macrosomic infants of diabetic mothers however, were essentially identical to the LGA infants of women with negative glucose screening, perhaps reflecting a level of glucose intolerance not detected by current screening techniques. In summary, this study showed no effect of hypertension on pulmonary maturity and that the effects of diabetes on fetal size are unrelated to its effects on fetal lung maturity.

84 **DOES MATERNAL DIABETES DELAY FETAL PULMONARY MATURITY?** J.Piper,[X] O. Langer, Dept. Ob/Gyn, UTHSC, San Antonio, TX.

Diabetes in pregnancy has been associated with fetal pulmonary immaturity even at term gestation. Thus, confirmation of maturity has been recommended prior to delivery at ≤39 weeks gestation. We hypothesize that adequate glucose control will prevent the delay in fetal lung maturation as compared to the nondiabetic population. To test this hypothesis, all amniocenteses performed for fetal maturity since 1986 were reviewed and combined with the patients' obstetric data for analysis. To date, 231 diabetic patients and 461 nondiabetic, nonhypertensive patients have been enrolled. Adequate control was defined as mean blood glucose ≤ 105 mg. /dL. (self-monitored). Pulmonary maturity was defined as presence of phosphatidyl glycerol (PG) in diabetics and either presence of PG or Lecithin/Sphingomyelin (L/S) ratio ≥ 2/1 in the nondiabetic patients.

PERCENT WITH AN IMMATURE AMNIOCENTESIS

	Diabetics			Non-
Weeks	x≤105	x>105	Total	Diabetics
<34	90%	89%	91%	68%
34-36.9	43%	47%	51%	27%
37-37.9	26%	38%	32%	7%
38 38.9	8%	20%	15%	13%
≥39	13%	17%	15%	6%

The relative maturity for gestational age was not significantly different in the term diabetic patients than the nondiabetic patients tested. Although there was a trend toward delayed maturity in poorly controlled diabetics beyond 37 weeks, statistical significance was not achieved. In addition, of the 41 diabetic patients delivered within a week of an immature amniocentesis, there were no cases of hyaline membrane disease. In summary, confirmation of fetal lung maturity prior to elective delivery is recommended in all pregnancies prior to 38 weeks. The need for a more aggressive approach to the diabetic patient beyond 38 weeks, cannot be supported by the results of this study.

85 **RANDOMIZED TRIAL OF ELECTIVE INDUCTION VS EXPECTANT MANAGEMENT IN DIABETICS.** OA Henry[A], SL Kjos, M Montoro[X], TA Buchanan[X], JH Mestman[X]. Univ. of So. Calif., Los Angeles, CA

The increased risk of term stillbirth in diabetic pregnancies has promoted elective delivery at term. The purpose of our study was to assess whether the accompanying high cesarean (CS) rate could be reduced. Women with insulin-requiring diabetes in good glucose control, without vascular disease or macrosomia were randomized at 38 weeks to either scheduled induction (IND, N=100) or expectant management (EXP, N=100) with twice weekly ante-partum testing. Induction of labor for obstetrical or medical reasons occured in 49% of the expectant group. Cesarean rates were not different: IND (25%) vs EXP (31%). The mean additional days of gestation age gained by expectant management after study entry was 13 ± 6 (vs 6 ± 4 days in IND). 25 infants in EXP had birthweights > 90th percentile (LGA) vs 15 in IND (p=.05). There were no perinatal deaths, anomalies or differences in neonatal morbidity. In women with uncomplicated insulin-requiring diabetes managed expectantly, only 51% achieved spontaneous labor. Expectant management was not associated a reduction in CS rate or increased morbidity but was associated with more LGA infants.

86 **MANAGEMENT OF PATIENTS WITH INCOMPETENT CERVIX AND BULGING FETAL MEMBRANES.** S.J. Schorr[X], W.J. Morales, Orlando Regional Medical Center, Orlando, FL

During the period of January, 1985 - June, 1991, 45 patients were admitted with a singleton pregnancy < 24 weeks and cervical dilatation ≥ 2.0 cm consistent with a diagnosis of incompetent cervix. Twenty-five had bulging of fetal membranes through the cervix and of these 18 underwent emergency cerclage and the remainder followed expectantly with bed rest. Twenty patients had cervical dilatation with membranes visible at the level of the external os and of these 16 underwent emergency cerclage. The data summarized below indicate a very favorable outcome in patients without bulging membranes. In contrast, although 67% neonatal survivors were achieved by emergency cerclage in those patients with bulging membranes as compared to none managed conservatively, the median duration of pregnancy was 12 (2-94) days resulting in a median gestational age of 25.0 (22-36) week with a documented risk of serious mental and neurological handicaps of 30% at corrected one year of life.

	No	GA	Dilatation	Duration	Survivor
BULGING MEMBRANES					
Cerclage					
Yes	18	22.8	3.2	12 (2-94)	12
No	7	22.8	4.0	2 (1-5)	0
VISIBLE MEMBRANES					
Yes	16	22.3	2.2	50 (30-102)	14
No	4	23.8	3.0	52 (31-74)	4

87 **GESTATIONAL DIABETES AND TIMING OF TREATMENT: IS THERE A DIFFERENCE IN NEONATAL OUTCOME?** O. Langer, E. Xenakis,[x] M. Berkus, A. Samueloff,[x] B. Elliott,[x] Department of Ob/GYN, University of Texas Health Science Center at San Antonio, Texas.

Early in gestation genetic factors dominate changes in fetal growth. The major effects of fetal insulin on delayed or accelerated fetal growth occur late in gestation due to an abnormal (glucose) maternal-uterine environment. In this study, we tested the following hypothesis: In gestational diabetics (GDM) with an abnormal glycemic profile, delayed treatment will result in a higher incidence of macrosomia. 513 GDM women utilizing memory reflectance meters to test their blood glucose 7 times daily and treated under a strict protocol participated in the study. For analysis, they were stratified into early (mean = 27.8±7 weeks' gestation) and late-treated groups (mean=34.5±2 weeks' gestation). The incidence of abnormal fetal growth was:

	Late entry (n=116)	*Early entry (n=397)*	*RR*	*95% CI*
LGA	19.8%	10.1%	2.4	1.4-4.3
SGA	12.6%	8.6%	NS	NS

The study further revealed: 1) in good glycemic control (mean blood glucose <105 mg/dl) late entry patients had 16.7% LGA and early entry patients 4.9% (RR 2.43, 95% CI 1.7-8-7); 2) in contrast, in poorly controlled patients (mean blood glucose >105 mg/dl) the incidence of LGA was similar in both late (28.9%) and early (21.1%) entry groups; and 3) the incidence of LGA/SGA was comparable for the diet only and insulin treated women within both groups. Therefore, prevention of macrosomia requires early timing of treatment as well as good glycemic control.

88 **THE RELATIONSHIP BETWEEN HOME GLUCOSE MONITORING, DATA VERIFICATION AND LEVEL OF CONTROL IN GDM OUTCOME: YOU CANNOT HAVE ONE WITHOUT THE OTHER.** O. Langer, A. Samueloff,[x] M. Berkus, E. Xenakis,[x] Department OB/GYN, Univ. Texas Health Science Center at San Antonio, TX.

Although failure to achieve glycemic control is axiomatically associated with adverse outcome, the majority of studies continue to report a 30% incidence of macrosomia. Controversy also persists regarding the appropriate method of glucose evaluation. We sought to investigate the impact of different methods of glucose assessment on glycemic control and fetal outcome. 2 groups of gestational diabetics (GDM), comparable in age, prepregnancy weight, height and parity were studied Evaluation of Group I (n=1545) was weekly fasting and 2 h postprandial during clinic visits and 4 daily visual glucose strip determinations by the patient. Group II (n=521) utilized memory reflectance meters (7 times daily) to assure accurate and reliable glucose data. The treatment goal in all patients was a blood sugar <105mg/dl.

	Group I	*Group II*	*RR*	*95% CI*
LGA (≥90th %)	27.5%	11.7%	2.86	2.1-3.8
≥4000gm	13.9%	6.3	2.4	1.6-3.5
SGA (≤10th %)	12.9%	12.7%	NS	NS
≤2500gm	6.2%	9.6%	1.6	1.2 2.3

The study further revealed: 1) Group I diet (26.9%) and insulin-treated (28.7%) patients had the highest LGA risk when compared to Group II (RR 4.9, 95% CI 2.10 and RR 5.7, 95% CI 3.3 9.8, respectively); 2) the incidence of SGA was comparable in diet and insulin treated subjects for group I (13.0% vs. 13.5%) and Group II (12.9% vs. 12.3%); 3) despite patient reported near normal mean fasting and 2 h blood glucose for Group I, a 23% incidence of LGA persisted, 36.6% LGA was found in the poorly controlled subjects; and 4) in contrast, in Group II, a 3 fold higher rate of LGA was found in poorly controlled (MBG >105mg/dl) when compared to near normal glycemia (MGB <105mg/dl) 6.6% vs. 21.8%, RR 3.9, 95% RI 2.3 6.8 Because level of glycemia is clearly related to neonatal size it is imperative to verifiy the true level of glycemia, especially when self monitoring of blood glucose is utilized.

89 **GESTATIONAL DIABETES AND INFECTION: AN INFANT AND NOT MATERNAL COMPLICATION.** O. Langer, M. Berkus, A. Samueloff, E. Xenakis,[x] N. Field,[x] Dept. OB/GYN, University of Texas Health Science Center at San Antonio, Texas.

Diabetes in non-pregnant women (characterized by severe glucose abnormality) has been associated with a high incidence of infection and resulting morbidity. In contrast, there is a dearth of information regarding gestational diabetes (GDM) represented by milder glucose abnormality and infection. Therefore, we sought to investigate thea relationship between GDM and infection. 1740 consecutive gestational diabetic women and 24500 non-diabetic controls were randomly selected from our data base. The 2 groups were comparable in infection-related factors such as maternal age, parity, duration of labor, time from rupture of membranes to delivery and incidence of internal FHR monitoring. To control for method of delivery, each of the 2 groups was stratified into vaginal (VAG), instrumental (INSTR) and cesarean section (C/S) and measured for infection variables.

	DIABETIC (n = 1740)			*NON-DIABETIC (n = 24500)*		
	VAG	*INSTR*	*C/S*	*VAG*	*INSTR*	*C/S*
Neonatal infect	4.0	12.3	8.4	4.0	7.2	10.0
Maternal infect	2.5	3.7	23.6*	2.1	4.0	32.3
Endometritis	2.4	3.7	19.0*	2.0	4.6	26.8
Wound infect	0.1	0	4.6	0.1	0.2	5.5
Chorioamnionitis	1.5	2.5	3.8	1.1	2.3	4.8
Pylonephritis	8.3	8.6	13.5*	7.9	9.4	9.3

*Significant ($p < .01$) between the groups for a given category; all others N.S.

The study further revealed: 1) when augmentation subjects were compared to spontaneous vaginal deliveries, a 3-fold higher risk for maternal infection was found in both groups; 2) the incidence of fetal distress, 5-min Apgar score <7, neonatal death and pneumonia were significantly higher in diabetic fetuses with infection when compared to non-diabetic fetuses; and 3) within each group, fetal morbidity and mortality was significantly higher in the infection population. Pregnant diabetics are not at higher risk to develop infection in comparison with the general population. In contrast, the maternal disease may be the catalyst for fetal infection and the resultant morbidity.

90 **PLATELET AGGREGABILITY IN PREGNANT DIABETICS IS CORRELATED WITH GLYCEMIC CONTROL BUT NOT DURATION OF DISEASE.** RD Jelsema[x], MC Eustice[x], SF Bottoms, and EF Mammen[x]. Wayne State Univ./Hutzel Hosp., Detroit, MI

Platelet hyperaggregability among non-pregnant diabetics has been demonstrated using whole blood aggregometry. This could be due to vasculopathy, but we have recently reported evidence suggesting glycemic control may be responsible. To clarify the roles of vasculopathy and glycemic control, we studied 14 non-diabetic pregnant controls, 7 insulin dependent gestational diabetics (GDM), and 24 diabetics with disease predating pregnancy (IDDM, mean duration 9.1 years). Platelet aggregability and ATP release in whole blood in response to ADP, collagen, and arachidonic acid were measured using a Chronolog® Lumi-aggregometer. Glycated hemoglobin was measured and glycemic control was categorized as good, intermediate, or poor based on fasting blood sugar. The GDM and IDDM groups had higher platelet aggregability than pregnant controls (MANOVA, $p<0.005$). There was no difference in aggregability between GDM and IDDM, and no significant relationship to the duration of diabetes. Among diabetics, canonical correlation of glycated hemoglobin and glycemic control to ATP release in response to ADP and collagen accounted for 34% of total variance ($p<0.005$). These findings are consistent with a prior study demonstrating increased platelet clumping in whole blood with the addition of glucose that was inhibited by apyrase, an ADP removing enzyme. We conclude that platelet hyperaggregability among pregnant diabetics is related primarily to glycemic control rather than duration of diabetes, which is in turn related to vascular disease.

91 **AFFINITY CHROMATOGRAPHY: EXCELLENT CORRELATION WITH HgbA1c.** RD Jelsema[x], MP Dombrowski, and SF Bottoms. Wayne State Univ., Hutzel Hospital, Detroit, MI.

Counseling diabetics for risk of fetal anomalies is based exclusively on studies using older techniques such as ion exchange column HgbA1c (intra- and inter-assay variation 4% and 6%). Newer affinity chromatography (AC) methodology has the following advantages: 1) greater precision (intra- and inter-assay variation < 3%), 2) measures all glycated Hgb, not just glycated A or A1c, 3) does not measure nonglycated Hgb variants S,C,F, and 4) is faster and less expensive. Correlation of these two methods in pregnant diabetics has not been reported. We prospectively performed both tests on blood samples from 83 pregnant diabetics over a period of 6 months. Using only the first determined level for each patient, and excluding all patients with hemoglobinopathies, 78 samples remained. The mean gestational age (GA) was 21 weeks, with 11 samples from the 1st trimester. Stepwise regression analysis was performed with HgbA1c as dependent, and GA and AC as independent variables. AC was highly correlated with HgbA1c ($r = 0.92$), regardless of GA, which had no significant effect. The regression equation was: HgbA1c = 0.66 x AC + 2.7. Using this formula, Ylinen's critical HgbA1c of 10% corresponds to an AC of 11%. Based on these results and the other advantages of AC outlined above, we recommend its use in diabetic pregnancy.

92 **EFFECT OF SUBSTANCE ABUSE REPORTING LAWS ON COCAINE USE IN SUBSEQUENT PREGNANCIES**
Lupo, V.R., and Kapernick, P.S. *
Hennepin County Medical Center, Minneapolis, Minnesota

Since 1987, all women at Hennepin County Medical Center delivering babies exposed to cocaine during pregnancy have been reported to the county Child Protective Services, for assessment, intervention and optional chemical dependency therapy. In 1988 and 1989, 176 women or their babies tested positive for cocaine at delivery. When these women presented for prenatal care in a subsequent pregnancy, they were prospectively identified and followed by social services and obstetrics for evidence of continued substance abuse. As of August 15, 1991, 43/176 women had completed another pregnancy at our institution. Maternal charts were reviewed and demographic data as well as pregnancy outcome were recorded. 3/45 women (7%) had no known substance abuse in pregnancy. 23/45 (51%) again tested positive at delivery for cocaine. 15/45 (33%) tested negative for cocaine at delivery but had documented use in pregnancy and 4/45 women (9%) had no evidence of cocaine use in the subsequent pregnancy but had documentation of heavy alcohol use. Of the 42 non-sober women, 15/42 (36%) delivered babies weighing <2500 grams, 15/42 (36%) delivered prior to 37 completed weeks gestation, 6/42 (14%) had no prenatal care and 31/42 (74%) had <7 prenatal visits. 10/23 (43%) positive at delivery had participated in some form of voluntary chemical dependency treatment since their previous delivery. 4/15 women who had used cocaine in pregnancy but were negative at the time of delivery were active in treatment programs at the time of delivery. We regretfully conclude that notification of child protective services and offering optional chemical dependency treatment does not appreciably alter substance abuse in future pregnancies. States considering implementation of mandatory substance abuse reporting laws such as the 1989 Minnesota law should consider this information. A more intensive program of child protective intervention including use of court-ordered chemical dependency treatment is now being implemented and its impact on recidivism must be assessed.

93 MATERNAL AND PERINATAL OUTCOME OF 18 CASES OF ADULT RESPIRATORY DISTRESS SYNDROME (ARDS) IN PREGNANCY.

B. Mabie, J. Barton,[X] B. Sibai. University of Tennessee, Memphis.

There is limited information available regarding maternal and perinatal outcome in pregnancies complicated by ARDS. The purpose of this clinical investigation is to report our experience with ARDS in patients managed in an Obstetric ICU at a tertiary care center. Patients and Methods: The study population consisted of 18 patients who developed ARDS in pregnancy or immediately postpartum in a 6-year period during which there were 47,200 deliveries. Results: The incidence of ARDS was 1 in 2,662 deliveries. Infection was the most frequent cause of ARDS (11/18, 61%) including pneumonia (4 varicella, influenza A, and pneumococcus), pyelonephritis (n=4), and chorioamnionitis (n=1). Other causes of ARDS were preeclampsia-eclampsia (n=3), massive hemorrhage (n=2), TTP (n=1), and smoke inhalation (n=1). Fifteen of 18 patients required mechanical ventilation (mean 13.5, range 3-54 days). Pneumothorax occurred in 7 patients; multiple organ failure developed in 10 patients. Maternal mortality was 39%. There was 1 ectopic pregnancy and 2 spontaneous second trimester abortions. Of 15 pregnancies that reached viability (≥24 weeks' gestation), 4 fetuses died (fetal distress secondary to maternal shock, trisomy 18, abruptio placenta, and uterine rupture). Of 11 surviving infants, 9 did well and 2 had major morbidity. Outcome of the 15 patients requiring mechanical ventilation is shown in the table below. Conclusions: ARDS is an uncommon complication of pregnancy with diverse etiologies and substantial morbidity and mortality. Multiple organ failure is associated with poor maternal and perinatal outcome.

	Respiratory Failure Only (n=5)	Multiple Organ Failure (n=10)
Maternal death #(%)	1 (20)	6 (60)
Days ventilation (mean)	6 (range 3-9)	17 (range 3-54)
Perinatal deaths #(%)	1 (20)	2/7 (29)*
Neonatal morbidity	0	2/5 (40)

*1 ectopic, 2 spontaneous abortions

94 PREECLAMPSIA IN HYPOTHYROID PREGNANCIES.

Anna S Leung MD,* Martin N Montoro MD,* Jorge H Mestman MD.* University of Southern California, Los Angeles, California.

The purpose of this study was to investigate the relationship between hypothyroidism and preeclampsia. A cohort of 97 hypothyroid pregnant patients were evaluated in our medical specialty clinic between 1978-1990. Patients with any other medical complications were excluded. Initial and subsequent thyroid function studies were obtained. Overall, the incidence of preeclampsia was 12.3% (12/97). Comparison was made between the patients with (P) and without preeclampsia (no P).

	P(N=12)	no P(N=85)	Pvalue
age	26.9	29.7	N.S.
parity	1.6	1.6	N.S.
initial FT4I	5.7	7.5	N.S.
initial TSH (mIU/ml)	72.4	24.5	0.0038
FT4I prior to delivery	6.2	10.0	0.0002
TSH prior to delivery (mIU/ml)	41.5	5.5	0.0000
No. positive antimicrosomal antibody	2	37	N.S.
No. positive antithyroglobulin antibody	2	26	N.S.
No. positive TSH receptor antibody	1	8	N.S.
No. never euthyroid during pregnancy	8	20	0.006

Preeclampsia was more likely to occur in patients who were more hypothyroid on presentation and remained hypothyroid at delivery. The presence of antimicrosomal, antithyroglobulin, and TSH receptor antibody was not a significant factor. The correction of hypothyroidism is essential in the management of these patients.

95 CHALLENGING THE NORMAL GLUCOSE CHALLENGE TEST: Zion Hagay[X], Gil Bolotin[X], Roni Levy[X], Vaclav Insler[X], E. Albert Reece*, Departments of Ob/Gyn, Kaplan University Hospital, Israel and Temple University School of Medicine, Philadelphia, PA*

The most widely used screening test for gestational diabetes is the 50 gr oral glucose load. A threshold value of 140 mg/dl or higher is recommended for use as a positive test, requiring a 3-hour oral glucose tolerance test. However, it remains unclear whether minimal glucose elevation even in this normal range is associated with perinatal complications. The purpose of the present prospective study was to determine whether a single glucose challenge test (GCT) result, currently considered to be in the normal range is associated with pregnancy complications. MATERIALS AND METHODS: A total number of 225 consecutive pregnant patients who underwent 50 gr oral GCT and who had negative test results (plasma glucose level of 139 mg/dl or less at 1 hour) were evaluated. All 225 patients were identified based on the following criteria: 1. Plasma glucose determinations performed at 24-28 weeks gestation. 2. Patients had one or no previous deliveries. 3. No previous history of cesarian section or gestational diabetes or any medical disorders. The 225 patients were divided into two groups according to their blood glucose level, Group A (n=221), women with plasma glucose levels less than 120 mg/dl, Group B (n=54), those with plasma glucose level of 120-139 mg/dl. RESULTS: Mean birth weight was not significantly different between the two groups (3,252±410 gr vs. 3,304±382 gr). Patients with elevated GCT, although in the normal range, had a significantly higher rate of cesarean section, preeclampsia or both (12.2% and 31.2% in Group A and B respectively) ($p<0.05$). Furthermore, minor congenital anomalies were also significantly ($p<0.05$) higher in Group B (9.3%) than in Group A (4%). CONCLUSION: The results of this study demonstrate that even mild degrees of hyperglycemia at the time of GCT can be associated with higher rates of adverse pregnancy outcome. Hence, the present data challenge the utility of the current threshold value for the GCT.

96 ACCELERATED FETAL GROWTH FOLLOWING EARLY GROWTH DELAY IN INSULIN-DEPENDENT DIABETIC PREGNANCIES.

T.A. Siddigi, B. Rosenn, J. Khoury,* M. Miodovnik, Dept. Ob/Gyn, Univ. Cincinnati Med. Ctr., Cincinnati, OH

Although macrosomia is a common complication in infants of diabetic mothers (IDMs), early fetal growth delay has been observed in insulin-dependent diabetic (IDD) pregnancies. This prospective longitudinal study was designed to establish fetal growth characteristics of IDMs compared to normal controls. Twenty-five IDDs and 32 normal, non-diabetic controls were recruited prior to 12 weeks' gestation. Gestational age (GA) was established by menstrual history and first trimester sonogram and confirmed at birth by physical examination. Patients in both groups underwent a complete ultrasound examination of the fetus during the first trimester and every 4 weeks from 20 weeks' gestation until delivery. Growth curves of the biparietal diameter (BPD) and abdominal circumference (AC) were established for fetuses in both groups. A biphasic growth pattern of the BPD was found in the IDM group, described by the cubic equation: $BPD = 9.64 - 1.01\ GA + 0.05\ (GA)^2 - 0.00068244\ (GA)^3$. BPD growth in the control group was described by a different cubic equation: $BPD = 5.769 - 0.5957\ GA + 0.03826\ (GA)^2 - 0.000532\ (GA)^3$. Compared to the growth pattern of normal controls, IDMs demonstrated early BPD growth delay followed by accelerated growth starting early in the third trimester. The AC growth pattern was linear in both groups, with a steeper slope in the IDMs. Thus, despite initial growth delay of AC in the IDM group, catchup with the control group was evident by the middle of the third trimester. Our findings support the suggestion that fetal growth in IDD pregnancies is biphasic, characterized by a phase of early delay followed by accelerated growth; however, the mechanisms underlying this phenomenon are yet to be determined. We speculate that the initial toxic effect of hyperglycemia causing stunted growth of the embryo is later followed by the effects of hyperinsulinism, once the fetal pancreas maturates and becomes metabolically active.

97 MATERNAL-PERINATAL OUTCOME IN WOMEN WITH CARDIAC DISEASE.

N. Meyer,[X] B. Sibai, B. Mercer,[X] A. Khoury,[X] R. Brazzel,[X] G. Portera.[X] University of Tennessee, Memphis.

The purpose of this study is to report maternal and perinatal outcome in pregnancies complicated by maternal cardiac disease. The study population included 54 women with documented cardiac disease prior to the onset of pregnancy. Eight women had various cardiac arrhythmias, 5 had mitral valve prolapse. These 13 women had 14 pregnancies at term without maternal complications. Three women had aortic insufficiency; 1 developed pulmonary edema during labor. Two women had tetralogy of Fallot; both pregnancies resulted in live full term babies; however, 1 patient developed postpartum left middle cerebral artery embolus. Two patients with myocardial infarction delivered 3 liveborn infants without any maternal complications. Pregnancy outcome in the remaining 30 women is summarized in the table. Conclusions: proper management of women with cardiac disease results in good maternal/perinatal outcome. However, women with tricuspid atresia and/or pulmonary hypertension and cardiomyopathy remain at increased risk for maternal morbidity and mortality.

	ASD/ VSD n=15	Aortic/ pulmonic stenosis n=8	Tricuspid atresia Pulm.HTN n=4	Cardio- myo- pathy n=7

98 PERINATAL OUTCOME AND DIABETES MELLITUS

L.B. Curet, L. Izquierdo, G. Gilson, M. Chatterjee, G. Del Valle, G. Joffe, D. Jones[x], M. Vill[x], Dept. of OB/GYN, University of New Mexico, Albuquerque, NM

125 insulin dependent patients were cared for during their pregnancies according to the following protocol: Diet: 24-30 calories/kg b.w., 20% as protein, 50% as CHO, 30% as fat, 3 meals and 3 snacks/day. Insulin 0.5-1.0 u. Reg insulin/kg b.w. with 40% before breakfast, 30% before lunch, 20% before supper and 10% at bedtime. 2-4 u. NPH h.s. Exercise: aerobic at least 3 times/week. Glucose determinations: fasting and 2-hour post prandials at least 3 times/week. Goal: Maintain FBS and 2-hour p.p. below 150 mgm/dl. Results: Mean b.g. by trimesters-first: 143 mgm/dl 2d:131 3d:131. Mean FBS-144 mgm/dl, post breakfast-146, post lunch-116, post supper-125. B.W. >4 kg-11%. Neonatal hypoglycemia-9%. Incidence of Iga with mean b.g. 120:17%, with b.g. 120-150: 30%, with b.g.>150:30%. Perinatal mortality: 3.1%, due to anomalies: 3/7 (43%).

Conclusion: 150 mgm/dl is an adequate endpoint with acceptable perinatal mortality/morbidity and a low incidence of maternal hypoglycemia. The size of the neonate is significantly lowered only if the maternal b.g. is kept below 120 mgm/dl. Preconceptional control seems mandatory to minimize congenital malformations and perinatal mortality.

99 PERINATAL OUTCOME IN PREGNANCY COMPLICATED BY MASSIVE OBESITY

Perlow JH[X], Montgomery DM[X], Morgan MA, Towers CV, Porto M
Long Beach Memorial Womens Hospital, Long Beach, California
University of California, Irvine Medical Center, Orange, CA

The purpose of this study was to evaluate the impact of massive obesity on pregnancy outcome. Between 1/1/86 and 12/31/90, women weighing >300 lb at delivery (n=111, 0.43% incidence) comprised the study group (G1). To control for confounding variables, another group (G2) was comprised of the massively obese patients without the complications of diabetes and/or hypertension. A control group (CG, n=112) matched for maternal age and parity, was consecutively selected following each case delivery. Perinatal outcome was analyzed between groups and is demonstrated below.

Outcome	%G1 n=111	%CG n=112	%G2 n=86	P values G1 v CG	G2 v CG
1° Cesarean	32.4	15.1	19.5	.0004	NS
BWT > 4kg	30.2	11.3	14.6	.0005	NS
BWT < 2.5kg	14.7	3.8	3.7	.008	NS
IUGR	8.1	0.9	4.9	.03	NS
NICU ADMIT	15.5	4.7	4.9	.01	NS
Preeclampsia	4.5	0.0	4.9	.07	NS
Class B DM	19.8	2.7		.00006	
Class A DM	5.4	0.9		NS	
Hypertension	27.0	0.9		.0001	

Conclusion: Massively obese patients without confounding medical complications had a pregnancy outcome similar to controls. These data may be useful in preconceptual and prenatal counseling, and in perinatal management of the massively obese patient.

100 SEVERITY OF ASTHMA AND PREGNANCY OUTCOME: A CASE CONTROL STUDY

Perlow JH[X], Montgomery DM[X], Morgan MA, Towers CV, Porto M
Long Beach Memorial Womens Hospital, Long Beach, CA
University of California Irvine Med Center, Orange, California

Between 1/1/81 and 12/31/90, 183 patients delivered who had the diagnosis of asthma (incidence 0.59%). 81 patients were identified as requiring medication control (ie steroids, theophylline, betamimetics, etc.) throughout pregnancy. These patients included 50 non-steroid dependent asthmatics (NSA) and 31 steroid dependent asthmatics (SA), and were compared with a group of 130 randomly selected patients (CG), excluding maternal transports. All three groups were similar for BWT <1500 gm, low 5 minute Apgar, IUFD, hypertension, preeclampsia, and anomalies. The remainder of perinatal outcome analysis is demonstrated in the table below:

Outcome	%SA n=31	%NSA n=50	%CG n=130	P values SAvNSA	SAvCG	NSAvCG
BWT <2500 gm (LBW)	45.2	14.0	4.6	<.01	<.01	.06
Deliv. <37wk (PTD)	54.8	14.0	3.9	<.01	<.01	.03
Preterm Labor (PTL)	48.4	10.0	1.6	<.01	<.01	.03
PROM	25.8	10.0	1.6	NS	<.01	.04
C/S Distress	16.1	14.0	1.6	NS	<.01	<.01
Class A_2 Diabetes	9.7	4.0	.78	NS	.03	NS
Class B Diabetes	6.9	2.0	0	NS	.04	NS

These data suggest that medication dependent pregnant asthmatics are at increased risk for perinatal morbidity. Risk factor counseling, preterm labor prevention and assessment, and early screening for diabetes should be considered.

101 OUTCOME OF PREGNANCY IN PATIENTS WITH PREEXISTING RENAL DISEASE. TK Sorensen,[X] TR Easterling, TJ Benedetti. University of Washington Medical Center, Seattle.

Thirty pregnancies in 27 patients with chronic renal disease were reviewed. Chronic renal disease was defined as serum creatinine ≥ 1.2 mg/dl or creatinine clearance < 90 ml/min during pregnancy or urine protein > 3 gm/24 hours. 5 patients had severe disease with serum creatinine > 2.5. Cardiac output was measured by Doppler technique.

Low birth weight (<2500 gr)	63%
premature (<37 wks)	63%
growth retarded (SGA)	44%
Chronic hypertension	92%
Preeclampsia	50%
Fetal distress	40%
Cesarean section	53%
Perinatal loss (after 2nd trimester)	17%
Anomalies	3%

Five of 6 (82%) diabetics had markedly elevated cardiac output in contrast to an underlying hemodynamic pattern of elevated total peripheral resistance in 60% of the remaining patients; pregnancy outcomes in the diabetics were similar to the group as a whole. Three of the 5 patients with severe disease had detioriation of disease requiring dialysis during pregnancy. In conclusion, our patients did not appear to have an increased rate of fetal anomalies, but were at high risk for prematurity, growth retardation, fetal distress, operative delivery, and preeclampsia. Renal function worsened only in patients with severe disease.

102 GESTATIONAL DIABETES SCREENING: RELATIONSHIP OF NON-FASTING PLASMA GLUCOSE AND 50 GM GLUCOSE CHALLENGE TEST VALUES TO TIME FROM THE LAST MEAL. Sermer M[X], Naylor CD[X], Farine D, Cohen H, Ritchie JWK, Gare D[X], Kenshole A[X], McArthur K[X], Biringer A[X], Holzapfel S[X]. University of Toronto Perinatal Complex, Toronto, Ontario, Canada

Background: Use of Non-Fasting Plasma Glucose [NFPG] as a screening test for Gestational Diabetes [GD] has been suggested, but variability in relation to meals is a concern. Glucose Challenge Test [GCT] has the advantage of a standard glucose load but might also be variable among non-fasting subjects. Objective: Assess influence of time since last food ingestion (to nearest hour) on NFPG and non-fasting GCT values. Setting: Three Toronto teaching hospitals. Subjects: 1318 consenting, consecutive patients, age 24 and over had NFPG and GCT at 26 wks gestational age. Time from the last meal was obtained. Of these 1199 (91%) went on to Oral Glucose Tolerance Test. National Diabetes Data Group criteria was used to define GD. Results: Mean age was 31 yrs with median G2-P1 status. Mean NFPG and GCT results (mmol/L) are shown by time since last meal.

Time	GCT	SE	NFPG	SE
1	6.61	0.091	5.11	0.058
2	6.41	0.077	4.73	0.047
3	6.39	0.090	4.54	0.047
4	6.89	0.152	4.32	0.065
5	7.02	0.131	4.28	0.043

ANOVA showed highly significant (p<0.0001) time-effects in both cases. For NFPG, using Tukey's studentized range test, all pairwise differences were significant at p<0.05 except 3v. 4h. and 4v. 5h. For GCT, the non-monotonic influence of time meant that only the 5v. (1,2,3) and 4v. (2,3) comparisons were significant.

Conclusions: Both NFPG and non-fasting GCT are highly influenced by time from the last meal. The monotonic relationship for NFPG contrasts strikingly with the J-shaped curve for GCT. Although sample size is still limited for proving definitive differences, ROC curve analysis supports the hypothesis that cut-point for non-fasting GCT should vary according to the time since the last meal. Analysis of additional 1700 patients will be completed by December 1991. Continuation to 4000 subjects is planned.

103 GESTATIONAL DIABETES SCREENING TEST PERFORMANCE REVISITED: INTERIM INSIGHTS FROM A PROSPECTIVE STUDY. Sermer M[X], Naylor CD[X], Farine D, Cohen H, Ritchie JWK, Gare D[X], Kenshole A[X], McArthur K[X], Biringer A[X], Holzapfel S[X]. University of Toronto Perinatal Complex, Toronto, Ontario, Canada

Background: Not since work by O'Sullivan have screening tests for Gestational Diabetes [GD] been fully appraised by attempting to administer a 100 gm Oral Glucose Tolerance Test [OGTT] to all subjects regardless of screening test results. Objective: Assess and compare GD screening performance of Non-Fasting Plasma Glucose [NFPG] and 50 gm Glucose Challenge Test [GCT], using National Diabetes Data Group criteria. Setting: Three Toronto teaching hospitals. Subjects: 1318 consenting, consecutive patients, age 24 and over had NFPG and GCT at 26 weeks gestational age. Of these 1199 (91%) went on to OGTT; they were similar to non-compliant subjects and the general obstetrical population. Results: Mean age was 31 yrs, with median G2-P1 status. Incidence of GD was 4.3%. Results (in %) are shown by NFPG and GCT cut-points (mmol/L):

GCT	6.8	7.0	7.2	7.4	7.6	7.8	8.0
Sens.	90	88	80	80	77	77	75
Spec.	58	65	69	73	77	79	82
PPV	9	10	10	12	13	15	17
NPV	99	99	99	99	99	99	99

NFPG	4.0	4.2	4.4	4.6	4.8	5.0	5.2
Sens.	94	92	82	78	65	63	51
Spec.	18	31	44	55	63	71	77
PPV	5	6	6	7	7	9	9
NPV	99	99	99	98	98	98	97

Conclusions: Balancing false positive [FP] and false negative [FN] rates, NFPG is clearly inferior to GCT. However, even the GCT has a large and significant 23% FN rate (1-sens.) with the standard 7.8 mmol/L cut-point. PPV of GCT and NFPG is poor, due to low prevalence and a high FP rate. Sample size is too small to rule out equivalence of NFPG and GCT, once NFPG is adjusted for time from the last meal, but current data are not promising. Analysis of additional 1700 patients will be completed by December 1991. Continuation to 4000 subjects is planned.

104 A COMPARISON OF PTU VERSUS TAPAZOLE IN THE TREATMENT OF HYPERTHYROIDISM

D. Wing, MD[X], L. Millar, MD[X], P. Koonings, MD[X], M. Montoro, MD[X], J.Mestman, MD[X]
University of Southern California, Los Angeles

We compared the efficacy of PTU and Tapazole in the treatment of hyperthyroidism in pregnancy. Between 1974 and 1990, 153 hyperthyroid patients were medically managed in our clinic. A total of 129 charts (84%) were retrieved. Of these, 95 patients were treated with PTU and 34 were treated with Tapazole. The time to remission with PTU and Tapazole was not statistically different. Twenty six of the 95 (27%) treated with PTU remained hyperthyroid; while 9 of the 34 patients (26%) treated with Tapazole remained hyperthyroid. Treatment with PTU or Tapazole reflecting a euthyroid state decreased the incidence of LBW infants equally in both groups. PTU was discontinued in two patients secondary to rash. The incidence of major congenital malformations was 3% in both groups. One tapazole exposed infant had an inguinal hernia. The anomalies seen with infants exposed to PTU included: VSD, pulmonic stenosis, and a PDA in a term infant. No scalp defects were seen in Tapazole exposed infants. In summary both PTU and Tapazole are equally efficacious in treating hyperthyroidism and have comparable fetal outcomes.

105 **LEFT VENTRICULAR (LV) SYSTOLIC (S) AND DIASTOLIC (D) FUNCTION IN PREGNANT PATIENTS WITH SICKLE CELL ANEMIA (SCA).** J.C. Veille, R. Hanson, Dept. of Ob/Gyn, Bowman Gray School of Medicine, Winston-Salem, NC

Patients with SCA may have a cardiomyopathy secondary to chronic anemia. The cardiovascular stress of pregnancy may compromise LVS and D function. Echocardiograms were done on 13 SCA (SS and SC) patients and compared to 20 normal pregnant patients. All studies were done in the third trimester (X GA 34 ± 2 weeks), with the patients in the left lateral decubitus. Results are expressed as X and SD; ANOVA test was used to determine statistical analysis.

HRs = 84.6 ± 11	EDDs = 52.1 ± 6	LAs = 38.4 ± 6
HRc = 87.6 ± 12	EDDc = 48.8 ± 4	LAc = 31.4 ± 6
p = NS	p < 0.02	p < 0.005
FSs = 38.6 ± 7	SVs = 88.5 ± 2.4	DDDTs = 11.7 ± 2
FSc = 37.3 ± 6	SVc = 66.6 ± 2.0	DDDTc = 9.0 ± 2
p = NS	p = 0.002	p = 0.001

(Legends: EDD=end diastolic dimension (mm); LA=left atrium (mm); FS=fractional shortening (%); SV=stroke volume (ml); DDDT=diastolic relaxation); s=sickle cell; c=control. Results: 1) No difference in HR and FS were found between the two groups; 2) Left ventricular and atrial dilatation was present in the SCA group; 3) Stroke volume was significantly increased in SCA; 4) Left ventricular relaxation was abnormal in the SCA group. Conclusions: In the presence of a chronic medical condition which decreases oxygen-carrying capacity, pregnant patients with SCA have a greater cardiac dilatation than the pregnant control. Even though systolic function is preserved, diastolic stiffness may compromise cardiac function in strenuous periods, one of those being active labor. (Supported in part by NIH Grant HL38296).

106 **DOES VARIATION EXISTS BETWEEN 100 GM VS. 75 GM OGTT?** L. Brustman,[x] B. Gela,[x] M. Moore,[x] K. Reilly,[x] O. Langer.[*] Depts. OB/GYN, Our Lady of Mercy Medical Center, Bronx, New York, *University of Texas Health Science Center at San Antonio, Texas.

Recently it was proposed (3rd International Workshop on Gestational Diabetes-Chicago) that the 75gm challenge test should replace the traditional 100gm OGTT load. Paucity of data exists regarding the variation between the 2 tests, translation criteria and association to fetal outcome. We set out to investigate, in an ongoing study, the variability in 75gm oral glucose tolerance test in comparison to 100gm OGTT. 23 subjects participated in the study in which each patient served as her own control performing 75 and 100gm OGTT within 1 week. Plasma glucose levels were measured by the Beckman Autoanalyzer which has been shown to have high (99%) test/retest reliability. The results are shown in the table below:

	100g OGTT	*75g OGTT*	*P*	*r (100g vs 75g)*
Gestational age (wks)	30.7 ± 3.0	31.1 ± 3.2	NS	
Fast (mg/dl)	88 ± 16	80 ± 16	.006	0.72
1 hour (mg/dl)	179 ± 47	169 ± 45	.01	0.92
2 hour (mg/dl)	159 ± 45	141 ± 42	.02	0.72
3 hour (mg/dl)	118 ± 42	97 ± 33	.002	0.75

9/23 women were diagnosed as gestational diabetics (GDM) using the modified O'Sullivan criteria (NDDG, 100gm load, ≥ 2 abnormal values). In contrast, only 4 of these 9 would have to be identified by the 75gm load using the same threshold in diagnostic criteria (as the 100gm load). Furthermore, the 5 subjects that were not diagnosed as GDM had 1 abnormal value on their test results. Our data suggest that despite the strong association between the 2 glucose loads, significant variation exists in the test results. Thus in order for 1 test to approximate a mirror image of the other, new thresholds of glucose abnormality need to be developed.

107 FETAL SEX AND HYPEREMESIS GRAVIDARUM. C.D. Hsu*, Frank R. Witter, Dept. Gyn/Ob. The Johns Hopkins University School of Medicine, Baltimore, MD.

Background: The cause of hyperemesis gravidarum remains largely undetermined and debated. It has been suggested that elevated human chorionic gonadotropin (hCG) or estradiol level is associated with hyperemesis gravidarum. A fetal sex related effect on hCG concentration in singleton and twin pregnancies has also been reported. Pregnant women carrying singleton female fetuses or twin female-female, female-male fetuses have higher hCG levels than male fetuses. The purposes of this study was to determine if pregnant women with hyperemesis gravidarum were carrying a higher incidence of female fetuses. Materials and Methods: We retrospectively studied ninety-two singleton hyperemesis gravidarum patients admitted to our antepartum institution over tens years period (1980 - 1990). Sixty-six out of ninety-two fetuses could be traced by delivery records or personal contacts through telephone calls. Results: In hyperemesis gravidarum women, forty-four female fetuses and twenty-two male fetuses were identified. The ratio of male to female fetuses was 1:2. In our population group, the ratio of male to female fetuses was 1:0.95. This female fetal predominance in patients with hyperemesis gravidarum was statistically significant ($p < 0.01$). Conclusions: We found that hyperemesis gravidarum women carrying a higher incidence of female fetuses than male fetuses. Whether hyperemesis gravidarum is caused by the female fetal effect on hCG or estradiol concentrations remained to be determined.

108 ESTIMATION OF FETAL RISKS IN ITP PREGNANCIES: A REVIEW OF THE LITERATURE. R.F. Burrows, J.G. Kelton[x], McMaster University, Hamilton, Ontario, Canada.

The management of the pregnant mother with idiopathic thrombocytopenic purpura (ITP) is difficult because it is not possible to predict the fetal platelet count without using invasive tests. The central issue is that the true risk of neonatal thrombocytopenia is not known. To try to obtain an accurate estimate of the actual neonatal risk, we reviewed all English language studies of ITP in pregnancy published in the last decade. Eighty-eight papers described 885 ITP pregnancies producing 893 living infants. To minimize worse case reporting bias, we restricted analysis to those reports that included ≥8 patients and provided all neonatal platelet data. This cohort consisted of 487 ITP pregnancies producing 492 infants. The prevalence of neonatal platelet counts at birth $\leq 50 \times 10^9$/L was 11% (95% CI 8.2-13.8%) and $< 20 \times 10^9$/L was 5.5% (95% CI 3.5-7.5%). Minor morbidity (petechiae, etc.) occurred in 3.3% (95% CI 1.7-4.9%) and major morbidity (intracranial hemorrhage) occurred in 0.4% (95% CI 0.0-1.0%). There was no mortality. Cordocentesis was utilized in 21.7% of this group, vaginal delivery occurred in 28% of those infants with counts $\leq 50 \times 10^9$/L and minor morbidity occurred in 33.3% of those infants $\leq 50 \times 10^9$/L delivered by cesarean section. We conclude: (a) the prevalence at birth of severe neonatal thrombocytopenia ($< 20 \times 10^9$/L) is low; (b) minor and major neonatal morbidities are rare; and (c) interventions are neither mandatory for a good outcome nor ensure one.

109 STILLBIRTHS: WHAT LABORATORY STUDIES ARE HELPFUL?
K. Gregory MD*, R. Settledge MD*, R. Paul MD. University of Southern California, Los Angeles, CA

There is a national need to standardize the review investigations into the etiologies of fetal demise. LAC-USC Women's Hospital, a large tertiary care referral center, has prospectively collected sociodemographic data, antenatal clinical data, maternal laboratory studies, and when possible, postnatal pathologic evaluation. While necropsy evaluation has recognized benefit, the role of routine laboratory studies remains unclear. This study characterizes the efficacy of common laboratory analyses used in an attempt to define associated causes of stillbirths (SB). METHOD: All SB delivered at LAC-USC during 1990 were identified, sociodemographic, antenatal and delivery data were recorded. On admission, maternal blood type and Rh, CBC, PT, fibrinogen(F), Kleihauer-Betke(KB), VDRL, HbA1C, ANA, and TORCH titers were drawn. RESULTS: 209 SB's and 18,094 total births occurred in 1990. The SB rate was 11.6/1000 in this predominantly Hispanic population. The mean maternal age was 25.8(±6.1). Most women were multiparous and 73% had at least one prenatal visit. Mean number of visits was 5.3(±3.7). Mean gestational age at delivery was 32.7(±6.4).

Table 1: LABORATORY RESULTS

TEST	N(%)	ABNL(%)	TEST	N(%)	ABNL(%)
TORCH	138(66.0)	23(16.6)	KB	82(39.2)	4(4.9)
DRUGS	52(24.8)	8(15.4)	PT	180(85.1)	7(3.9)
ANA	133(63.6)	13(9.7)	F	182(87.1)	4(2.2)
VDRL	108(51.7)	9(8.3)	HbA1C	119(56.9)	1(.8)

CONCLUSION: Contrary to popular belief, markers for hyperglycemia and hematologic abnormality occurred infrequently in mothers with SB. Routine screening of maternal serum for HbA1C, PT, F, and KB should be guided by clinical presentation. Conversely, markers for infection, possible collagen vascular disease and acute drug ingestion may provide diagnostic clues to the etiology of demise in SB. The seroprevalence of ANA and TORCH warrants further evaluation in Hispanic women of reproductive age before widespread screening can be advocated.

110 **EXPECTANT MANAGEMENT OF RESOLVING HYDRAMNIOS.** J. Yu,[X] A. Medearis, R. Paul, University of Southern California, Los Angeles, CA

This study evaluates the efficacy of frequent surveillance measures in patients with hydramnios. Hydramnios was defined as a 4 quadrant vertical pocket amniotic fluid sum of >24 centimeters. Over an 18 month period, 66 patients exhibiting hydramnios entered a tertiary referral center for evaluation. Each patient underwent ultrasonic evaluation of amniotic fluid volume, fetal anatomy, non-stress testing, biophysical profiles, and prenatal visits of increased frequency. Hydramnios resolved spontaneously in 52 (79%) pregnancies. A soft palate cleft was the only anomaly found in these 52 infants. Three infants with suspected anomalies had none found at delivery. The serial ultrasound evaluations, antepartum tests, and weekly visits did not change the management or outcome of these pregnancies. Hydramnios failed to resolve in 14 (21%) pregnancies. This group included five infants with identified antepartum anomalies confirmed at birth and two infants with sonographically undiagnosed anomalies found postpartum. The remaining 7 (50%) infants had normal newborn examinations. In conclusion, it appears that once hydramnios has resolved little is gained with frequent use of antepartum surveillance. Also, half of patients with persistent hydramnios will have a normal newborn examination.

111 M ANTIGEN ISOIMMUNIZATION IN PREGNANCY: A SERIES OF 34 PATIENTS. KE Kern*, TCC Peng and MJ Dinsmoor. Dept of Ob/Gyn, Medical College of Virginia/Virginia Commonwealth of Virginia, Richmond, Virginia.

M antigen is present in 70% of the general population. Although maternal antibody to M antigen (ANTI-M) is listed as a cause of severe hemolytic disease of the newborn (HDN), there are only 5 reports of patients with pregnancy complications attributed to ANTI-M, 4 with no titers reported and one with "low titers". To assess the frequency and outcome of ANTI-M in our pregnant population, we reviewed blood bank records from 12/6/88-5/2/91. 34 patients with ANTI-M were identified, for an approximate incidence of 3.1/1000 deliveries. Titers were performed in 16 patients and ranged from 1:1 to 1:128. Review of maternal and neonatal records reveal that 4/6 (67%) paternal blood types were M-positive. Delta OD450 values were all Zone 1 in the 5 patients who had amniocentesis (Titers 1:4 to 1:128). Mean gestational age and birthweight at delivery were 39.3 wk and 3214 gm (N=33, excluding one Trisomy 18 fetal demise). Review of nursery laboratory records and 25 neonatal charts reveals no cases of HDN, anemia, hyperbilirubinemia or positive direct Coombs. We conclude that although common, ANTI-M rarely causes adverse neonatal outcome.

112 **PREGNANCY IN THE SPINAL CORD INJURED WOMAN.** E. Baker,[X] D. Cardenas,[X] T. Benedetti, University of Washington, Seattle, WA

A retrospective chart review was performed of all patients with traumatic or infectious spinal cord injury (SCI) or spina bifida who delivered at the University of Washington Hospital from 1980-1990. 16 patients with lesions ranging from C4 to S1 levels had 19 pregnancies. There were 10 cases of traumatic SCI, 1 transverse myelitis and 5 spina bifida. Prior medical problems included urinary tract infection (UTI) in 90% and anemia in 63%. The patients' obstetrical care was only remarkable for tocolytic use in 26% and 1 preterm delivery at 34 weeks. Antepartum medical problems included UTI in 70%, pyelonephritis in 26%, and decubitus ulcers in 26% of the patients. 70% of the patients were delivered vaginally and 30% by cesarean section. 5 patients were at risk for autonomic dysreflexia (AD) with lesions at or above T6. 3 patients had 4 episodes of AD treated by spinal anesthesia, delivery or control of preterm labor. Modern medical and obstetrical care allow good outcomes for pregnant spinal cord injured women although significant maternal medical risk exists including urinary tract infections and decubitus ulcers. Autonomic dysreflexia remains a serious complication of labor and delivery occuring in most patients with lesions at or above T6.

113 INITIAL REQUIRED INSULIN DOSE IN GESTATICNAL DIABETICS. J Binderman[X], JC Pastorek II, JM Miller Jr, LSU Medical Center, New Orleans, LA.

Initiating insulin therapy in newly diagnosed gestational diabetics has traditionally been based on formulas using ideal body weight (IBW), correcting for trimester of gestation. We evaluated formulas using both IBW and actual body weight (ABW) to predict the actual amount of insulin (ACTINS) required for glucose control. Charts of 37 insulin-requiring gestational diabetics of a 2 year period were reviewed. Formulas tested were F1: Ins =.7(ABW), F2: Ins =a(ABW), F3 =a(IBW) (a = .6 in 1st trimester, .7 in 2nd, .8 in 3rd). The ABW insulin dose formulas predicted actual dose required. For F2 the mean difference ±SE was -.5±3.5, and for F1 the difference was -4.6±3.5, both not different from zero. The IBW formula differed from actual requirements by -30.5±3.5 (p=.001). Stepwise regression of IBW, ABW, and trimester reaffirmed the value of ABW: Ins = 23.3 + .5ABW (r=.455, p=.005). Using ABW will better predict the actual insulin needed, thus decreasing the time and cost spent in attaining close glucose control.

114 PREGNANCY LOSS AND THROMBOSIS WITH PROTEIN C DEFICIENCY IN PREGNANCY J Trauscht-Van Horn[A], E Capeless, EG. Bovill[A], TR Easterling, B Hermanson[A], Univ of Washington, Seattle & Univ of Vermont College of Medicine

Protein C, a vitamin K dependent plasma protein, inhibits coagulation and promotes fibrinolysis. The deficiency, inherited in an autosomal dominant pattern, increases the risk of venous thrombosis. This study investigates pregnancy loss and thrombotic disease during pregnancy in protein C deficient women.

Materials and Methods: A single New England kindred of 15 protein C deficient cases and 37 related non-deficient controls was studied. An obstetrical history was obtained by phone from all women of child bearing age. Data were analyzed by t test and logistic regression analysis.

Results:

	Cases (15)	Controls (37)
Pregnancy loss(es)	5 (33%)	7(19%)
<12 wks	3	4
>12 wks	2	3
Premature births (<2kg)	0	0
Mean birth weight	3168g	3156g
Birth weight range	2040-4184g	2152-4198g
Thrombosis in pregnancy	5 (33%)	2 (5%)
without anticoagulation	5 (45%)	
Successful pregnancy	15 (100%)	37 (100%)

The odds ratio for thrombosis in pregnancy associated with protein C deficiency was 7.37, (P=.026).

Conclusions: Protein C deficiency is not associated with increased pregnancy loss and is associated with an increased risk of thrombosis in pregnancy.

115 PREDICTING THE NECESSITY FOR INSULIN THERAPY IN THE GESTATIONAL DIABETIC. G.L. Goyert, Y.A.H. Daoud,[X]D.J. Wright,[X]D.B. Schwartz. Dept. Ob/Gyn, Div. MFM, Sinai Hospital, Wayne State University School of Medicine, Detroit, MI.

A minority of gestational diabetics require insulin therapy to maintain fasting glucose < 100 mg/dl and two hour post-prandial glucose < 120 mg/dl. This study was undertaken to model 3-hour oral GTT results to predict the necessity for insulin therapy. Three hour GTT results of 317 patients referred for management of gestational diabetes between 1988-91 were analyzed via step-wise logistic regression. Independent variables entered into the analysis included the four values of the 3 hour GTT individually, the difference between each post-ingestion value and the fasting value, and the mean of the values obtained following ingestion of the glucola. Sixty nine patients required insulin therapy. The average of the three post-ingestion values (improvement χ^2=59.3) and the fasting value (improvement χ^2=11.7) were the two most significant predictors for necessity of insulin therapy. These data facilitate counselling the gestational diabetic and may influence the timing of insulin therapy initiation, especially "prophylactic" insulin regimens.

116 IMPROVED PERINATAL OUTCOME AFTER ENHANCED PRENATAL CARE FOR OPIATE ADDICTS.
G Chang*, KM Carroll*, HM Behr*, NJ DeGennaro*, TR Kosten*, RS Schottenfeld*, and RR Viscarello.

Chemical dependency during pregnancy is frequently correlated with poor prenatal care and adverse perinatal outcomes. Nearly 75% of the estimated 300,000 female narcotic addicts in the United States are of childbearing age. Pregnant opiate addicts have a six-fold increase in maternal complications including IUGR, premature labor, third-trimester bleeding, and malpresentation. Newborn complications include neonatal withdrawal syndrome, failure-to-thrive, SIDS, and neurobehavioral problems. In order to improve perinatal outcome for opiate-addicted women, we developed an enhanced program which combines on-site prenatal care, methadone maintenance, supervised childcare, and relapse-prevention strategies. As part of our pilot phase, 12 of 23 pregnant women currently on methadone maintenance agreed to participate in the enhanced program. The 11 patients who declined were followed in a traditional prenatal care setting. Both groups had similar demographics including age, years of education, marital status, racial breakdown, parity, and daily methadone dose. Six of the patients in the enhanced group have delivered, 3 elected TOP, and 3 remain undelivered; while in the routine group, 6 have delivered, 1 miscarried, 2 underwent TOP, and 2 are lost to follow-up. Despite a greater mean number of urine toxicology screens (43 vs. 15), subjects in the enhanced program demonstrated a lower percentage of positive results (59% vs. 76%). The enhanced group had significantly more prenatal visits (8.8 vs. 2.7), longer gestations (38.2 wks vs. 35.7 wks), and larger infants (2943g vs. 2280g). Preliminary results suggest improved outcomes in opiate-dependent patients receiving enhanced as compared to routine prenatal care. Such a therapeutic approach also provides the addicted woman with the structural framework to organize her own life and thereby improves parenting skills.

117 MANAGEMENT OF PREGNANCIES IN DIABETIC WOMEN: CAN WE DO BETTER? U. Lang*, G. Braems*, K. E. Clark*, W. Kuenzel, Frauenklinik der Justus -Liebig - Universitaet, Giessen, Germany and Univ. Cincinnati, Cincinnati, Ohio.

Modern management of pregnancies in diabetic women (PD) in specialized centers has improved the rates of perinatal mortality and morbidity to approach those in the non-diabetic population. To determine whether these rates of improvement are valid for a large population, data from the Hessische Perinatalstudie, a computerized system of collecting information on obstetrical care in the State of Hesse, Germany (Pop. 5.6 million) were used to compare 446 PD (0.4% of 111836 pregnancies recorded from 1982-86) to 707 PD (0.5% of 145025 pregnancies recorded from 1987-89). Patient histories, pregnancy risks, birth risks, fetal outcome and maternal well-being were evaluated in the specific setting of widely decentralized obstetric care. Perinatal mortality in infants of diabetic mothers (IDM) dropped from 4.9% to 2.4%, but still remained substantially higher than in the non-diabetic population (0.7% and 0.6% respectively). Two thirds of fetal loss occurred before birth. Although neonatal morbidity decreased, the percentage of anomalies and the percentage of macrosomic IDM remained unchanged. These data show, that changes in management and awareness of the PD's problems improved the perinatal outcome, but not to the extent possible in specialized facilities. Preconceptional counseling and therapy (anomalies), glycemic control during pregnancy (macrosomia), fetal monitoring (intrauterine deaths) and experienced care have to be further stressed.

118 **A COMPARISON OF SONOGRAPHIC INDICES IN THE EARLY PRENATAL DIAGNOSIS OF HYDROCEPHALUS:** I. Goldstein[X], Reece EA, Pilu G, Hobbins JC, Departments of Obstetrics and Gynecology at Rambam Medical Center, Israel, Temple University, PA, The University of Bologna, Italy and Yale University, CT

Hydrocephalus is a condition which affects primarily the lateral cerebral ventricles with variable involvement of the other ventricles. Since the incidence of chromosomal anomalies and other structural malformations is increased with hydrocephalus, prenatal diagnosis is desirable. Although various ventricular biometric parameters have been used, the relative accuracy of each remains undetermined. In this study, 51 pregnancies were examined prospectively until frank hydrocephalus developed. Sonographic indices which were applied during early pregnancy (16-24 weeks) were compared to assess the relative accuracy of the various measurements of the lateral ventricle (Lv) and to aid in the early prenatal diagnosis of hydrocephalus. The diagnostic accuracy of each parameter was as follows:

Ventricular Dimensions		Diagnostic Accuracy
Lateral ventric width/ Hemispheric width (LVW/HD)	=	86%
Atrial width/Cerebroatrial distance (AW/CAD) or atrial with <1cm	=	94.1%
Cerebrosprontal distance/ Hemispheric width (CFD/HW)	=	76.3%

CONCLUSIONS: These data demonstrate that abnormal ventricular biometry is present even in early ventriculomegaly. However, the atrial dimension seems to be the most accurate diagnostic parameter and a useful tool for the early prenatal diagnosis of hydrocephalus.

119 **ARDS IN THE OBSTETRIC PATIENT – 18 RECENT CASES**

V. Catanzarite, D Wilms*, J G Quirk, L Cousins, J Schneider
Maternal-Fetal Medicine, Sharp Memorial Hospital, San Diego, CA and UAMS, Little Rock, Arkansas.

Adult respiratory distress syndrome is emerging as a major cause of maternal mortality. We have treated 18 cases over the past four years; all but two patients were delivered at or transferred to, UAMS or Sharp. Causes were obstetric in seven patients (preeclampsia 4, acute fatty liver 2, amnionitis 1), and nonobstetric in 11 (aspiration 2, malignancy 2, viral infection 3, bacterial sepsis 3, and status epilepticus with multiple organ failure 1).

Two mothers in extremis at initial consultation at outside hospitals were hemodynamically unstable and could not be transported. Both died. Of the 16 managed at Sharp or UAMS, there were 5 maternal deaths - two patients with malignancy and sepsis, 2 with HELLP syndrome, sepsis and multiple organ system failure, and one with aspiration with motor vehicle trauma. One survivor required 28 days of extracorporeal support (ECCOR) and a total of 61 days intubation; others required 3 to 26 days of intubation.

Two previable fetuses died with the mother. There were two additional fetal deaths prior to perinatal consultation, for a perinatal mortality rate of 333 per 1000. Two very premature infants died after delivery.

From our experience:

1) Excepting two patients with malignancy, four of five maternal deaths occurred in patients with multiple organ system failure; only two patients with ARDS and failure of two or more other organ systems survived.
2) All of our patients with antepartum ARDS either miscarried, delivered, or had a demise prior to extubation.
3) Seven of eight patients requiring prolonged intensive support survived, all without residua.

120 **VERY TIGHT GLYCEMIC CONTROL IN GESTATIONAL DIABETES: A BENEFIT OR A DETRIMENT?** Michele K. Presinger, M.D.,[X] Sophia Scarpelli, Michael Y. Divon, M.D., from the Departments of OB/GYN, Albert Einstein College of Medicine, Bronx, N.Y. and Temple University School of Medicine, Philadelphia, PA

Gestational diabetes mellitus (GDM) is classically associated with fetal macrosomia; however, tight glucose control may result in decreased substrate availability. Purpose: to evaluate the incidence of intrauterine growth retardation (birthweight ≤10th percentile) in GDM and its association with maternal mean blood glucose (MBG). 661 consecutive GDMs were studied: 293 were diet controlled (GDM-D), 368 received diet and insulin therapy (GDM-D&I), and 468 low-risk, non-diabetics served as controls. IUGR was detected in 17.4% of GDM-D&I which was significantly elevated over the 7.2% detected in GDM-D and 5.8% detected in controls (P <0.0001). Of the 85 GDMs with IUGR, 41 consecutive patients (31 GDM-D&I, and 10 GDM-D) had multiple daily glucose determinations. Similar glucose data were available for 82 GDMs matched for mode of therapy and gestational age at delivery who delivered appropriate for gestational age sized infants (AGA).

The odds ratios for IUGR in GDM-D&I were 3.5 (95% C.I.=1.3-9.8) with a MBG of 90-100 mg/dl and 5.7 (95% C.I.=1.2-26.3) with a MBG <90 mg/dl. The incidence of C/S for fetal distress and of NICU admissions was significantly higher in GDM-D&I with IUGR (p <0.05). Hypertension, smoking, maternal body mass index and maternal weight gain were not significantly different between IUGRs and their controls. Conclusion: the incidence of IUGR is significantly increased in GDM-D&I, and the likelihood of IUGR increases as the MBG decreases.

Table 1-Incidence of IUGR

Diag/Rx	Incidence-IUGR
GDM-D&I	64/368(17.4%)*
GDM-D	21/293(7.2%
Nondiab	28/486(5.8%) *

*p<0.000001

Table 2-MBG & IUGR

	(90-100mg/dl	<90 mg/dl)
odds ratio	3.58%	5.7%
95%conf int	1.3-9.8%	1.2-26.3%
p value	0.009	0.02

121 **PREDICTION OF THE NEED FOR INSULIN THERAPY IN GESTATIONAL DIABETES:** N Vohra, G Berkowitz, R Lapinksi*, L Lynch, CJ Lockwood. Mt Sinai School of Medicine, New York, NY

Insulin therapy in gestational diabetes mellitus (GDM) is often unduly delayed and fails to prevent diabetic fetopathy. This study sought to identify demographic and laboratory indices associated with the need for insulin therapy. Employing an obstetric database 913 GDM patients were identified by an abnormal glucose tolerance test (GTT) between 1986-1990. Despite dietary intervention, 220 patients (24%) required insulin therapy due to fasting whole blood glucose levels > 95 mg/dl or post-prandial levels > 120 mg/dl. Significant differences between patients requiring insulin (IRx) and those responding to diet alone (DRx) included:

Variable		IRx mean (SD)	DRx mean (SD)	t-test/X^2
Pre-pregnancy Wt.	(lbs.)	161 (44)	141 (35)	0.0001
Body Mass Index	(kg/m^2)	28.8 (7.1)	25.4 (6.0)	0.0001
1 hr. glucola	(mg/dl)	165 (29)	156 (27)	0.0004
Fasting GTT	(mg/dl)	101 (20)	93 (14)	0.0001
1 hr. GTT	(mg/dl)	207 (31)	196 (24)	0.0001
2 hr. GTT	(mg/dl)	179 (36)	169 (27)	0.0004
3 hr. GTT	(mg/dl)	136 (41)	129 (32)	0.02
Gest. Age at GTT	(wks)	24 (7)	28 (6)	0.0001
Non-white race		81.8%	53.4%	0.0001
Family History DM		39.5%	23.3%	0.0001
Prior History GDM		19.5%	9.0%	0.0001
Prior insulin use		8.1%	1.6%	0.0001

Logistic regression analysis confirmed that the maternal race, family history of DM, prior insulin use, glucola, fasting and 1 hour GTT values were independent predictors of future insulin use. Therefore a cumulative score for each patient was assigned by multiplying the presence or absence, or value of each risk factor by the appropriate beta and summing. The optimal cut off score, for prediction of insulin use, as assessed by the Receiver-Operator Analysis displayed a sensitivity of 70% and specificity of 70%. SUMMARY: The need for insulin therapy in GDM can be predicted by using a combination of maternal characteristics and laboratory values at the time of initial diagnosis.

122 POLYCISTIC OVARY (PCO): A RISK FACTOR FOR GESTATIONAL DIABETES (GD)? A. Caruso [X], N. Di Simone [X], A. Lanzone [X], S. De Carolis [X], S. Mancuso [X]. Dept Ob/Gyn, Catholic University, Rome, Italy.

We found that patients with PCO had a greater secretion of Insulin (I) than controls and about 60% of them showed an hyperinsulinemic (HI) response to OGTT (Hum. Repr.,1990). Eight pts became pregnant within 6 months following the evaluation of metabolic status (2 obese, 2 HI obese, 2 HI, 2 not HI not obese patients). They were tested at 28-30 wks of gestation by OGTT. All these pts had an increase of I secretion from 100 to 200%. The integrated secretory area of insulin (ISA I), calculated by trapezoidal rule, of PCO pts was greater than that found in 10 healthy women ($p<0.01$) or in 10 non PCO pts with GD ($p<0.01$) tested at the same gestational age and with the same body mass index. GD group had also a decreased ISA I in comparison with controls ($p< 0.05$). Furthermore the four HI PCO pts developed GD ($n=2$) or IGGT ($n=2$). Their ISA I was 50% greater than controls; the other non HI PCO pts showed an ISA I after OGTT at the highest values of control group. These data suggest that PCO pts may be considered a specific subgroup of subjects, who may develop a derangement of the glycemic control in spite of their remarkable increase of I secretion during pregnancy. Additional studies need to the knowledge and clinical management of both normal and hyperinsulinemic GD and IGGT in PCO pregnant patients.

123 MATERNAL COCAINE AND MARIJUANA USE DETERMINED BY ANALYSIS OF AMNIOTIC FLUID AND CORD BLOOD AT DELIVERY. C Lowery, C Lawler[X], JL Valentine[X], Departments of Obstetrics & Gynecology and Pediatrics, University of Arkansas for Medical Sciences, Little Rock, Arkansas

Nineteen women presenting for delivery were suspected to be at high risk for substance abuse. Maternal urine and blood, amniotic fluid (AF), and cord blood were collected at delivery. Urine was screened for benzodiazepine, marijuana and cocaine metabolites, opiates and amphetamines using the enzyme multiplied immunoassay technique (EMIT). Only marijuana and cocaine metabolites were found. Three patients had a positive urine screen for cocaine metabolite, two were positive for cocaine and marijuana metabolites, and two were positive for marijuana metabolite only (36% positive for substance abuse). Amniotic fluid testing for these metabolites using EMIT was negative. Maternal blood and urine, AF, and cord blood were analyzed using gas chromatography/mass spectrometry (gc/ms). Cocaine and its major metabolite, benzoylecgonine were found in all body fluids; 11-nor-9-carboxy-Δ^9-tetrahydrocannabinol, a major metabolite of the psychomimetic agent found in marijuana, was identified in both urine and AF. The relationship between levels found in the four body fluids was variable and is most likely due to differences in metabolism and excretion of the drugs following dosing intervals (which could not be determined). These results represent the first report of cocaine and marijuana metabolites in human AF as determined by gc/ms. Conclusion: Amniotic fluid may represent a potential pharmacokinetic compartment to assess fetal exposure.

124 AN ANONYMOUS COMPARISON OF SUBSTANCE ABUSE BETWEEN CLINIC PATIENTS AND LABOR & DELIVERY PATIENTS IN A RURAL SOUTHERN STATE. CL Lowery, C. Crone,[X] JM Benanti, R Kirby,[X] J Valentine,[X] Departments of OB/GYN and Pediatrics, University of Arkansas for Medical Sciences. Little Rock, Arkansas.

Maternal urine was collected during a 30 day period from all patients seen in prenatal clinic (N=386) or on the Labor & Delivery (L&D) Unit (N=227). Urine samples were analyzed for benzodiazepine, marijuana, cocaine metabolites, opiates and amphetamines using enzyme multiplied immunoassay technique (EMIT), and all positive results were confirmed with gas chromatography/mass spectrometry (gc/ms). Prevalence rates for marijuana and cocaine were 6.7% and 2.2%, respectively, among in-patients, and 7.6% and 0.8%, respectively, among out-patients. No difference in the prevalence rate for marijuana or cocaine was found between in- and out-patients according to race, maternal age, gestational age, or payment source. Among out-patients, black women were more likely than white women to use cocaine; in general, women $\geq$ 37 weeks were more likely to be positive for cocaine ($p<.005$). Among in-patients, lower gestational age was associated with marijuana use ($p<.05$), and lack of prenatal care was associated with cocaine use ($p<.005$). In this study, a lower positive rate was found during urine drug screening than has been reported elsewhere from socioeconomically similar populations. This lower rate presumably reflects a lower incidence of substance abuse at a teaching hospital in a rural southern state.

125 ANONYMOUS DRUG SCREENING OF PRENATAL PATIENTS BY PAIRED URINE COLLECTION AND DRUG HISTORY. CL Lowery, C Crone,[x] R Kirby,[x] J Valentine.[x] Departments of OB/GYN and Pediatrics, the University of Arkansas for Medical Sciences. Little Rock, Arkansas.

Concerns over legal ramifications and confidentiality imposed by universal urine drug screening prompted a study to compare urine screening to a nurse-administered drug screening form. During a 30 day period all patients (N=386) receiving prenatal care in the outpatient clinics were screened by both. Urine (collected anonymously) was analyzed by enzyme multiplied immunoassay technique (EMIT) for benzodiazepine, marijuana, cocaine, opiates, and amphetamines. Smoking correlated most with urine results (sensitivity: 83.3%, positive predictive value: 20.7%). Only 23.3% of women testing positive admitted current use; of those admitting to current use, only 50% tested positive. Since urine screening alone will miss users, nurse-administered questionnaires offer a reasonable alternative to universal urine screening.

	Sensit. %	PPV %	Number Pos. (%)
Current Use	23.3	50.0	044 (03.6)
Past Use	56.7	20.0	100 (25.9)
Smoking	83.3	20.7	121 (32.8)

126 THE EFFECT OF CONTINUOUS AND PULSE COCAINE EXPOSURE ON ENDOTHELIAL CELLS OF HUMAN UMBILICAL CORD

D.S. Mastrogiannis[x], W.F. O'Brien. Depts. of OB/GYN at Temple University School of Medicine, Phila., PA, and University of South Florida College of Medicine, Tampa, FL.

There is an apparent association between cocaine abuse and adverse perinatal outcome. It has been postulated that some of the adverse effects of cocaine usage in pregnancy may be due to a disturbance of the endothelium with a secondary reduction in the release of vasodilatory prostaglandins. We have recently shown (SGI, 1991, Abstract #3) that cocaine decreases prostacyclin production when pharmacological doses of cocaine are added in human umbilical vein endothelial cell (HUVEC) culture. In the present study, we examined the effect of low dose cocaine concentrations and for variable time periods in a continuous and pulsed in vitro model. Confluent cultures of human umbilical cord endothelial cells, in 24 well plates were incubated with culture medium containing 0, 250, 500 ng/ml of cocaine for 6 days, 24 hr. a day in the continuous experiment and 2 hr. a day in the pulsed one. The medium was changed daily and was assayed for 6 keto-$PGF_{1\alpha}$ the stable metabolite of prostacylin (PGI_2) by RIA.

RESULTS: 6 keto $PGF_{1\alpha}$ (µg/.1ml)

	PULSE			P	CONTINUOUS			P
Cocaine	0	250	500		0	250	500	
Day 1	448	431	410	NS	619	535	476	NS
Day 3	285	283	257	NS	478	508	546	NS
Day 4	399	379	327	NS	449	464	388	NS
Day 5	313	322	294	NS	304	381	395	NS
Day 6	408	446	294	NS	347	361	403	NS

CONCLUSIONS: Cocaine in low doses and variable time periods did not affect the production of prostacyclin when incubated with HUVEC in our in vitro model. These data suggest that PGI_2-mediated adverse perinatal complications might require higher doses and thus greater prenatal surveillance is warranted.

127 PRENATAL COMPLICATIONS IN INSULIN-DEPENDENT DIABETIC PREGNANCIES. B. Rosenn, M. Miodovnik, J. Khoury,[x] T.A. Siddiqi, Dept. Ob/Gyn, Univ. Cincinnati Med. Ctr., Cincinnati, OH

Insulin-dependent diabetic women are considered at high risk for prenatal complications of pregnancy; however, sound descriptive data are scarce and most suffer methodologic drawbacks. In order to establish the actual rates of these complications in our diabetic population and to improve our ability to provide patients with prenatal counseling, we retrospectively studied 254 insulin-dependent diabetic women (White classes B-RT) enrolled in our multidisciplinary program of diabetes in pregnancy prior to 20 weeks' gestation and followed every 1-2 weeks throughout pregnancy. Goals of glycemic control were fasting blood glucose < 100 mg/dl and 90 minutes postprandial blood glucose < 140 mg/dl. A control group of 508 non-diabetic women were randomly selected from the obstetric population enrolled in the hospital's prenatal clinics prior to 20 weeks' gestation, and matched to the diabetic group (ratio 2:1) by age, race, and parity. Diabetic patients had significantly higher rates of preeclampsia (34% vs. 7.7%; p<.001), polyhydramnios (31% vs. 0.6%; p<.001), pyelonephritis (4.1% vs. 1.4%; p<.03), meconium stained amniotic fluid (11.4% vs. 4.5%; p<.001), and spontaneous preterm delivery (12.4% vs. 7.3%; p<.05). No difference was found in the rate of premature rupture of membranes. Preeclampsia and polyhydramnios were associated with microvascular disease and higher mid-trimester glycohemoglobin concentrations. We conclude that the rate of prenatal complications of pregnancy is indeed increased in insulin-dependent diabetic pregnancies. We speculate that the factors predisposing to such complications are already established by mid-pregnancy and that early glycemic control may be required to decrease their frequency.

128 RISK FACTORS FOR INTRAUTERINE FETAL DEATH

RL Copper[x], RL Goldenberg, MD DuBard[x], RO Davis. The University of Alabama at Birmingham, Birmingham, Alabama.

Risk factors and medical origins of 403 stillbirths which occurred in 5 perinatal centers from 1982-86 were studied. The population included 34,351 births of women screened as part of the March of Dimes Multicenter Preterm Birth Prevention Trial. Stillbirth (SB:Apgar=0 at 1 and 5 min at ≥ 20 wks GA) occurred in 1.2% of all births. 51% of SBs occurred before 28 wks and only 18% occurred at term. Blacks had an increased risk of SB compared to whites (RR 1.5, p<.001) and Hispanics had a reduced risk (RR .7, p<.05). Work, parity, and age < 17 were not associated with SB, but age >35 (RR 2.2, p<.001) and single marital status (RR 1.7, p<.001) were associated. Thin women did not have increased risk of SB but women >85kg had a RR of 2.4 (p<.001). Both prior spontaneous (RR 1.95, p<.001) and indicated PTDs (RR 3.2, p<.001) were associated with SB. Preeclampsia resulted in no increased risk, yet the RR of SB related to chronic hypertension was 2.1 (p<.001). Class A Diabetes (DM) had no increased risk while the RR of SB in Class B-R DM was 2.1 (p=0.05). Conditions resulting in the highest RR of SB were hemoglobinopathies, (7.2, p<.001), Rh sensitization (4.4 p <0.01), and abruption (14.9, p<.001). These data may assist in identifying a fetus at risk for SB and provide data upon which to base studies aimed at reducing fetal death.

129 **THE INCIDENCE AND NATURAL HISTORY OF ASYMPTOMATIC CHOLELITHIASIS IN PREGNANT PATIENTS.** J. Williams III, R. Willis-Hassan[X], D. Aiken-Hunting[X], B. Caro[X], J.S. Greenspoon, The Prenatal Diagnostic Center of So. CA & Dept. of Ob/Gyn, Cedars-Sinai Med. Ctr, Beverly Hills & Los Angeles, CA

We prospectively evaluated 186 patients for cholethiasis to determine the incidence and natural history of cholelithiasis in women diagnosed during pregnancy. Symptomatic gallstones diagnosed during pregnancy are associated with a 15% rate of pregnancy complications. We hypothesized that asymptomatic gallstones infrequently become symptomatic, and are seldom associated with pregnancy or medical complications. A realtime ultrasound examination of the biliary tract was performed at the time of an indicated second trimester fetal evaluation. Patients included in the study were referred for genetic or obstetrical indications. No patient was referred for evaluation of biliary tract disease. The mean (SD) maternal age was 35.7 (4.5) years. The mean maternal weight was 68.2 (11.8) kilograms. The mean maternal height 1.64 (0.06) meters. The mean body mass index (BMI) was 25.3 (4.2). The gestational age at the time of the examination was 16 to 24 weeks. An adequate examination of the biliary tract was achieved in 176 (95%) of patients. An adequate exam was obtained as frequently in overweight patients with a BMI$\geq$27 as in patients with a BMI<27. Although 5 of 55 (9%) patients with BMI$\geq$27 had inadequate examinations compared to 5 of 131 (3%) non-obese patients (BMI<27), the difference was not statistically significant. Four of 176 (2%) evaluable patients had cholelithiasis. In retrospect, symptoms attributable to cholelithiasis were elicited from one of the 4 patients with cholelithiasis. None of the 4 patients has required therapy, although pregnancies are ongoing. Further enrollment of consecutive patients is in progress to test the hypothesis.

130 SEXUAL ASSAULT IN PREGNANCY: A SURVEY OF 2404 WOMEN. AJ Satin,[X] J. Paicurich,[X] S. Millman,[X] G.D. Wendel, Dept. Ob/Gyn, U. Texas Southwestern Med Center., Dallas, TX

A women is sexually assaulted every 6 minutes in the U.S., however little data exists on the prevalence of and effect of rape on an obstetric population. In a previous retrospective study of assault victims we estimated an incidence of rape of 0.55/1000 pregnancies. The purpose of this investigation was to determine the prevalence of sexual assault in urban gravidas, characterize pregnancy complications and report pregnancy outcome of assault victims. Women (n=2404) were interviewed within 48 hours of delivery regarding forced sexual contact before or during the current pregnancy. Reported pregnancy complications were confirmed by review of obstetric, medical & police reports. A history of sexual assault was elicited in 50:1000 (n=120) women. The incidence of assault during the current gestation was 2:1000 (n=5). Rape victims were more likely to be white (43v.16%, P<.001), employed (28v.19%, P<.02), high school graduates (23v.14%, P<.005) and separated or divorced (13v.5%, P<.001), compared to non-victims. Rape victims had a higher incidence of STD's (9v.4%, P<.01), UTI's/vaginitis (32v.21%, P=.02), drug use (9v.2%, P<.001), and multiple hospitalizations (15v.8%, p<.01) during pregnancy. There were no differences in neonatal outcome reflected by umbilical artery acidosis, EGA at delivery, or birthweight. Thus in our gravid population a history of sexual assault is common. Rape in pregnancy occurs four times more often than previously estimated. Assault victims have more frequent pregnancy complications, but achieve normal pregnancy outcome.

131 **3 HOUR GLUCOSE TOLERANCE TEST (GTT) RESULTS ARE UNRELATED TO OUTCOME IN A SELECTIVELY SCREENED POPULATION.** Michael J. Lucas, Thomas W. Lowe, Lisa Bowe,[X] Donald McIntire,[X] Dept. Ob/Gyn, Univ. Texas Southwestern Medical Center, Dallas, TX

Selective GTT testing of a large cohort of antepartum clinic patients resulted in the identification of 126 class A_1 diabetics and 139 gravidas with normal glucose tolerance based on a 100 gm, 3 hr GTT. These two groups were compared to evaluate the relationship of glucose intolerance to perinatal outcome. The Class A_1 diabetics received dietary counseling and had fasting blood sugars checked at the time of antepartum clinic visits, but otherwise received routine obstetric care. There was no significant difference between groups in average birthweight, EGA at delivery, stillbirths (one each), cesarean section delivery rate, meconium staining of fluid, cord pH (or % < 7.2) or Apgar scores. There were very few small for gestational age (SGA) neonates (2 in each group), and although there were 36% large for gestational age (LGA) neonates in the diabetics, this was not statistically different from the 31% LGA delivered in the normal GTT group. There was no significant difference in the 3 hr GTT profiles between mothers of LGA neonates and the others within each group. There was a 5% incidence of shoulder dystocia in the LGA neonates, and half of these had evidence of injury. There was no apparent relationship between neonatal size and route of delivery. Maternal weight, on the other hand, was significantly higher in cesarean deliveries and in LGA mothers, but was not significantly different between the GTT result groups. The high incidence of LGA neonates observed in both GTT groups suggest that either the abnormal 50 gm result or the indications for screening selected for this outcome. It should be noted that maternal obesity was not an indication for screening. Prior delivery of a macrosomic infant was the indication in 22% of mothers screened yet cortributed 44% of the LGA neonates. While not surprising that factors other than maternal glucose tolerance affect fetal size, the lack of association with GTT results indicates that targeting glycemic control in this population would not significantly reduce the incidence of LGA outcome.

132 CHARACTERISTICS AND OUTCOMES ACCORDING TO DIAGNOSTIC CRITERIA FOR GESTATIONAL DIABETES. G. Berkowitz[X], R. Lapinski[X], M. Alvarez, C. Lockwood, R. Berkowitz. Mount Sinai School of Medicine, New York, NY

The criteria endorsed by the National Diabetes Data Group (NDDG) for determining abnormal plasma glucose values were converted from O'Sullivan's original values based on whole blood without taking into account differences between whole blood and plasma values. Carpenter and Coustan (1) have calculated lower thresholds based on an adjustment for this difference. Our institution, which routinely screens all patients on the clinic service for diabetes, has adopted the lower thresholds. The aim of this study was to assess whether maternal characteristics and neonatal outcomes differ betwwen those who meet the NDDG criteria and those who only meet the criteria of Carpenter and Coustan. A total of 233 patients were diagnosed with gestational diabetes (GDM) based on the NDDG criteria and an additional 121 patients met the lower threshold criteria. The distributions of maternal age, race/ethnicity, body mass index, weekly maternal weight gain, a family history of diabetes, and a history of stillbirths or spontaneous abortions were very similar for the two groups. However, insulin use was more common in the NDDG group (p=0.046) and there was a suggestion that a prior history of GDM was more frequent in this group (p=0.06). With regard to neonatal complications, there were no significant differences between the two groups although a birth weight >.90th percentile for gestational age tended to be more common in the NDDG group (p=0.06). SUMMARY: Although there was some suggestion that the patients fulfilling the NDDG criteria exhibit more sequelae of glucose intolerance than those who only meet the criteria proposed by Carpenter and Coustan, no clear distinctions were observed in terms of maternal characteristics or adverse neonatal outcomes between the two groups.

(1) Carpenter M, Coustan D. Am J Obstet Gynecol 144:768, 1982.

133 *THE ROLE OF AMNIOTIC FLUID DISTRIBUTION PREDICTING PERINATAL OUTCOME IN PATIENTS WITH RUPTURED MEMBRANES.* *TD Myles, HT Strassner, Rush Medical Center, Chicago, IL*

In our previous study amniotic fluid index (AFI) distribution was predictive of perinatal outcome in patients presenting for delivery with intact membranes. This study evaluated whether similar predictive values existed for patients presenting with spontaneous rupture of membranes. An AFI was performed on 84 patients. Those with >50% of the AFI in the upper quadrants were placed in the upper greater group (UG). All others were classified lower greater (LG). The LG AND UG groups were compared in relation to meconium staining (MEC), 1 or 5 minute Apgars <7, persistant variable decelerations (VD), late decelerations (LD), umbilical artery or vein pH <7.20, NICU admission, and cesarean sections for fetal distress (CSFD). These findings were similar to those in our earlier study. Patients in the UG group had a higher incidence of MEC (29.8% vs 2.7%, p <.002), 1 minute Apgar <7 (19.1% vs 2.7%, p <.021), VD (61.7% vs 24.3%, p<.001), LD (23.4% vs 0%, p<.002), and CSFD (12.8 vs 0%, p<.024). There were no significant differences between groups with regard to overall AFI.

134 **THE FETAL HEART RATE CHANGES DURING THE FIRST STAGE OF LABOR IN LOW-RISK PREGNANCIES.** N. Field,* A. Samueloff,* M. Berkus, E. Xenakis,* L. Ridgway, O. Langer. Dept. OB/GYN, Univ. of Texas Health Science Center, San Antonio, TX.

Few studies document the changes in the characteristics of fetal heart rate (FHR) during the first stage of labor. Therefore we investigated the natural history of the FHR tracing throughout the first stage of labor in normal, uncomplicated pregnancies. Five hundred and twenty-nine women who met all of the following admission criteria were included in the study: gestational age >36 and <43 weeks, vertex presentation, vaginal delivery, birthweight >2500 gm, and good neonatal outcome. Infants with a good outcome went home in 2-5 days with no NICU admissions. Cases with either twins, malformations, or maternal disease (diabetes, hypertensive complications, antepartum bleeding, chorioamnionitis, materna substance abuse, suspected growth retardation) were excluded from analysis. The entire first stage of labor was documented in all study cases. Two 30-min segments of fetal heart tracing, one immediately upon admission and the second, one hour prior to complete dilation, were evaluated. The following parameters of the tracing were compared between the two different time frames:

FHR Parameter	FHR at admission	FHR 1 h prior to complete dilation	p value
Baseline (bpm)	138±9.2	138±9.9	NS
No. oscillations/min	6.8±2.1	7.1±2.6	.02
Total no. accel./min	4.5±3.6	2.9±3.1	<.0001
No. accel. >15 beats	3.7±3.8	2.3±3.0	<.0001
Highest accel. (beats)	21±14	17±16.7	<.0001
No. contractions/min	8.2±3.9	11.6±3.6	<.0001
Total no. decel./min	0.5±1.6	2.8±3.7	<.0001
No. variable decel./min	0.3±1.2	2.6±3.6	<.0001

Additionally, 19.2% of cases with a normal tracing (after Krebs) on admission ended the first stage of labor with abnormal scores. Furthermore, 56.5% of cases with abnormal tracings at entry completed the first stage with normal scores. In conclusion, our data show some deterioration of the FHR pattern during the first stage of labor in a population of low-risk pregnancies with good neonatal outcomes.

135 **PROLONGED BRADYCARDIA: HOW LONG IS LONG ENOUGH?** N. Field,* A. Samueloff,* M. Berkus, E. Xenakis,* M. McFarland,* O. Langer. Dept. of Ob/Gyn, UTHSC, San Antonio, TX.

Disagreement exists regarding the significance of prolonged bradycardia occurring in the second stage of labor. We hypothesized that the duration of the prolonged bradycardia in the second stage is not associated with adverse perinatal outcome in the absence of clinically-evident obstetrical emergency, e.g., placental abruption or uterine rupture. In an ongoing study, we analyzed the fetal heart rate tracings in the entire second stage of labor for 1,500 consecutive deliveries. Prolonged bradycardia was defined as either a fetal heart rate ≤90 beats per minute or a drop in the previously established baseline of ≥30 beats lasting for ≥2.5 minutes. Perinatal outcome was assessed by 1 and 5 minute Apgar scores and umbilical cord pH at delivery. Additionally, infants who went home within 2.5 days with no NICU admissions were defined as having a good outcome. Ninety-four cases of prolonged bradycardia in the second stage of labor were identified, representing an incidence of 6.5% of all cases analyzed. The length of the bradycardia ranged from 2.5 to 20 minutes, with a mean duration of 5.6±1.9 minutes. The mean drop in fetal heart rate from baseline was 53.4±36 beats. Forty six (63.0%) of the patients had a normal spontaneous vaginal delivery and twenty-six (35.6%) were delivered by vacuum extraction or forceps; only one patient (1.3%) underwent cesarean section.

	Length of Prolonged Bradycardia (Minutes)			
Outcome Variable	*<3 min (n=28)*	*3-5 min (n=29)*	*5-7 min (n=19)*	*>7 min (n=18)*
pH >7.20	75.0%	86.4%	68.8%	71.4%
1 min Apgar >7	81.0%	95.5%	87.5%	92.9%
5 min Apgar >7	100.0%	100.0%	93.8%	100.0%
Good outcome	100.0%	82.6%	78.9%	91.7%

The study further revealed: 1) the absolute length of the second stage of labor did not seem to influence outcome in the presence of prolonged bradycardia, and 2) the mode of delivery did not affect the fetal outcome. Thus, our data suggest that in the face of a prolonged bradycardia in the second stage of labor, expeditious delivery is not a necessary intervention to guarantee a good fetal outcome.

136 CORD CREATINE KINASE BB ISOENZYME CORRELATES WITH FETAL METABOLIC ACIDOSIS. R. Soper, U. Verma, N. Tejani, NY Med., Coll., Valhalla, N Y.

Background Conventional methods of peripartum fetal assessment have poor sensitivity and predictive value for immediate and long term fetal outcome. Tissue damage derived enzymes may be indicators of fetal injury. Creatine Kinase (CK) an energy transfer enzyme, exists in three isoenzyme forms. The BB form is derived predominantly from neural tissue. **Object** Correlation of cord CKBB with fetal metabolic acidosis in the term fetus. **Method** 139 consecutive deliveries of ≥35 weeks gestation were studied. Patients were divided into 2 groups based on the umbilical artery base deficit (BD), acidotic BD≤-10mMol/L and non-acidotic BD> -10 mMol/L. Total CK and CKBB in the umbilical artery and vein were correlated with acidosis. **Results** umbilical artery and vein CKBB correlated significantly with metabolic acidosis. **(TABLE)**

		BD≤ -10mM/L (#21)	BD> -10mM/L (#118)	P
Artery	CKBB U/L +/-SEM	62.1 +/-35	19 +/-2.7	0.02
Vein		26.7 +/-5.4	18.9 +/2.4	0.03

Conclusions CKBB correlates with fetal metabolic acidosis and may be a more specific predictor of neurological injury than other outcome markers.

137 INTRAPARTUM FETAL HEART RATE ASSESSMENT: MONITORING BY AUSCULTATION. J.C. Morrison, B.F. Chez,[X] I.D. Davis,[X] J.R. Allbert,[X] R.W. Martin, W.E. Roberts, J.N. Martin, Dept. Ob/Gyn, Univ. Mississippi Med. Ctr., Jackson, MS

Objective: To determine if intermittent auscultation of fetal heart rate (FHR) using strict frequency of evaluation and documentation criteria is feasible under clinical conditions in a busy labor and delivery suite in a tertiary center. Patient Population: During a 3-month period, 862 consecutive women in labor with live fetuses between 24 and 43 weeks' gestation were available for intrapartum auscultation of FHR (case series study design). Main Outcome Measured: Whether or not auscultation could be initiated and maintained for evaluation of FHR during the intrapartum period with a frequency requirement of auscultation and documentation of 15 minutes in the first stage of labor and 5 minutes during the second stage. Results: In 420 patients, this modality was not begun due to inability of the nurses to meet 1:1 staffing requirements. In 19 patients, auscultation was not performed due to obesity (12) or patient refusal (7) while in the remaining 423 patients it was begun. Auscultation was initiated during a contraction and extended for 30 seconds after the uterine activity ceased. It was repeated every 15 minutes in the first stage and 5 minutes in the second stage of labor. Of the 423 assessed by auscultation, 392 were unable to complete monitoring due to the frequency requirement (n=212) or the recording criteria (n=163). Of the 31 patients where ausculation was used successfully, labor was < 6 hours in 22 patients. In 9 patients who successfully completed ausculation, there was a 1:1 nurse ratio during the entire labor. Conclusion: Auscultation offered during the intrapartum period using stringent evaluation and recording criteria is not feasible under normal labor and delivery suite conditions unless a 1:1 nursing ratio is always available. This degree of staffing is rarely possible for the majority of obstetric areas in the United States during the entire labor.

138 EFFECTS OF MAGNESIUM SULFATE ON FETAL HEART RATE MONITORING IN THE PRETERM FETUS. JW Wright,[1,2] BD Wright,[1X] LE Ridgway,[2] DL Covington,[1X] JR Bobitt.[1] [1]Area Health Educ. Ctr, Wilmington, NC; [2]Univ. of Texas Health Science Ctr at San Antonio

Previous studies have reported that magnesium sulfate ($MgSO_4$) alters important characteristics of fetal heart rate monitoring. However, the results of these studies are inconsistent and most used preeclamptic patients near term. Because preterm labor is associated with other high risk conditions, the effects of $MgSO_4$ tocolysis on fetal heart rate monitoring are clinically important. We sought to evaluate these effects using 1) objective criteria with decreased variability defined as oscillation band width <6 bpm, normal variability as 6-25 bpm, and increased variability as >25 bpm; and 2) subjective evaluation with variability graded as absent, decreased, normal or increased. Agreement of 2 of 3 blinded examiners was used to define the categories. We prospectively collected fetal heart rate tracings for 30 minutes before and after $MgSO_4$ loading in 48 preterm labor patients. We compared pre- and post-therapy results using McNemar's test for categorical data and a paired t-test for baseline fetal heart rate. No monitor tracings were read as having absent or increased variability.

Results	Pre (n=48)	Post (n=48)	p
Baseline FHR	140.8	137.3	.001
NST Reactive	26	21	NS
Objective Variability			.13
Band width 6-25	48	44	
Band width <6	0	4	
Subjective Variability			.006
Normal	46	36	
Decreased	2	12	

Subjective evaluation demonstrated a greater likelihood of decreased variability after $MgSO_4$ loading. However, loss of variability was not shown by objective measurement. We conclude that $MgSO_4$ tocolysis may be associated with subjectively decreased variability.

139 FETAL PULSE OXIMETRY DURING LABOUR

J Gardosi[X], C Schram[X], D Damianou[X], EM Symonds[X]
Perinatal Research & Monitoring Unit,
Queens Medical Centre, Nottingham, England

Pulse oximetry, the non-invasive measurement of arterial oxygen saturation, has become a principle form of monitoring in several specialities. In perinatology, its application has been hampered by poor access to the fetus. We have developed a fetal oximeter probe which is held on the scalp by means of a double Copeland clip. The probe can be applied from 2 cm cervical dilatation and a continuous, on-line trend of oxygen saturation can be recorded straight onto the cardiotocograph paper. Preliminary results (105 labours) showed that saturation values on the fetal scalp present a stable baseline during normal labour (70 - 90%, median 82%). An unstable trend and a fall to below 60 % saturation was observed during the development of fetal acidosis. Our in vitro and animal studies have confirmed that fetal Hb dissociation curves are sensitive to the Bohr shift and give lower oxygen saturation levels during acidosis. Artifacts may arise due to non-arterial pulsations - e.g. from caput - and we have shown that this error can be excluded by signal processing which analyses both electronic (ECG) and optic (plethysmographic) signals and rejects non-synchronised readings. Incomplete apposition of the probe results in false-low readings; we have quantified this error and shown that the AC and DC components of the oximeter signal are affected differentially, thus affecting the calculations by the oximeter. Our probe failed in the presence of thick fetal hair, and a new probe is being developed which avoids this problem by apposing sensors to fetal skin away from hairy scalp. Pulse oximetry holds enormous promise for improving fetal surveillance during labour but successful adaptation requires attention to the particular difficulties and errors that may arise from this new application.

140 MECONIUM: MARKER FOR HIGH-RISK PREGNANCIES. M. Berkus, A. Samueloff,[X] E. Xenakis,[X] N. Field,[X] L. Ridgway, O. Langer. Dept. OB/GYN, The Univ. Texas Health Science Center, San Antonio, TX.

Traditionally, meconium (MEC) portends impending or ongoing fetal compromise, but recently this association has been questioned. Controversy exists regarding the relationship of MEC with abnormal fetal heart tracings, Apgar scores, pH and outcome. In this study, we sought to characterize the outcome of the patient with MEC-stained amniotic fluid. Over 2,000 consecutive deliveries were analyzed by a team of perinatologists, including scoring of the cardiotocograms (after Krebs). The incidence of term (>2500 g) babies with moderate or thick MEC was 16.7%. Mothers with chorioamnionitis and gestational diabetes had an increased incidence of MEC (35.6% and 21.4%, respectively; p<.03). In contrast, no significant increase in MEC was found in SGA (14.3%), hypertensive (14.4%) or prolonged pregnancies (19.4%) when compared to the non-MEC group. Infants with MEC were found at significantly increased risk for:

	MEC (%)	NOMEC (%)	RR (95% CI)
1st stage FHR abnormal	20.9	13.5	1.5 (1.2 2.0)
2nd state FHR abnormal	49.8	20.2	2.5 (1.9 3.1)
APGAR 1" <7	15.4	5.8	2.7 (1.7 4.1)
APGAR 5" <7	2.5	0.5	5.0 (1.6-15.6)
pH<7.2	26.9	13.6	2.0 (1.4 2.7)
Sepsis	4.1	1.1	3.6 (1.6-8.1)
Oxygen support	9.2	3.0	3.1 (1.2-8.0)
NICU admission	13.5	2.9	4.6 (1.9 11.3)

The study also revealed that MEC infants were more likely than non-MEC to: 1) be delivered by emergency C/S (15.4% vs 9.8%, p<.03); 2) experience adverse neonatal outcome (8.3% vs 3.9%, p<0.2), as defined by NICU stay, respiratory distress, or abnormal neurological sequelae; and 3) have significantly more adverse outcome when associated with bradycardia or decreased variability (p<.03), but not with tachycardia or lack of accelerations. Our data suggests that, even with modern OB care, a pregnancy with meconium is at increased jeopardy and should be considered high risk.

141 A NEW DIMENSION IN UMBILICAL CORD BLOOD pH: NEONATAL pH. K.G. Goldaber,* K.J. Leveno, L.C. Gilstrap III, M.A. Kelly,* M.L. Sherman,* Dept. Ob/Gyn, Univ. Texas Southwestern Med. Ctr., Dallas, Texas

Umbilical cord blood gases are increasingly being used in the evaluation of infant outcomes. Logically, infant outcomes should also be measured in relation to acid-base events occurring during the neonatal period, especially the first hours of extrauterine adaptation. We correlated umbilical artery blood pH to arterial pH measured within 2 hours of birth in 476 high-risk infants. Results are summarized in the following table showing the number of infants within cord blood pH groups and their corresponding initial neonatal pH:

	Neonatal pH					
Cord pH	<7.00	7.00-7.09	7.10-7.19	7.20-7.29	7.30-7.39	≥7.40
<7.00	3	6	3	4	1	0
7.00-7.09	1	2	2	8	6	1
7.10-7.19	1	0	7	21	32	4
7.20-7.29	0	3	20	87	72	21
7.30-7.39	0	7	9	50	67	16
≥7.40	1	1	1	10	5	4

The shaded numbers include 42 (9%) infants with cord blood pH values 7.20 or greater and neonatal values 7.19 or less. 12 (3%) of these infants had neonatal pH values 7.10 or less. Conclusion: Acidemia can occur in the immediate newborn period.

142 THE EFFECT OF MAGNESIUM SULFATE ON FETAL HEART RATE VARIABILITY IN THE TERM PREECLAMPTIC PATIENT. L.E. Ridgway, O. Langer, A. Samueloff,[X] M.D. Berkus, N.T. Field,[X] E. Xenakis,[X] Dept. of Ob/Gyn, UTHSC, San Antonio, TX.

Controversy exists regarding changes in fetal heart rate (FHR) variability associated with use of magnesium sulfate ($MgSO_4$). We investigated changes in FHR variability associated with $MgSO_4$ infusion. FHR tracings of 1500 consecutive deliveries were prospectively analyzed by blinded MFM specialists in 2 time windows: 1) first 30 min period after admission to L&D and 2) a 30 min window 1 h prior to 2nd stage. Variability was defined by: 1) amplitude–from the baseline and 2) oscillations–number of times the FHR crossed the baseline, both defined in the best 1 min period of the window. For analysis, patients were stratified into 2 groups: 1) preeclamptic patients (PRE) with gestational age (EGA) ≥36 wks who did not receive narcotics and had normal outcome (n=57), and 2) non-hypertensive subjects with EGA ≥36 wks who did not receive narcotics and had normal outcome (NL; n=852).

	Time 1		Time 2†	
	Amplitude bpm	Oscillations	Amplitude bpm	Oscillations
Group I PRE, n=57	7.3 ± 2.6*	6.5 ± 1.9	6.4 ± 3.2*	6.4 ± 2.7
Group II NL, n=852	7.8 ± 3.2	6.8 ± 2.1	7.6 ± 3.3	7.0 ± 2.6
p	ns	ns	<.01	ns

*p<.05; †Group 1 at Time 2 on $MgSO_4$ infusion

We further analyzed the relations of amplitude in PRE and NL: a) during Time 1 comparable rates of normal amplitude were found between PRE (100%) and NL (96%); b) in contrast, a 3 fold increase in the rate of reduced amplitude (<3 BPM) was found in the PRE (14%) when compared to NLs (5%, p=.01); c) comparing Times 1 and 2 in PREs, there was a change in reduced amplitude from 0% to 14% (p=.006); and d) no significant difference exists in the incidence of reduced variability comparing Times 1 and 2 in NLs (4% vs. 5%). A similar significant change was found in oscillation even though there was no difference in the means. Thus, a physiological and clinical decrease in variability is seen with MgSO4 infusion.

143 PROLONGED BRADYCARDIA IN THE FIRST STAGE OF LABOR: WHEN TO DO WHAT. M. McFarland,* E. Xenakis,* O. Langer, A. Samueloff,* N. Field,* M. Berkus. Dept. OB/GYN, University of Texas Health Science Center at San Antonio, Texas.

It is generally accepted that prolonged fetal bradycardia in the 1st stage of labor signifies fetal compromise and warrants immediate intervention, but little exists in the literature to support this conclusion. We investigated the effect of 1st stage prolonged bradycardia, defined as a drop in the fetal heart rate of ≥30 bpm to ≤90 bpm for ≥2.5 min, on fetal outcome. 1500 consecutive deliveries were evaluated; the overall incidence of prolonged bradycardia was 4%. Fetal heart tracings were analyzed for 30 min prior to and after the episode of bradycardia for multiple parameters, e.g., presence or absence of accelerations, decelerations, variability and duration of bradycardia. 100 women (2:1 ratio) matched by gestational age and fetal heart rate score (after Krebs) served as controls. For purpose of analysis, newborns were stratified into outcome groups: good (infant went home in 2.5 days, was not admitted to the NICU); and adverse (NICU admission with respiratory support and/or other complications, i.e. hypotonia, IVH, sepsis or neonatal death). Overall, a significantly greater number of infants had low arterial cord pH (<7.2) in the bradycardia group (47.2% vs. 25.5%, p<0.05). Further analysis, evaluating outcome by mode of delivery, is shown below:

	Bradycardia		Control	
	C/S	Vag	C/S	Vag
Good	81.1%	88.9%	77.4%	97.1%
Adverse	11.5%	18.5%*	22.6%	2.9%*

*p<0.05

Finally, stepwise logistic regression was used to evaluate fetal heart rate components in order to predict adverse outcome. The total number of accelerations and late decelerations explain 38% of the variance. Duration of the bradycardia, time to recovery, baseline and variability were not found to be significant predictors. Our data suggest that although presence of prolonged bradycardia is not an indication for immediate delivery, caution should be exercised when allowing these patients to continue labor.

144 THE INCIDENCE OF INTRAPARTUM FETAL DISTRESS IN COCAINE ABUSING GRAVIDAS. K. Piacquadio[X], O.W. Jones III[X], P. Herbig[X], R. Resnik, Dept. Repro. Med. UCSD, San Diego, CA.

Women between the ages of 18-34 comprise 15% of the regular cocaine users in the U.S. Previous studies have shown that cocaine use during pregnancy is associated with abnormal fetal growth, preterm labor and delivery and an increased incidence of abruptio placenta. The purpose of this study was to determine if maternal cocaine use was correlated with an increased incidence of intrapartum fetal distress. The fetal heart rate and uterine contraction tracings from 75 women in labor with positive urine toxicology for cocaine on admission were read by two blinded observers. These tracings were compared with those of 166 women with no antepartum cocaine use. Data were analyzed by Group t test, Chi square or Fischer's Exact test where appropriate. The results of this study showed a significantly lower gestational age (p<0.01), birth weight (p<0.01) and one minute Apgar score (p<0.01) among cocaine-using gravidas as well as increased gravidity (p<0.01) and parity (p<0.01) when compared to the control group. The fetuses of the cocaine users had a significantly higher incidence of non-reactive tracings (p<0.01) and one observer found significantly decreased beat-to-beat variability (p<0.05). Neither observer found a significant change in baseline fetal heart rate or incidence or severity of variable or late decelerations. Arterial cord pH values were obtained in 26 of the cocaine exposed and 19 of the control fetuses. There was no significant difference between the two groups (cocaine pH 7.26 ± 0.11, control pH 7.24 ± 0.09). The results of this study suggest that cocaine use is not associated with significant intrapartum fetal distress.

Poster Session II

Thursday, February 6, 1992
4:00 p.m.-6:00 p.m.

145 **IS THE 5-STEP ECHOCARDIOGRAPHIC APPROACH FEASIBLE THROUGHOUT PREGNANCY?**

Danielle M. Blake, E. Albert Reece, Dimitrios Mastrogiannis[X]. Department of Obstetrics and Gynecology, Temple University School of Medicine, Philadelphia, PA.

Fetal echocardiography utilizes various ultrasound modalities for detailed heart study. The five principle views which are considered essential for a 2-D realtime cardiac study include the 4-chamber view, ventricular outflow tracts, cardiac inflow vessels, aortic and ductal arches, and the long and short axis great vessels. However, a complete echocardiogram is thought to be hampered by advanced gestational age. This claim, however, has not been subjected to study. An ongoing prospective study was therefore initiated to address this issue. All patients undergoing an ultrasound examination were invited to participate in this study. The five principle cardiac views were attempted by two operators. Three groups of gestational ages were analyzed: Group 1, 20-24 weeks; Group 2, 25-32 weeks; Group 3, 33-40 weeks. To assess the degree of difficulty in obtaining each view in each of 3 gestational age groups the length of time in minutes was determined. Our preliminary data summarized in the table, demonstrate the feasibility of obtaining these basic views throughout pregnancy and showed a lack of significant difference in time spent per study in either the second or third trimester.

	Time (minutes) Gestational age groups		
Cardiac views	1	2	3
4 chamber view	1.33± .96	1.65±2.11	.81± .62
ventricular outflow tracts	1.50± .42	1.38± .41	1.30± .39
cardiac inflow vessels	.67± .30	1.65±1.34	3.48±2.95
aortic & ductal arches	2.87±2.88	3.82±2.30	2.33± .88
long/short axis GV	2.37± .78	3.03±1.75	3.47±2.63
all views	8.73±1.02	11.53±5.91	11.40±3.40

CONCLUSION: Although additional time is always spent and other ultrasound modalities are used reviewing cardiac structure and function in detail, the above data indicate that the 5 step approach to 2-D realtime fetal echocardiac exams is applicable throughout pregnancy. Therefore, advanced gestational age should not be considered a precluding factor to a complete cardiac exam.

146 SONOGRAPHIC DETECTION OF DECREASED FETAL HEAD GROWTH SECONDARY TO ALCOHOL AND COCAINE EXPOSURE. S.S. Martier,[X] R.J. Sokol, J.W. Ager,[X] Dept. Ob/Gyn, Wayne State Univ /Hutzel Hosp., Detroit, MI

Decreased head circumference (HC) at birth has been previously reported to be associated with prenatal alcohol and drug exposure. In a large study on prenatal alcohol exposure, approximately 10,000 Black gravidas were interviewed prospectively in a core city prenatal clinic. To examine the relationship, if any, of decreased HC *in utero* to polydrug exposure, a sample of 1,137 consecutive gravidas who had ultrasound examinations at 28.5 ± 7.6 weeks gestation as part of their antenatal care was evaluated. Head circumference *in utero* (HCIU) was calculated using morphometric measurements of head biparietal diameter (BPD) and occipito-frontal diameter (OFD) measures taken *in utero* (3.14 × (1.5 + BPD + OFD)/2). HCIU was residualized for gestational age at time of ultrasound exam on the part of the sample unexposed to drugs or heavy alcohol, i.e., ≤.5 ounces of absolute alcohol per day, and then applied to the entire sample. In multiple regression analyses, exposures (alcohol, cannabis, cocaine, narcotics) and covariates (maternal age, prepregnancy weight and cigarette smoking) were related to HCIU. The proportion of drinking days reported at the time of conception and use of cocaine related significantly to smaller HCIJ ($F(2,1136) = 9.9$; $R^2 = 1.7\%$). This finding supports the hypothesis of an adverse impact of prenatal cocaine and alcohol exposure on decreased head growth which has been associated with increased risk of aberrant neurobehavioral development. These findings suggest that effects of heavy maternal alcohol and cocaine use may be detectible *in utero*, closer to the time of the insult.

147 FETAL FEMUR LENGTH: THE IDEAL ASSESSMENT OF GESTATIONAL AGE? A RETROSPECTIVE AND PROSPECTIVE ANALYSIS OF TWO DISTINCT RACIALLY DIFFERENT POPULATIONS. H.O. Thompson, M.D.,[X] J.S. Abramowicz,M.D., C.Cox,Ph.D,[X] Depts. Obs/ Gyn and Biostatistics, University of Rochester Medical Center, Rochester, New York.

Exact determination of gestational age (GA) and assessment of fetal growth are two primary tasks of prenatal care providers. Femur length(FL) is less affected than other feta. measurements in growth disturbances. The data is inconclusive on the effect of race on biparietal diameter(BPD), abdominal circumference(AC), FL and birth weight(BW) with respect to GA primarily due to sample size and poorly defined populations. To evaluate the hypothesis that there are racial differences,AC, BPD, FL and BW were compared in a cross-sectional study (24-43 weeks) in 1401 singleton, live, black(507) or white(894) infants born within seven days of an ultrasound examination. The statistical analysis consisted of X^2, unpaired t-test, ANOVA, and analysis of covariance (ACOVA) with regression coefficients comparisons(RCC) with GA as the independent variable and parity, race and fetal sex as modifiers. The maternal and fetal demographic variables were similar in the two groups. The mean BW and BPD in black fetuses were smaller($p=0.05$ and 0.009) while there were no difference in the FL and AC. Males had significantly heavier BW and larger mean BPD than the females ($p=0.019$ and 0.010) while there were no differences in FL or AC. White males weighed more with the largest mean BPD while black females were lightest with the smallest mean BPD (ANOVA $p=0.037$, $p=0.004$). The ACOVA and the RCC confirmed that there was an effect of race on BPD, AC and BW with respect to GA while FL was uneffected ($P=0.009, <0.001, <0.001$). A prospective analysis was performed on a second sample of 195 fetuses(88 Black and 107 White) using the models developed during the ACOVA of the first population with Similar results. This suggests separate GA equations may have to be developed for each race if parameters other than FL are used. FL may be the measurement of choice to determine gestational age regardless of maternal race.

148 **TRANSCEREBELLAR MEASUREMENTS IN TWIN PREGNANCIES AND THE EFFECT OF INTRAUTERINE GROWTH RETARDATION.** L. Lettieri, A. Vintzileos, D. McLean, J. Rodis, W. Campbell, E. Wolf, Univ. of CT Health Ctr, Farmington, CT

Transcerebellar diameter (TCD) and transcerebellar diameter/abdominal circumference (TCD/AC) measurements have been established for singleton, but not for twin pregnancies. In singleton pregnancies, controversy exists on whether or not cerebellar growth is affected by intrauterine growth retardation (IUGR). We undertook this retrospective study of 171 patients with twin pregnancies in order to establish nomograms for both TCD and TCD/AC ratios in twin fetuses and to analyze the effect of growth retardation on these measurements. The data was analyzed in a cross-sectional manner. The TCD measurements for twin A & B were grouped together after analysis revealed no difference in TCD between the twin pairs (mean TCD (±SD): twin A 2.57 (±.86) vs. twin B 2.56 (±.85), $p=.8$). Of 342 fetuses, 322 were available for analysis. The gestational age ranged from 14 38 weeks. The nomograms were established from these fetuses. The TCD increased linearly with gestational age ($r=.94$, $p<.001$). The TCD/AC ratio was stable throughout gestation ($r=.005$), with a mean TCD/AC (±SD) of 13.7 (±1.2). The 5th and 95th percentiles were 12.0 and 15.9, respectively. Twenty-four twin fetuses with IUGR (EFW ≤ 5th%ile by Yarkoni) were then analyzed; 10 (42%) of these fetuses had a TCD of ≤5th%ile for gestational age. The mean TCD/AC (±SD) of the IUGR fetuses was 14.6 (±1.6). However, only 4 of the 24 IUGR fetuses had an abnormal TCD/AC ratio for a sensitivity of 17%. The specificity, positive and negative predictive values were 95%, 21% and 94%, respectively. All fetuses with a TCD ≤ 5th %ile had a normal TCD/AC ratio. We conclude therefore, that an abnormal TCD/AC ratio is not very helpful (sensitivity of only 17%) in identifying growth retardation in twin fetuses. These findings also suggest that intrauterine growth retardation may affect cerebellar growth in twins since 42% of the IUGR fetuses had TCD of ≤5%ile.

149 PROSPECTIVE ANALYSIS OF MALFORMATIONS DIAGNOSED BY ULTRASONOGRAPHY IN CHROMOSOMALLY ABNORMAL FETUSES. B.R. Elejalde, [X]J.M. Acuña, [X]M.M. de Elejalde, Medical Genetics Institute, S.C. Milwaukee, WI.

2,547 patients underwent prenatal diagnosis, 15 had a chromosomal abnormality other than trisomy 21. 6 had trisomy 18, 4 were 45,X, 2 were triploidies, 1 had trisomy 9, 1 was a trisomy 13 and 1 had a ring 14. 147 abnormalities were found by ultrasonography (US) before the karyotype was known. 203 abnormalities were found postnatally. The 56 that were not found by US were divided into: 1) recognizable by US (9), 2) recognizable under special circumstances (14), 3) not recognizable by US (33) and 4) not recognizable postnatally (9). Out of 156 diagnosable by ultrasound, 147 (94.2%) were diagnosed. If those recognizable under specific circumstances are included, 147 out of 170 (86.5%) were diagnosed. Syndromic diagnosis, before karyotyping, was correctly done in 4 trisomies 18, 2 triploidies, 1 trisomy 13 and 3-45,X. The above distribution of abnormalities defines ultrasound resolution and the bases for quality control

150 PROSPECTIVE STUDY OF THE ULTRASONOGRAPHIC RESOLUTION OF NORMAL FETAL CHARACTERISTICS. B.R. Elejalde, [X]M.M. de Elejalde. Medical Genetics Institute, S.C. Milwaukee, WI.

3,900 patients underwent 8,200 ultrasonographic examinations. Fifty one structures were measured, 68 ossification centers and 173 anatomical structures were scored as: seen, not clearly seen, not seen, not present and abnormal. Nineteen patterns of fetal activity were similarly recorded and their frequency scored. Only normal pregnancies 10 to 39 weeks were included. Descriptive statistical analysis was used for the analysis of each one of the 311 items per week. Centiles 1st to the 99th were established for each measurement and week. A table including the characteristics for each week based on this analysis was constructed and constitutes the bases to determine the mean and the range of expected results of the fetal ultrasonographic examinations at weeks 10 to 39. They define the bases to determine the levels of ultrasound resolution. Resolution is affected by the knowledge of the operator, obesity and fetal position.

151 AMNIOTIC FLUID VOLUME ASSESSMENT IN HUMAN PREGNANCY: COMPARISON OF SONOGRAPHIC ESTIMATES VERSUS DIRECT MEASUREMENTS USING A DYE-DILUTION TECHNIQUE. Gary Dildy, Noe Lira[X], Kenneth Moise Jr, Gerry Riddle[X], Russell Deter[X]. Department of Obstetrics and Gynecology, Baylor College of Medicine, Houston, Texas.

Abnormalities in amniotic fluid volume (AFV) are associated with poor perinatal outcome. The purpose of this study was to compare the accuracy of indirect real-time sonographic techniques of AFV assessment with a direct technique of AFV measurement. METHODS: A water-soluble dye (aminohippurate sodium) was instilled into the amniotic sac of women undergoing amniocentesis for fetal lung maturation during the third trimester. Thirteen distinct semiquantitative sonographic techniques in both the supine and lateral recumbent positions, including the amniotic fluid index (AFI), were performed. A second amniocentesis was performed to determine dye concentration in order to calculate actual AFV. Optimal polynomial regression functions of sonographic measurements (independent variable) versus actual AFV (dependent variable) were determined. Predicted AFV was calculated by introducing the value of the sonographic measurement into the equation. The percent difference between the actual and predicted AFV was determined for each measurement, and the mean, standard deviation, and 95% range were calculated. The Student t-test, ANOVA, and F-test were used to determine differences between techniques, with $p<0.05$ considered significant. RESULTS: 50 patients were enrolled into the study. Mean actual AFV as determined by the dye technique was 1066 ml (range 129 to 4444 ml). Mean AFI was 16.4 cm (range 2.7 to 31.3 cm). The regression equation for the AFI technique was: $y = -713 + 258x - 17.1x^2 + 0.437x^3$; $R^2 = 72.1\%$, mean percent error = 11.5%, standard deviation of percent error = 53.0%, and 95% range of percent error was -51.7 to 103.7%. Among the 13 techniques, there were no differences in mean error as determined by ANOVA. Four of the techniques showed a statistically significant reduction in standard deviation of error as determined by the F-test, when compared to the AFI. CONCLUSIONS: The AFI overestimated the actual AFV by as much as 104 % at low ranges and underestimated the actual AFV by as much as 52 %, especially at higher ranges. Although there were statistically significant reductions in measurement error among several of the sonographic methods compared to the AFI, these differences did not appear sufficient to recommend changes in current clinical practice.

152 SERIAL HOURLY FETAL URINE PRODUCTION IN FETUSES WITH BILATERAL HYDRONEPHROSIS. SJ Carlan, D Adkins[1], M Gore[1], D Mastrogiannis, Depts Ob/Gyn U of S FL,Tampa, FL, ORMC, Orlando.

Since some ultrasound detected fetal hydronephrosis,(H), cases are not present after birth, it is possible that this finding may be functional and related to the greater urine production in the fetus compared to the neonate. The purpose of this study was to compare hourly fetal urine production (HFUP) in fetuses with bilateral H to a group of normal fetuses. Fourteen normal fetuses and five fetuses with bi-lateral H were scanned serially from 20 wks until delivery, and HFUP measurements were attempted. All fetuses with H had major calyceal system dilatation with kidney longitudinal length\ collecting system length ratios >30% for both kidneys throughout gestation. There were no detectible cases of hydroureter or extrarenal anomalies in either group. There was no difference in fetal kidney length or AFI during gestation. Glucose screens were performed on all women, and there were no maternal disorders in either group. There was no significant difference in maternal age,GTPAL,smoking or C-section rate. Mean BW was 2979 and 3569 for the H group and normal group respectively. Neonatal urologic workup in the H group was normal in all cases except one infant with persistent hydronephrosis (this fetus also demonstrated minor calyceal dilatation).

SERIAL HFUP cc/hr (MEAN ±1SD)

WKS	N	Bilateral H	N	Normal	P
20	5	3.6 ± 1.1	14	4.1 ± 1.9	NS
22	5	4.8 ± 1.2	14	5.0 ± 1.7	NS
24	5	9.8 ± 2.7	14	8.3 ± 2.7	NS
26	5	12.2 ± 4.1	14	10.6 ± 3.6	NS
28	5	12.4 ± 3.0	14	15.5 ± 4.2	NS
30	4	20.5 ± 4.6	13	23.6 ± 4.7	NS
32	4	24.7 ± 4.1	13	28.9 ± 5.6	NS
34	4	24.6 ± 3.8	13	37.3 ± 12.2	NS
36	3	37.1 ± 7.7	13	43.8 ± 13.9	NS
38	3	39.2 ± 8.3	8	58.3 ± 21.9	NS
40		]	8	47.9 ± 12.9	

We conclude that fetuses with ultrasound detected bilateral H have similar HFUP as fetuses without bilateral hydronephrosis.

153 ESTIMATED FETAL WEIGHT IS A POOR PREDICTOR OF MACROSOMIA AND SHOULDER DYSTOCIA.

H F Andersen, G Pridjian, C Maluska[X], C E Nugent, A Ng[X], R H Hayashi. Dept Ob/Gyn, University of Michigan, Ann Arbor, MI.

We evaluated the utility of ultrasound estimated fetal weight (EFW) to predict macrosomia (birthweight >4.0 kg) and shoulder dystocia (SD) in 566 patients (53 diabetics) with EFW performed within 28 days of delivery. 7 SD's occurred in the study group. EFW was determined by three methods (Shepherd, Hadlock, Spinnato) and projected to the date of delivery using a standard fetal growth curve. Mean error of EFW was 17.9 g overestimation (1 standard deviation = 0 348 g); mean absolute error was 8.8% of birth weight. Receiver operator characteristics of EFW to predict macrosomia were plotted. EFW > 4.0 kg was less efficient for predicting macrosomia in diabetic patients; non-diabetics: sensitivity = 0.60, specificity = 0.96; diabetics: sensitivity = 0.33, specificity = 0.96.

Birth-weight	Total N	Vaginal Deliveries N	EFW>4kg	SD	SD+EFW>4kg
<3 kg	308	222	0	0	0
3 - 4 kg	289	199	11	4	1
>4 kg	69	32	15	3	2

A policy of primary cesarean delivery for EFW >4.0 kg would have resulted in 26 additional cesarean sections and prevented only 3 SD's (40%). We conclude that EFW is a poor predictor of macrosomia and SD. Recommendations to perform primary cesarean section for macrosomia based on studies utilizing birthweight, a parameter unknown to obstetricians prior to delivery, are of little clinical value.

154 ANTEPARTUM ULTRASOUND ASSESSMENT IN TWIN GESTATIONS AS PREDICTOR OF FETAL COMPROMISE

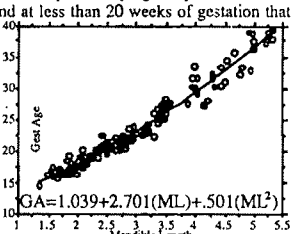
B. Campbell, R. Newman, L. Laham[X], J. Ellings[X], D. Eller, Med Univ of S.C., Charleston, S.C.

Multifetal gestations are associated with rates of perinatal mortality that are 5 to 10 times higher than seen with singleton gestations. Because of the risk inherent to multifetal gestations, appropriate antepartum surveillance is intensely debated but poorly studied. Besides prematurity, the majority of complications which contribute to this excessive perinatal mortality can be diagnosed by ultrasonography (US) including twin discordancy, IUGR, oligohydramnios, polyhydramnios, monoamniotic twins, and anomalies. The current study was designed to assess the ability of monthly antepartum ultrasound examinations to predict multifetal gestations at risk for intrauterine compromise. One hundred six twin gestations were followed in a special antepartum twins clinic from 1-1-88 to 7-31-91. The mean gestational age at diagnosis of these twins and their mean gestational age at delivery were 18.7 ± 6.6 weeks and at 35.6 ± 2.9 weeks respectively. Ultrasound examinations were performed every 4 weeks. Of the gestations followed, 91 (86%) had an US performed within 4 weeks of delivery. Non-stress testing was begun at 34 weeks unless otherwise indicated. The US was considered normal if there was no evidence of IUGR (≤10th percentile), fetal discordance (≥25), or fetal anomalies and an intervening membrane and were normal amniotic fluid were noted. Seventy-seven percent had a normal US and 23% had at least one abnormal finding. Pregnancy outcome was then compared for the women with normal vs. abnormal antepartum ultrasound examinations. The incidence of antepartum, intrapartum, or neonatal compromise defined by fetal distress, five minute APGAR <7, cord arterial pH less than ≤7.10, meconium aspiration or neonatal seizures was 11 of 23 (48%) in the abnormal US group which was significantly higher than the 4 of 78 (5%) among the normal US group. (P < 0.001). Of those with the abnormal US findings, 36% had abnormal antepartum fetal heart rate testing compared to only 1.3% of the normal US group. The incidence of preterm labor or preterm rupture of membranes was not different between the two groups. The study suggests that serial ultrasonography effectively identifies abnormal multifetal growth and development and is an important screening tool to identify multifetal gestations at risk for utero placental insufficiency and in need of more intensive antepartum surveillance.

155 ROUTINE AMNIOCENTESIS IS NOT INDICATED TO EVALUATE AN UNEXPLAINED ELEVATED MATERNAL SERUM ALPHA-FETOPROTEIN.

M Albini[X], W. Cusick[X], J. Rodis, L. Lettieri, M. McMahon[X], A. Vintzileos, University of Connecticut Health Ctr, Farmington, CT.

Although routine amniocentesis is the standard of care as part of the evaluation for an elevated second trimester maternal serum alpha-fetoprotein (MSAFP), we do not routinely perform this procedure when investigating an elevated MSAFP. Our management plan consists of a targeted ultrasound examination with amniocentesis offered selectively as indicated by our ultrasound. A retrospective analysis was conducted of all targeted ultrasound examinations performed for evaluation of an elevated MSAFP at the Connecticut MSAFP Screening Program from November 1988 to June 1991. An elevated MSAFP was considered to be greater than or equal to 2.0 multiples of the median (MOM). A total of 392 patients were included in the study population. The mean gestational age at presentation was 20.3 weeks and the average MSAFP was 2.73 MOM. The final outcome was obtained of 379 patients (96.6%) and this group constitutes the focus of our report. Nine fetal-placental anomalies (2.4%) were detected by ultrasound which accounted for the elevated MSAFP: omphalocele (3); anencephaly (2); gastroschisis (1); myelomeningocele (1), encephalocele (1) and placental abruption (1). All nine patients underwent an amniocentesis for fetal karyotyping. One fetus with an omphalocele was proven to have trisomy 18. The remaining 370 patients (97.6%) were left with an unexplained MSAFP elevation. Forty-four patients (44/370 or 11.8%) underwent an amniocentesis due to inadequate fetal visualization or maternal preference. There was one pregnancy loss (1/44 or 2.3%) within 4 weeks of the amniocentesis. No abnormal fetal karyotypes were identified in these 44 patients. Also, no phenotypically abnormal infants were observed in the 326 patients who did not undergo an amniocentesis. Most importantly, no fetal anomalies were missed by ultrasound (sensitivity 100%). We conclude that amniocentesis is not routinely indicated for the evaluation of an unexplained MSAFP elevation.



156 ENDOLUMINAL CATHETER-ASSISTED TRANSCERVICAL ULTRASOUND OF FIRST TRIMESTER PREGNANCY.

N. Ragavendra,* M. B. Beall, J. McMahon,* E. G. Grant.* Depts. of Radiology and Ob/Gyn, UCLA Medical Center, Los Angeles, Ca.

Transvaginal sonography is an excellent technique for confirming the intrauterine location of pregnancy, and determining the presence of cardiac activity and age of the first trimester conceptus. However, its ability to display anatomic structures in the developing embryo is less than satisfactory. In order to enhance the visualization of anatomic structures of the early human embryo, we have utilized a commercially available, catheter-based, miniaturized ultrasound transducer (12.5 MHz) and introduced it into the gravid uterus through the cervix in twenty-five women about to undergo therapeutic abortions of first trimester pregnancies. In embryos of 6.5 - 8.5 menstrual weeks, transcervical ultrasound showed brain vesicles, limb buds, cardiac chambers, spine and in cases where umbilical cord was seen, blood flow was noted. Early detection of gross embryonic malformations is potentially possible with this technique.

157 BIOMETRY OF THE FETAL MANDIBLE. C. Otto, L.D. Platt, Dept. Ob/Gyn, Cedars-Sinai Med. Cntr./UCLA, Los Angeles, CA

The fetal mandible has not previously been studied in an objective fashion. A plane was established that measures one ramus of the jaw. The proximal landmark, the temporomandibular joint, is visualized below the level of the orbits in an axial section and the anechoic cartilaginous area between the mandibular rami, the symphysis mentis, is the distal landmark. One hundred and thirty two subjects were identified and studied in a cross sectional manner. All measurements were made by one author (C.O.) with commonly available ultrasound equipment. Patients studied were without known medical or obstetric complications and had a known last menstrual period(LMP) and either a positive pregnancy test within 6 weeks of the LMP or an ultrasound at less than 20 weeks of gestation that confirmed the LMP. No fetus studied had an abnormal karyotype or structural malformation identified at birth. Measurement of three separate images of mandible length were obtained and averaged. Statistical analysis was performed on a Macintosh II using Stat View II statistical software package. With the mandible length as independent variable, an equation for predicting gestational age was derived by polynomial least squares regression. There was a high degree of correlation with an adjusted R^2 of 0.963. The accompanying figure is a scatterplot of the data and the regression formula. An additional 31 fetuses were measured by the authors to evaluate interobserver variation. There was no significant difference in the measurements of the two observers.

Conclusion: The size of the fetal mandible correlates well with and may be used to predict gestational age. The landmarks of the measurement are reproducible and interobserver variation is acceptable. Further studies may allow delineation of growth of the fetal jaw in pathologic conditions and precise, objective determination of micrognathia.

158 BIPARIETAL DIAMETER PREDICTS NEONATAL SURVIVAL AS WELL AS ACTUAL BIRTH WEIGHT IN THE 500-1,000 GRAM INFANT. RS Smith[x], and SF Bottoms. Wayne State Univ., Hutzel Hospital, Detroit, MI.

Determining neonatal prognosis for the severely premature fetus is difficult but important in counseling and guiding obstetrical management. The obstetrician must rely on survival rates based on birth weight; error in estimated fetal weight limits the confidence regarding prognosis before delivery. In an attempt to improve the accuracy of prenatal predictions of survival we studied 130 singleton liveborn infants having birth weights of 500-1,000 grams and complete ultrasound examinations within 3 days of delivery. Birth weights were uniformly distributed. 80 infants survived; 50 died. For purposes of comparison, estimated fetal weight, biparietal diameter (BPD), femur, birth weight, and pediatric estimate of gestational age were evaluated as screening tests for neonatal survival using receiver-operator characteristic (ROC) curves. In this model, sensitivity and false positive rate were calculated using each value of every parameter as a cut point to predict survival. Visual inspection of the ROC curves indicated that BPD was the best single predictor. Prognostic tables based directly on obstetrical parameters were generated. Among infants < 800 grams, discriminant function analysis revealed that cesarean birth was associated with a higher survival rate, and that underestimation of fetal weight was linked with a lower cesarean rate and a worse prognosis. Irrespective of controlling for route of delivery, BPD did as well as actual birth weight and all other parameters in predicting survival. We speculate this is due to BPD being less subject to variation in growth; it may provide the most accurate estimate of gestational age in this weight range.

159 ASSESSMENT OF EARLY FETAL GROWTH IN DIABETIC PREGNANCIES BY VAGINAL SONOGRAPHY. Laxmi Baxi, Tessie Tharakan[x], Ana Monteagudo[x], Ilan Timor. Dept. of Ob/Gyn, College of P & S, Columbia Univ. & Columbia Presbyterian Medical Center, New York,

Inadequate glycemic control early in diabetic pregnancies is associated with an increased incidence of congenital malformations. Pedersen has reported early growth delay in these patients. We prospectively studied early fetal growth in 37 diabetic and 30 control pregnancies, all of whom had at least two vaginal sonograms between 40 and 112 days of gestation. Glycosylated hemoglobin (HbA1) measurements reflected glycemic control in early pregnancy. A discrepancy of >0.5 wks. was labeled as early growth delay.

Control of Diabetes	Early growth delay		No growth delay		Tot
	No malform	*malform	*No malform	*malform	
Poor HbA1 >8.5	9	2	14	2	27
Good HbA1 <8.5	1	0	9	0	10
Total	10	2	23	2	37

*caudal regression syndrome, *bilateral hydrothorax, *tetralogy of Fallot, *megaloureter, *4 spontaneous abortions, X^2-3.147, P-ns.

Of 37 diabetic patients, 27 had elevated HbA1 (>8.5%), indicating poor control, in the first trimester. Eleven of these had growth delay (40.7%). Delayed growth was seen in 1/10 in patients with well controlled diabetes (P-ns). In conclusion, using vaginal ultrasound, we did not detect increased incidence of early growth delay in all diabetic pregnancies. However, the delay was significant in patients with suboptimal glycemic control as compared to non-diabetic patients (X^2-4.079, P<.05). *(Supported by a grant from the Diabetic Foundation)*

160 ABNORMAL AMNIOTIC FLUID VOLUME AND FETAL STRUCTURAL DEFECTS. H.M. Wolfe, M.P. Dombrowski, S.F. Bottoms, I.E. Zador*, R.J. Sokol, Dept. of Ob/Gyn, Hutzel Hosp./Wayne State Univ., Detroit, MI

To date, studies of amniotic fluid volume (AFV) have focused primarily on extremes of AFV (oligohydramnios (oligo) and polyhydramnios (poly)) and their association with specific anomalies. We studied 3456 patients at greater than 15 weeks gestation. Abnormal (abn) AFV, by subjective and objective criteria, was grouped as oligo, decreased (decr), increased (incr) and poly. Each was compared to normal AFV for sonographically detected abnormalities of major organ systems. Odds ratios and 95% confidence limits (CL) were calculated. As expected, oligo was associated with an increased frequency of GU anomalies (39.2x) and poly with GI (21.0x) anomalies. Interestingly decr AFV was associated with an increase in heart (40x) and GI anomalies (12.9x). Heart (19.4x), umbilical cord (3.8x) and GI (27.8x) anomalies were also more common with incr AFV as indicated below (*p < .05).

	Oligo	Decr	Nl	Incr	Poly
Stomach	0/48	0/236	1/3006	1/111*	0/19
Bladder	2/51*	0/234	0/2994	0/110	0/19
Kidney	2/49*	1/219	4/2848	1/111	0/18
Umbilical Cord	0/13	0/155	5/2396	1/107	1/18*
Heart	1/20*	6/125*	2/1589	2/84*	0/16
Intestines	0/40	3/209*	2/2944	2/109*	1/17*
Ventricles	1/51*	0/215	3/2288	0/107	1/17*
Total Odds Ratio:	18.9	6.3	1.0	11.0	26.6
95% CL	7.3-49.2	2.9-13.6		4.8-25.5	7.2-98.3

Overall, the risk of anomalies is 6-26x greater with any departure from sonographically normal AFV. In fact, the incidence among cases of oligo and poly is not significantly increased when compared to incr and decr AFV. AFV reflects a continuum of risk. Patients with abn AFV, even those not meeting formal criteria for poly or oligo, should be considered at substantially increased risk for anomalies and carefully evaluated prenatally for their presence.

161 **CLINICAL EVALUATION OF A FETAL GROWTH PREDICTION MODEL** J. Owen, S.P. Cliver, M. Hardin, F.L. Goldenberg, H.J. Hoffman. The University of Alabama at Birmingham

Because normative values for sonographically determined biometric parameters are generally population-based, the growth-disturbed fetus could be overlooked unless its measurements fall outside of a predetermined, usually arbitrary, range. The Rossavik growth model [$P=c(t)^{k+s(t)}$] has been reported to define the growth potential of individual fetuses based on their own biometric parameters obtained prior to 26 weeks' gestation. We sought to confirm the validity of the model in a population of 581 gravidas who were followed with serial sonography as part of an NIH-funded protocol of fetal growth. Overall the model predicted the fetal abdominal circumference (AC), femur length (FL), and head circumference (HC) on the last sonogram (mean GA=35.9 wks) prior to delivery (mean GA=38.6 wks) with very small mean errors (AC=-1.25%, FL=-0.91%, HC=-3.99%). We then examined the model in the context of growth-disturbed newborns. Observed deviations from the model's mean predicted growth values were computed for each biometric parameter and expressed as percentiles above and below the mean. Only 2 of 46 growth restricted newborns (<10th birthweight percentile) had a measured AC growth deviation (on their last sonogram) above the 90th percentile of the model's predictions (suggesting that the fetus was exceeding its potential) compared to 23 of 46 whose measurements were below the 10th percentile. Conversely, 20 of 45 large-for-gestational age infants (birth weights >90th percentile) had AC deviations above the 90th percentile, while none fell below the 10th percentile. We conclude from these observations that this growth model may be of value in the prenatal identification of the growth-disturbed fetus. We will report the utility of the model in this population with respect to other clinical parameters including ponderal index, skin fold thickness and perinatal complications.

163 THE INCIDENCE OF DUCTAL CONSTRICTION AND OLIGOHYDRAMNIOS DURING TOCOLYTIC THERAPY WITH IBUPROFEN. M.D. HENNESSY, M.D.*, E.C. LIVINGSTON, M.D.*, J. PAPAGIANOS, M.D.*, A.P. KILLAM, M.D., Duke Univ., Durham, NC

Indomethacin is being used increasingly in the treatment of preterm labor, however, it has been associated with up to a 50% incidence of fetal complications. Foremost among these is premature closure of the ductus arteriosus (DA) and oligohydramnios. Consequently, at our institution we began using Ibuprofen (1,200-2,400 mg/day) as a tocolytic agent up to 32 weeks gestation. Doppler echocardiography was performed within one week of instituting therapy and every 1-2 weeks thereafter until discontinuation of the Ibuprofen. Patients received biophysical profiles with evaluation of amniotic fluid every 1-2 weeks. Constriction of the DA was defined as a systolic velocity greater than 120 cm/sec with a diastolic velocity greater than 30 cm/sec. We retrospectively identified 52 pregnancies including 61 fetuses that were treated in this manner. There were no cases of maternal intolerance or morbidity secondary to the medication. There were no cases of oligohydramnios. There were 3 cases of low-normal fluid (Phelan index 5.0-8.0) that occurred after institution of Ibuprofen therapy and resolved after discontinuation. In 54 of 61 fetuses, adequate studies were obtained revealing only 4 (7%) with increased ductal velocities consistent with mild constriction. Three of these fetuses demonstrated constriction within one week of starting Ibuprofen. All had normal echocardiograms within one week of discontinuing therapy. There was no relation between the dosage of Ibuprofen used and the incidence of ductal constriction.

We conclude that Ibuprofen use before 32 weeks gestation in preterm labor has a low incidence of ductal constriction. Our study population did not demonstrate true oligohydramnics.

162 **DO SEMIQUANTITATIVE AMNIOTIC FLUID(AF) INDICES REFLECT ACTUAL VOLUME?** C.Croom,* B.Banias,* E. Ramos,* L.Devoe, A.Bezhadian* A. Hiett* Dept. OBGYN, Med. College of Georgia,Augusta,GA.

To determine how well ultrasound measures of maximal AF pocket depth(MAPD) and AF index (AFI) reflect actual AF volumes (AFVs), we studied 40 near-term patients, prior to amniocentesis for fetal lung maturity, who had **normal** AFV estimates by **"eyeball"** exam. Each patient had MAPD and AFI performed by the same examiner and received intraamniotic injection of a 10% paraamino hippurate (PAH) solution. AFV was quantitated by spectrophotometric assay of PAH concentration. Oligo- and polyhydramnios were defined as < 400 ml and > 1500 ml, respectively, for AFV (Queenan:Am J Obstet Gynecol:1972:114:34).. Regression values were 0.79 and 0.33 for AFV on AFI and on MAPD, respectively. True positive rates for oligohydramnios defined as AFI < 5cm or MAPD < 2 cm were 33% and 0%, respectively; false positive rates were 0%. True positive rates for polyhydramnios, defined as AFI > 20 cm and MAPD > 8cm were 100%; false positive rates were 20%. Overall predictive accuracies were 73%(AFI) and 58% (MAPD). AFI is superior to MAPD or "eyeball" for actual AFV estimation;both indices **overestimate** actual AFV at **both** of its extremes.

164 INTRA- AND INTER-OBSERVER VARIABILITY OF THE AMNIOTIC FLUID INDEX J. Bruner, A. Harrington*, M. Goodman*, A. Sarno, Dept. of OB/GYN, Vanderbilt Univ. Medical Center, Nashville, TN.

In an attempt to assess intra- and inter-observer variations in performance of the amniotic fluid index (AFI), 34 women in the third trimester with intact membranes were examined twice by each of 3 examiners. The AFI was measured once by each of the 3 examiners in order, then repeated by each examiner in the same order. Numerical displays on the video terminal screen were covered so that the examiners were blinded to actual measurement values. Results were recorded on hard copy for later data analysis. A senior investigator supervised all examinations in order to monitor consistency of technique. Overall, AFI measurements varied from about 15% within examiners to about 25% between examiners. Both between and within variation of absolute differences increased as the AFI value increased, while the percent difference decreased. For those AFI values <150 mm, SD was 9.85 mm, while SD of values >150 mm was 16.4 mm. If a discriminatory AFI value of $\leq$ 50 mm was used to identify oligohydramnios, a single value at the cutoff point (50 mm) could vary on average from 35 to 65 mm. If a value of $\geq$ 250 mm was used to identify polyhydramnios, a single value at the cutoff point (250 mm) could vary on average from 215 to 285 mm. Simply repeating the test by the same examiner for those values that fall in the discriminatory zone will decrease the variability on average to 40 to 60 mm (oligo), and to 225 to 275 mm (poly).

165 SONOGRAPHICALLY THICK PLACENTAS: INCREASED PERINATAL MORBIDITY AND MORTALITY. MP Dombrowski, HM Wolfe, AA Saleh, MI Evans, Dept of Ob/Gyn, Hutzel Hosp./Wayne State Univ., Detroit MI

In order to determine the incidence and significance of sonographically thick placentas, we reviewed the computerized records of 18,827 viable, singleton pregnancies. Of these, 116 (0.6%) had placentas which appeared subjectively thick and measured at least 4 cm by ultrasound. Thick placentas, initially diagnosed at a mean of 28.6±5.5 weeks (range = 15 to 38), were associated with shorter gestations (36.6±4.5 v 38.5±3.1 wks, $p < .0001$), decreased birth weights (2832±967 v 3070±718 g, $p < .05$), 31 (26.7%) had decreased amniotic fluid (AFV), 8 (6.9%) had oligo, 13 (11.2%) had increased AFV, and 6 (5.2%) had polyhydramnios. Odds ratios and 95% confidence limits (CL) for adverse pregnancy outcomes associated with thick placentas are listed below:

5-min Apgar < 7	6.7 (CL 4.0 to 11.3)
Abruptio placentae	2.9 (CL 1.1 to 8.1)
NICU admission	4.1 (CL 2.8 to 6.1)
Anomalies	8.4 (CL 4.9 to 14.4)
Perinatal mortality	12.0 (CL 7.5 to 19.4)
Total morbidity/ mortality	4.5 (CL 3.1 to 6.6)

Possible causes of the 116 thick placentas included: Rh isoimmunization = 6, diabetes = 11, abruptio = 4, but none with syphilis. Congenital anomalies, and not the above, were the leading cause of perinatal mortality. On the basis of these data, pregnancies with thick placentas are at risk for compromised perinatal outcome; sonographic evaluation should be peformed to rule out coexistent anomalies.

166 PERINATAL OUTCOME WITH SONOGRAPHICALLY THIN PLACENTAS. MP Dombrowski, AA Saleh, SM Berry, DB Cotton, Dept Ob/Gyn, Hutzel Hosp./Wayne State Univ., Detroit, MI

In order to determine the incidence and significance of sonographically thin placentas, we reviewed the computerized records of 18,937 viable, singleton pregnancies. Of these, 122 (0.6%) had subjectively thin placentas by ultrasound. The diagnosis of a thin placenta was initially made at a mean gestational age of 29.4±7.4 weeks (range = 8.6 to 40.1 weeks). Thin placentas were not associated with shorter gestations (38.6±3.0 v 38.5±3.1 wks), but 20.5% had polyhydramnios, 19.7% had increased amniotic fluid volume (AFV), 12.3% had decreased AFV, and 1.6% had oligohydramnios. Odds ratios and 95% confidence limits (CL) for thin placenta adverse pregnancy outcomes are listed below.

Weight < 10th %tile	2.4 (CL 1.5 to 3.8)
Abruptio placentae	2.0 (CL 0.6 to 6.5)
NICU admission	2.2 (CL 1.4 to 3.5)
Anomalies	3.6 (CL 1.7 to 7.4)
Perinatal mortality	3.4 (CL 1.7 to 7.1)
Total morbidity/ mortality	2.1 (CL 1.4 to 3.1)

Possible causes of the 8 perinatal mortalities with thin placentas included: esophageal atresia, sacrococcygeal teratoma with abruptio, anencephaly, placental hemorrhagic endovasculitis, thoracic dysplasia, abruptio, diaphragmatic hernia, and ventricular septal defect. In conclusion, pregnancies with thin placentas are at increased risk for perinatal morbidity and mortality; a careful sonographic evaluation should be performed to rule out coexistent fetal anomalies.

167 **SIMPLE GEOMETRIC RELATIONSHIPS BETWEEN AMNIOTIC FLUID INDEX AND AMNIOTIC FLUID VOLUME.** Robert A Brace[X]. Division of Perinatal Med, Dept of Reproductive Med, University of California, San Diego, CA 92093

The 4 quadrant amniotic fluid index (AFI) is used increasingly as an indicator of amniotic fluid volume (AFV) even though no established relationship exists between these two variables. The purpose of this study was to establish idealized relationships among AFI, AFV, and fetal size by treating the uterus and the fetus as either spheres or circular ellipsoids (len/dia=2). Using a computer, the weight of the fetus was varied from 0 to 3000 gm and the AFI from 20 to 300 mm. AFV (ml) was determined as the difference between uterine and fetal volumes. We found that the size of the fetus had dramatic effects on the relationship between the AFI and AFV. That is, as fetal weight increased, there were large shifts upward and to the left in the curve relating AFI (x) to AFV (y). For example, for AFI = 100 mm, AFV for a 3000 gm fetus (876 ml) was 26.1, 7.9, and 2.0 times that of a 10, 100, and 1000 gm fetus, resp. In addition, when the size of the fetus was near zero, there was a cubic relationship between AFI and AFV. As fetal weight increased, the relationship between AFI and AFV became progressively less curvilinear. For a fetal weight of 3000 gm, the relationship was nearly linear (AFV = 10.7 x AFI - 162, $r=0.998$, $p<0.00001$ for spheres and AFV = 14.6 x AFI -271, $r=0.996$, $p<0.00001$ for ellipsoids). These relationships help explain the near linear relationships between the AFI and AFV previously observed in animal and human studies. Thus, the relationship between the AFI and AFV is unique for each gestational age because of the strong dependence on fetal weight.

168 FETAL ILIAC BONE AND FEET MEASUREMENTS: NOMOGRAMS AND APPLICATION IN SKELETAL DYSPLASIAS. R. Jaffe, W. Meyer,[X] S. Warsof University of Illinois, Chicago, IL.

Skeletal dysplasias is a heterogenous group of disorders affecting the skeleton. With detection of disorders of bone growth a general diagnosis is often made in-utero because many anomalies have similar features. This study was performed to create nomograms for growth of iliac bone(IB), length and width of fetal feet as well as their growth relative to the femur. The study included 250 women. Correlation between gestational age (GA), femur length (FL), iliac length and feet measurements were established. The growth of IB and feet were found to correlate linearly with GA with a R^2 of 0.933 for IB, 0.828 for length and 0.820 for width of fetal foot. There was a linear relation between feet measurements and FL with a R^2 of 0.875 for length and 0.805 for width of foot. The IB is affected in many skeletal dysplasias and other anomalies whereas in some it is unaffected. The fetal feet measurements were shown to correlate well with both GA and FL. Both IB and feet measurements improved the diagnosis of skeletal dysplasias found in-utero. CONCLUSION: The addition of nomograms for IB and fetal feet measurements will enable improved recognition of specific anomalies and patient counseling.

169 COMPARISON OF DIFFERENT ULTRASOUND PARAMETERS IN THE PREDICTION OF SMALL-FOR-GESTATIONAL AGE (SGA) INFANTS.

[X]TC Chang,[X]SC Robson,[X]JALS Spencer, Dept. of Ob/Gyn, University College Hospital, London ;[X]R Boys, Dept.of Statistics, Newcastle University, England.

Many different ultrasonic parameters have been used to predict birthweight below the 10th percentile (SGA). Results have invariably been presented as sensitivity and positive predictive value; the latter being highly prevalence dependent. No previous reports have attempted to present summary statistics for each ultrasound variable for comparison. We have reviewed the literature from the past 15 years (72 studies) regarding the ultrasonic prediction of SGA. Studies were included if; a) the reported population was high risk; b) the outcome measure was a birthweight < 10th centile (using appropriate population charts); and c) the necessary information to construct a 2 x 2 table was reported. Only ultrasound variables reported in at least 2 different studies were included. For each variable a pooled sensitivity and common odds ratio with 95% confidence intervals is reported.

Results

U/sound parameter	Sensitivity	Common Odds Ratio	95%confidence interval
BPD<10th centile	63.7	5.83	(3.62 -9.37)
HC / AC >95th	47.6	3.34	(1.55 - 7.99)
FL / AC >23	49.	2.82	(1.71 - 4.66)
EFW < 10th	77.9	39.07	(28.9 - 52.7)
AC < 10th	84.4	18.38	(9.83 - 34.33)
Grade III Placenta	61.7	3.05	(1.7 - 5.25)

Conclusion: In a high risk population, AC has the highest sensitivity and EFW the highest common odds ratiofor the prediction of SGA. Comparable data for low risk populations and for the prediction of neonatal ponderal index will also be presented.

170 EVALUATION OF OBSTETRICAL ULTRASOUND AS A LABORATORY TEST AT FIRST VISIT. Browne PC, Hamer LH, Vroon DH[X], Clark WS[X] Department of Gynecology/Obstetrics, Emory University School of Medicine, Atlanta, GA

We compared routine obstetrical ultrasound to other standard laboratory tests performed at the first obstetrical visit in an indigent, inner-city patient population. We examined "normal" and "abnormal" values for blood type, rhesus group, antibody screen, rubella serology, syphilis serology, hepatitis serology, HIV serology, urine culture, GC test, chlamydia test and cervical cytology. A routine obstetrical ultrasound identified many clinically important findings such as fetal demise, multiple gestation, incorrect dating, fetal anomalies, etc. in more that half of patients studied. In our clinic population, routine obstetrical ultrasourd compares favorably with other recommended laboratory tests obtained at first visit.

ULTRASOUND		STANDARD LABORATORY TEST	
Incorrect Dates	28.6%	Rubella Non-immune	13.1%
Adnexal Masses	06.0%	Rhesus Negative	07.0%
Non-viable Pregnancy	04.9%	Abnormal Hemoglobin	06.1%
Uterine Anomalies	02.5%	Positive Drug Screen	04.7%
Abnormal Fluid Volume	02.2%	Positive Antibody Screen	01.4%
Placenta Previa	00.6%	HIV Positive	00.6%
Fetal Anomalies	00.6%	Hepatitis B Positive	00.5%

171 ADVERSE FETAL CARDIAC EFFECTS OF ORAL RITODRINE TOCOLYSIS. D.M. Friedman[X], J. Blackstone[X], I. Hoskins, Div. Pediatric Cardiology/Mat-Fetal Med, New York Univ. Med. Ctr. NY

The beta-sympathomimetic oral tocolytic, ritodrine (R), can cause maternal tachycardia and hypotension, and may cross the placenta. A new echo-Doppler technique was developed to explore fetal and placental R effects in 76 controls and 18 studies on stable oral R doses, at baseline and 30 min later. Data collected: maternal pulse and BP, fetal cerebral and umbilical Doppler waveforms, and FHR. A new index of fetal myocardial contractility, combined ventricular shortening fraction (CVSF), was derived from 2D directed M-mode. RESULTS: Maternal pulse and BP, FHR and fetal heart size, and all Dopplers were normal, without dose-response effects. In normals, CVSF fell with increasing gestational age (CVSF=-.27 EGA + 49, F=5.8, P≤.001, SEE=11). CVSF in R pts. was abnormally decreased, at either peak or trough, in 72% of cases. The mean CVSF in normals was 43 ± 5% but in R pts. was 31%. CONCLUSION: Premature labor and/or oral R is associated with reduced CVSF. Since there was no change in placental resistance, cerebral hypoxia, FHR, or heart size (preload), then low CVSF may be due to increased fetal systemic vascular resistance (BP) or decreased myocardial contractility.

172 SIGNIFICANCE OF THE ULTRASONOGRAPHIC DIAGNOSIS OF AMNIOTIC BAND IN RELATION TO FETAL OUTCOME AND MATERNAL COMPLICATIONS.

H. Wehbeh[X], M.D., A. Karimi[X], M.D., E. Ioannou[X], B.A., H. Minkoff, M.D. State University Health Science Center at Brooklyn, New York.

Introduction: In the routine practice of obstetrics, the ultra-sonographic diagnosis of an amniotic band is not rare and presents the physician and the patient with a counseling dilemma. Specifically, reports of limb disruptions and craniofacial anomalies raise major concerns. Materials: In an attempt to assess the prognostic significance of an ultrasonographic diagnosis of amniotic band, a retrospective review of ultrasonographic records at SUNY Health Science Center at Brooklyn and Kings County Hospital was performed. Between 1986 and 1991 25 cases of amniotic band were diagnosed. Cases were compared to 25 control patients who had ultrasound evaluations at the same gestational age (GA). Outcomes included anomalies (amniotic band syndrome), obstetrical complications (e.g. preterm labor, premature rupture of membranes (PROM), birth weight) and maternal factors that might predispose to bands (e.g. previous cesarean section, previous termination of pregnancy). Results: All cases had normal fetal anatomy and unrestricted fetal movement on the index sonogram (1 in the first trimester, 13 in the second and 11 in the third). No component of the amniotic band syndrome was found in the newborns, all of whom were liveborn. Sixteen (64%) had ultrasound follow up of which 9 revealed the disappearance of the amniotic band. No significant difference was found in fetal outcomes, maternal risk factors or complications between the two groups, except for preterm labor which was more common among cases. [Table 1]. Conclusion: This study suggests that the ultrasonographic diagnosis of an amniotic band in conjunction with sonographic findings of normal fetal anatomy and unrestricted fetal movement may carry minimal risk to the fetus and the mother. Preliminary evidence of an association with preterm labor needs to be confirmed.

Table 1. Obstetrical Outcome

	Case (n = 25) mean (SD)	Control (n=25) mean (SD)	P
Birth Wt (g)	2813 (680)	3045 (929)	.31
GA (wk)	37.4 (2.8)	37.4 (5.9)	.95
PROM	12% (.33)	16% (.37)	.95
Preterm Labor	20% (.41)	0.0 (0.0)	.02

173 **CLINICAL SIGNIFICANCE OF UTERINE LEIOMYOMATA IN PREGNANCY.** A. Ghidini[X], P. Vergani[X], N. Strobelt[X], N. Roncaglia[X], A. Spelta[X], A. Locatelli[X]. Mt. Sinai School of Medicine, New York, NY, St. Gerardo Hospital, Monza, Italy.

The clinical significance of uterine myomas in pregnancy has only been examined in small retrospective studies, leading to conflicting results. From Jan. 1983 to Jan. 1988 we followed prospectively 209 pregnant patients with sonographically identified myomas and 7523 pregnant women, without myomas. Site, number and location of myomas were documented. Among patients with fibroids, 12 had elective abortions performed, one had an ectopic pregnancy and 16 delivered elsewhere, leaving 180 cases for analysis. Spontaneous abortions (SAb's) were not more common in cases compared with controls (7.8% vs 8.3%, p=NS). SAb's were not related to myoma size, or location; however SAb's were more common with solitary compared with multiple myomas (5.5% vs 17%, p=0.02). Preterm deliveries were not more frequent in cases than in controls (9.6% vs. 9.7%). Cesarean sections were more common in cases than in controls (23% vs 14%, p<0.001), in lower uterine segment compared with fundal myomas (38% vs 17%, p<0.01), and when the mean myoma diameter was > 5cm (35% vs 16%, p<0.01). There were no increased occurrences of placental abruptio (1.2% vs 0.4%), fetal growth retardation < 5th percentile (3.6% vs 4.5%), preterm membrane rupture (2.4% vs 4.0%), post-partum hemorrhage > 500 cc (16.5% vs 17.6%), or post-partum endometritis (0.8% vs 0.9%), in cases compared with controls. However there was an increased prevalence of placenta previa in cases compared with controls (3.6% vs 0.6%, p<0.01). SUMMARY: Uterine myomas were found to be associated with an increased occurrence of cesarean sections and placenta previa, but not of SAb or preterm delivery.

174 **WHAT IS THE PREDICTIVE VALUE OF A FOUR-CHAMBER VIEW OF THE FETAL HEART IN THE PRENATAL DIAGNOSIS OF CONGENITAL HEART DEFECTS?** A. Ghidini[X], P. Vergani[X], S. Mariani[X], R. Schiavina[X], I. Ciarla[X], A. Spelta[X], N. Strobelt[X]. Mt. Sinai School of Medicine, New York, NY and St. Gerardo Hospital, Monza, Italy.

In January 1987 we introduced the four-chamber fetal heart view to screen for congenital heart defects (CHDs) during all prenatal ultrasound examinations. We now compare the detection rate for CHD during the subsequent three years (1987-89) to that during the two preceding years (1985-86). Routine ultrasound examinations were performed on 9016 women during the period 1985-89. All patients were followed through delivery or termination of the pregnancy, and neonatal clinical or autopsy confirmation of prenatal findings were available on all cases. The four-chamber view was considered abnormal if any of the following findings were detected: ventricular disproportion, myocardial hypertrophy, dilation or hypoplasia of any cardiac chamber, septal defect, or atrio-ventricular valve deformity. The overall prevalence of CHDs was 0.53% (48/9016). A four-chamber view of the fetal heart was obtained in 95% of cases. During the years 1985-86, 16 neonates with CHDs were identified, 7 of which were prenatally diagnosed (sensitivity 43%). During the period 1987-89, 32 cases of CHDs occurred, 26 of which were diagnosed antenatally (sensitivity = 81%, p = 0.01). No false positive diagnoses were made in either time-period, therefore the specificity was 100%. The four-chamber of the fetal heart is easily obtained, does not significantly increase the duration of a routine ultrasound examination and has an excellent sensitivity for the identification of CHDs.

175 **USE OF THE TRANSVERSE CEREBELLAR/ABDOMINAL CIRCUMFERENCE RATIO TO IDENTIFY GROWTH RETARDED FETUSES.** W.A. Campbell, A.M. Vintzileos, J.F. Rodis, G.W. Turner, J.F.X. Egan, D.Nardi.[X] University of Connecticut Health Center, Farmington, CT

SPO 1990-Abstract #519 reported that the transverse cerebellar/abdominal circumference ratio (TCD/AC) is gestational age independent and might be useful to diagnose intrauterine growth retardation (IUGR). We undertook this study to evaluate this. **Methods:** Patients were prospectively enrolled if, they had sure dates (1st trimester prenatal care and/or ultrasound ≤ 20 weeks), and their pregnancy was at risk for IUGR (eg. hypertension, drug abuse). At each ultrasound examination a transverse cerebellar diameter was obtained along with standard growth measurements. The TCD/AC was calculated for each examination. IUGR was defined as a birth weight (BW) ≤ the 10th %ile for gestational age. A TCD/AC was abnormal when > 15.9%. The examination to delivery interval was ≤ 14 days for all cases. **Results:** Eighty-seven (87) patients were analyzed. Based on BW, 48/87 (55%) neonates had IUGR. Comparing IUGR and non-IUGR groups, there was no significant difference in the mean gestational age at delivery, or examination to delivery interval (4 days). Growth measurements were significantly smaller in the IUGR cases (p< .05). The exception was the TCD measurement, which was not significantly different between the groups (p=.2). The mean TCD/AC ratio was 16.6% for the IUGR cases; significantly larger than non-IUGR cases (14.8%- p <.05). There were 14/48 (29%) IUGR cases missed by the TCD/AC; 57% of these cases had a BW < 3rd %ile. The TCD/AC had a sensitivity of 71%, specificity 77%, positive predictive value 79%, negative predictive value 68%. **Summary:** The TCD/AC ratio can be a useful adjunct for evaluation of fetuses at risk for IUGR. If BW is < 3rd%ile this ratio may be normal.

176 TRANSVERSE CEREBELLAR DIAMETER (TCD) IN TWIN GESTATIONS. T Shimizu[X], S Gaudette[X], C Nimrod, Division of Perinatology, Dept. of Ob/Gyn, Ottawa General Hospital, Ottawa, Canada.

Fetal biometric measurements are accepted to be useful for assessing intrauterine fetal growth in twin pairs. Although TCD is reported to be unaffected by IUGR in singleton pregnancy, there has not been any study on TCD in twin pregnancy. The present study compared TCD measurements in singletons with those in twins and also the effect of the chorionicity and discordancy on TCD growth. TCD was measured in both 94 fetuses of 47 normal concordant twin pairs and normal 329 singleton fetuses between 15 and 36 weeks. There was no significant difference in TCD measurements between normal singleton and twin gestations. TCD is unaffected by the chorionicity in normal concordant twin pairs. Mean % intrapair differences in BPD, TCD, HC, AC, FL, and estimated fetal weight were compared between concordant (n = 13) and discordant (n = 11) twin pairs. Only TCD and HC did not show significant differences (P = 0.801); P = 0.095). This study suggests that TCD is not impaired in discordant twin pairs and singleton normograms may be useful in all types of twin growth assessment.

177 TRANSCEREBELLAR DIAMETER IN TWIN GESTATIONS.

Anna S Leung MD*, Bruce Kovacs MD*, Jerry Yu MD*. University of Southern California, Los Angeles, California

Often there is a size discordance between the twins. This can be due to primary factors such as genetic differences or secondary to transfusion syndrome or intrauterine growth retardation. Previous studies using standard ultrasonographic biometry of biparietal diameter (BPD), abdominal circumference (AC) and femur length (FL) have begun to establish normative growth curves. Importantly however, the use of these measures often results in significant differences in the gestational age (GA) estimates for co-twins. This is especially troublesome when ultrasongographic examinations are performed late in the gestation. Therefore, in these circumstances the clinician is hampered in attempts to determine the precise GA. In order to address the problem of different BPD's in twins we sought to use another measure which would have good correlation with GA and which would be more consistent between co-twins. We performed a prospective, cross sectional ultrasound examination on 43 well dated, uncomplicated twin gestations between 18 to 34 gestational weeks. The examination included measurements of transcerebellar diameter (TCD), BPD, AC and FL. A statistically significant linear relationship was found between TCD and GA (R^2=0.91; P<0.0000) and a curvilinear relationship between BPD and GA (R^2=0.94; P<0.0000) when the average TCD and BPD between co-twins were used for analysis. GA was derived from either BPD using Hadlock formula or TCD using Goldstein's formula. When these calculated GA's were compared with the known GA's, there was a significant difference in GA estimates derived from the BPD and TCD (P=0.0126). The average difference in GA between co-twins using TCD was 4.4 days versus 8.9 days using BPD. In conclusion TCD is a useful measurement to estimate the GA more accurately when there is a difference in BPD between the co-twins.

178 ULTRASOUND PREDICTORS OF FETAL MACROSOMIA AND BODY COMPOSITION IN INFANTS OF DIABETIC MOTHERS

RJ Kehl,PM Catalano,MA Krew, S Amini[X],A Thomas[X],LI Mann
MetroHealth Medical Center,Cleveland Ohio

The purpose of this study was to prospectively analyze which ultrasound(US) parameters are most predictive of fetal macrosomia in infants of diabetic mothers(IDM);and to estimate whether fetal fat or lean body mass was increased in macrosomic(MAC)versus nonmacrosomic(NMAC) IDM and whether this could be determined using US. 34 women with gestational diabetes (n=25) and insulin dependent (n=9) women were prospectively examined in the third trimester. US measurements include BPD HC,FL, abdominal circumference (AC),transcerebellar diameter,kidney and liver length,SC abdomen and thigh fat.Each subject had at least 3 US's performed a minimum of 3 weeks apart.Each neonate had skinfold measurements and total body electrical conductivity (TOBEC) to estimate body composition.MAC was defined as birthweight>90% and NMAC was defined as <90% for gestational age(EGA).Twelve(38%) IDM were MAC and 22(62%) were NMAC and EGA at delivery was similar,MAC 37.6±1.4 NMAC 38.1±1.4wks p=.30.The overall mean growth rate of US measurements were compared using a Wilcoxon rank sum.There was a significant increase in AC,(mean±SD)MAC 12.2±2.0 NMAC 10.0±2.3mm/wk p=.02,SC abdomen fat,MAC 0.41±0.15 NMAC 0.22±0.16mm/wk p=.006,thigh fat,MAC 0.35±0.01 NMAC 0.19±0.18mm/wk p=.011,and liver length MAC 3.1±1.2 NMAC 1.9±0.92mm/wk P=.01 in the MAC as compared with the NMAC US measurements. In addition to birthweight,MAC 3874±334 NMAC 3070±420 p=.0001,MAC infants also had significantly greater skinfold measurements,MAC 12.5±2.3 NMAC 9.4±1.8 p=.0001,% body fat MAC 17.2±4.1 NMAC 10.8±4.2 p=.0002,and lean body mass,MAC 3215±146 NMAC 2726±345 p=.0001.Our results support previous findings that AC growth is predictive of MAC in IDM.Furthermore, the increase in AC appears to be secondary to an increase in both fetal fat (SC fat) and lean body mass (liver).Supported by NIH RR-00210 and 22965.

179 **A NEW ALGORITHM FOR RISK ASSESSMENT OF DIABETES-ASSOCIATED COMPLICATIONS DURING PREGNANCY:** E.A. Reece, G. Francis[X], Z. Hagay[X], Departments of Ob/Gyn at Temple University School of Medicine, Philadelphia, PA and Yale University School of Medicine, New Haven, CT

Classification schemes have failed to provide measurable means for prospective risk assessment of diabetes-associated complications making periconceptional counseling vague and imprecise. This study was undertaken to create mathematical models using both pre-pregnancy and intra-pregnancy conditions to quantitatively predict a patient's relative risk for adverse maternal and fetal outcome. The study population included 361 gestational diabetics (GDM), 205 uncomplicated pre-gestational diabetics (P-GDM), 82 complicated P-GDM, and 150 controls. Multivariate analysis was used to determine a patient's overall relative risk for a given outcome. A model was derived based on whether the variable was dichotomous or continuous. All the individual β values were entered into an equation: For dichotomous variables, the overall RR = $e^{(b_1 X_1 + b_2 X_2 + \ldots)}$. For continuous variables, the predicted outcome = $(I + b_1X_1 + b_2X_2 + \ldots)$ where I is a constant representing the intercept calculated during the multivariate analysis; b_1 = beta value for first independent variable; X_1 = actual value for first independent variable in model. For example, the relative risk for fetal distress can be assessed prior to pregnancy or during pregnancy as follows:

RISK FOR FETAL DISTRESS

Model I (Pre-Pregnancy Conditions)	Model II (Intra-Pregnancy Conditions)	Model III (Pre- and Intra-Pregnancy Cond.)
duration: RR=1.06/yr	Proteinuria: RR=1.92	duration: RR=1.06/yr
HBP: RR=1.8	Late HTN: RR=2.2	Proteinuria: RR=1.7
Gravidity: RR=1.18		Gravidity: RR=0.8

CONCLUSION: This new algorithm provides for the first time a measurable and thus useful means of estimating possible fetal and/or maternal complications that may arise during the antepartum or peripartum periods.

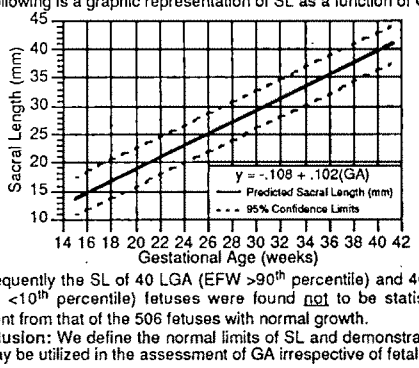
180 **THE POSITIVE PREDICTIVE VALUE OF A SONOGRAPHIC DIAGNOSIS OF FETAL MACROSOMIA.** Raphael N. Pollack[X], Michael Y. Divon, Dept. Ob/Gyn, The Albert Einstein College of Medicine, Bronx, NY.

The positive predictive value (PPV) of the sonographic diagnosis of fetal macrosomia was prospectively evaluated in 519 pregnancies of > 41 weeks gestation examined within 1 week of delivery. Estimated fetal weight (EFW) was obtained using measurements of abdominal circumference and femur length and the table of Hadlock et al. The PPV of varying sonographic EFWs in predicting birthweights of ≥4000 and ≥4500 grams, respectively, is shown:

Ultrasound EFW (Gms.)	Probability of Actual BW ≥4000 Gms.	≥4500 Gms.
3500	36%	7%
3600	40%	8%
3700	44%	9%
3800	49%	11%
3900	56%	14%
4000	66%	17%
4100	70%	19%
4200	71%	20%
4300	75%	21%
4400	80%	26%
4500	83%	29%
4600	80%	20%
4700	86%	29%

We conclude that the PPV of a sonographic diagnosis of macrosomia increases with increasing EFW. 75% of fetuses with an EFW of 4300 grams or larger will indeed be macrosomic by birthweight criteria.

181 "FETAL GROWTH CHARTS": COMPARISON OF CROSS SECTIONAL ULTRASOUND EXAMINATIONS WITH BIRTHWEIGHT. IM Bernstein, MC Meyer, GM Simmons, EL Capeless. Dept. Ob/Gyn, Univ. Vermont, Burlington, VT.



We examined the hypothesis that fetal growth curves derived from birthweight data underrepresent normal fetal weight in preterm gestation due to a high incidence of growth deficiency in premature newborns. We compared growth curves created from birthweight data with curves generated from ultrasound examinations collected cross-sectionally. We matched 350 ultrasound examinations with 350 newborn weights. Groups were evenly distributed by gestational age between 26 and 39 weeks gestation (25/wk). Ultrasound examinations were performed for size/dates discrepancy. Menstrual dating was confirmed by early ultrasound or index examination BPD. Regression lines for the growth curves were different ($p<0.001$). Between 26 and 35 weeks the ultrasound derived regression predicted higher fetal weights ($p<0.05$). We conclude that for preterm infants (<35 weeks) estimation of percentile rank for growth will differ between birthweight and ultrasound derived growth curves. Sonographically derived "fetal growth charts" provide an improved standard when characterizing ultrasound estimates of fetal weight.

182 FETAL SACRAL LENGTH IN THE ASSESSMENT OF GESTATIONAL AGE. David M. Sherer, Jacques S. Abramowicz, Mark A. Plessinger*, James R. Woods, Jr. University of Rochester, Rochester, NY.

The fetal sacrum is a consistent sonographically identifiable structure. In a prospective cross-sectional study of 506 singleton fetuses between 15-41 weeks, with normal growth and no structural anomalies, the sacral length (SL) ranged between 15-43 mm. Models to predict SL based on gestational age (GA), biparietal diameter (BPD), head circumference (HC) and femur length (FL) and 95% confidence limits were derived by least squares regression analysis. The SL was analyzed as the dependent variable paired with the GA, BPD, HC and FL as the independent variables. Scatterplots of the data for each model along with the standard error of the estimate (SEE), coefficient of determination (R^2) and adj. R^2 demonstrated excellent correlation:

SL/GA: SEE=0.1707, R^2=95.9%, Adj. R^2=95.9%
SL/BPD: SEE=0.2082, R^2=93.9%, Adj. R^2=93.8%
SL/HC: SEE=0.2048, R^2=94.1%, Adj. R^2=94.0%
SL/FL: SEE=0.2352, R^2=92.2%, Adj. R^2=92.1%

The following is a graphic representation of SL as a function of GA:

Subsequently the SL of 40 LGA (EFW >90th percentile) and 40 SGA (EFW <10th percentile) fetuses were found not to be statistically different from that of the 506 fetuses with normal growth.

Conclusion: We define the normal limits of SL and demonstrate that SL may be utilized in the assessment of GA irrespective of fetal size.

183 UNEXPLAINED MIDTRIMESTER POLYHYDRAMNIOS: SONOGRAPHIC FOLLOW-UP AND PERINATAL SIGNIFICANCE

Jacques S. Abramowicz, MD, David M. Sherer, MD, J. Christopher Glantz, MD, James R. Woods, MD. University of Rochester, Rochester, NY.

Third trimester polyhydramnios has been associated with suboptimal perinatal outcome such as higher incidence of preterm labor, pre-eclampsia,placental abruption, and fetal anomalies. The significance of midtrimester polyhydramnios is less clear. We examined the outcomes of 47 singleton gestations from 16 to 27 weeks gestation with unexplained polyhydramnios but with no known structural anomalies or evidence of maternal diabetes. Polyhydramnios was defined as mild-moderate if the greatest vertical fluid pocket visualized on ultrasound measured > 6cm and severe if it measured >10cm. A group of 87 gestations with normal amniotic fluid and identical inclusion criteria constituted the control group.

Results: Demographic and obstetrical data were similar in both groups. In the study group, 44 patients (94%) were diagnosed as mild-moderate and 3 as severe polyhydramnios. Follow-up scans were performed on 40 patients. Among these, polyhydramnios had resolved in 30 (75 %). Of those with mild-moderate polyhydramnios who were rescanned, it had resolved in 74%. In severe polyhydramnios with subsequent scans, it resolved in all (n=2). Gestational age at delivery, mean birthweight, 5min Apgar scores, incidence of pre-eclampsia, and placental abruption were similar in both groups. In the study group, 3 infants were subsequently diagnosed as having an anomaly: two cases of trisomy 21 and a third with unilateral multicystic dysplastic kidney. No anomalies were demonstrated in the control group ($p<0.025$).

Conclusions: Resolution of unexplained midtrimester polyhydramnios is common. Further antenatal investigation, however, may be indicated, even in the absence of additional abnormal sonographic findings.

184 FOOT:LEG LENGTH AND FOOT:FEMUR LENGTH RATIO IN NONINVASIVE SCREENING FOR TRISOMY 21. Mark Paul Johnson[X], Mason Barr Jr.[2X], Marjorie C. Treadwell[X], Nelson B. Isada, Peter G. Pryde[X], David B. Cotton, Mark I. Evans. Dept. OB/GYN, Hutzel Hospital/Wayne State Univ., Detroit, MI., and Depts. OB/GYN, Pediatrics & Pathology, Univ. of Michigan, Ann Arbor, MI.

Ultrasound screening for trisomy 21 has had limited success. However, fetuses with T21 tend to be growth restricted and may have shortened limb lengths. In order to delineate the pattern of IUGR in T21, gravimetric measurements were collected from 436 fetal necropsies (gestational ages (GA) 100-200 days) from the Teratology Database at the Univ. of Michigan (391 morphologically normal and 45 karyotype confirmed T21 fetuses) Using the power equation analytical approach we have previously described, we confirmed that *foot length* and *leg length vs. GA* are linear relationships. We then generated a *foot to leg length ratio* and found it to be linear vs. GA in both normal and T21 populations. However, the generated regression curves were found to be significantly different between groups ($p<.0001$) with higher ratios noted in T21. Using a *foot to leg length ratio* of >0.44 to screen for T21, the following were calculated: sensitivity=0.69, specificity=0.91, +PV=0.61, and -PV=0.94. In this population, with a T21 prevalence of 17%, this measurement provides a high +PV and -PV for the identification of T21. We conclude that 1) *foot to leg length ratios vs. GA* is a linear relationship, and 2) regression curves are significantly different between T21 and normals. This finding now provides a rational anatomic basis for ultrasound screening for T21. Since completion of this analysis, and based on our observations that T21s have shortened upper leg lengths, we have begun a prospective study using *foot to femur lenth ratios* measured by ultrasound during routine prenatal screening. Preliminary data reflects the differences found in our *foot to leg length* necropsy studies and has encouraged our continued work to define the role of this measurement in prenatal screening for T21 in a low risk population.

185 **NECK CIRCUMFERENCE MEASUREMENTS IN SECOND TRIMESTER FETUSES WITH DOWN SYNDROME.** G.W. Turner, A. Vintzileos, D. Nardi[X], L. Feeney[X], W. Campbell, J. Rodis, University of Connecticut Health Center, Farmington, CT

Excessive nuchal skin thickening has been described as one of the features of Down syndrome (DS) during the second trimester as well as after birth. The purpose of this prospective study was to investigate the usefulness of fetal neck circumference (NC) during the second trimester to detect fetuses with DS. Single sonographic examinations of 132 patients referred for genetic amniocentesis between 12 and 25 weeks of gestation were used to generate the nomograms of fetal NC versus gestational age (GA), biparietal diameter (BPD), head circumference (HC), abdominal circumference (AC) and femur length (FL). All fetuses were subsequently proven to be karyotypically normal. The fetal NC was determined by placing the transducer at a right angle to the cervical vertebrae so that the fetal neck was imaged at a plane in which the cross sectional area was the largest and as round as possible. From this view, the NC was indirectly calculated from two perpendicular diameters which were measured from outer to outer border. The mean intraobserver and interobserver variabilities in NC measurements were 6.1% (range: 1.3%-16.1%) and 6.8% (range: 0%-14.5%), respectively. Plotting of fetal NC measurements vs. GA, BPD, HC, AC and FL revealed linear relationships. The 5th, 50th and 95th percentiles were established. Subsequently, nine fetuses with DS were identified between 16 and 21 weeks of gestation among 1,186 fetuses (prevalence of DS in this population 1:132). Only 1 of the 9 fetuses had an abnormally increased NC (sensitivity 11.1%). The remaining 8 fetuses were equally distributed above and below the 50th percentile. The sensitivity, specificity, positive and negative predictive values of the fetal NC versus GA were 11% (1/9), 95% (1,119/1,177); 1.6% (1/59), and 99% (1,119/1,127), respectively. Our observations suggest that fetal NC measurement in the second trimester is not useful in the prenatal diagnosis of DS.

186 **CORRELATION OF UTERINE FUNDAL HEIGHT WITH ULTRASOUND IN TWIN GESTATIONS.** James FX. Egan, Anthony Vintzileos, Garry Turner, John Rodis, Winston Campbell, Edward Wolf, James Balducci, Luanna Lettieri, Judith Mead, Department Ob/Gyn, University of Connecticut Health Center, Farmington, CT

Due to the lack of fundal height nomograms in normal twin gestations, it has been a standard recommendation to use frequent ultrasound examinations in order to diagnose discordant fetal growth. The rationale of such a practice however, has not been established. The purpose of this prospective, cross sectional study of 152 twin pregnancies was to determine a nomogram for FH in normal twin gestations (n=132) and to see if FH can detect discordant (≥20%) growth in twins (n=20). After a scan FH measurements were obtained by both attending physician and fellow. Maternal age, gravity, parity, height and weight, gestational age (GA), fetal presentation, placentation, amniotic fluid volume, estimated fetal weight and % discordance were also recorded. Examinations were performed from 18 to 38 weeks (wks) GA. Results: Mean FH (±SD) was 5.9 (±2.9) cm greater than GA in wks; in concordant twins and 6.5 (±5.2) cm for discordant twins (p=NS). If the maternal weight was <200 lbs the FH averaged 5.4 (±2.9) cm more than GA in wks, while if the maternal weight was > 200 lbs the fundal height averaged 8.1 (±2.7) cm more. The mean (±SD) interobserver difference in FH measurements was 1.6 (±1.2) cm. FH did not adequately detect discordant growth in twins. The sensitivity was 12%, specificity 75%, positive predictive value 76%, negative predictive value 11%. It is concluded that FH measurement cannot be used as a screening clinical test for discordant fetal growth. Because of the low sensitivity (12%) our study supports that routine monthly ultrasound monitoring is necessary for the diagnosis and follow up of discordant fetal growth.

187 **FETAL STOMACH MEASUREMENTS ARE NOT REPRODUCIBLE.** E. Z. Zimmer[X], C. R. Chao[X], G. Abramovich[X], I. E. Timor-Tritsch, Dept. of Ob/Gyn, Columbia University, New York, NY

Several groups have published tables of normal dimensions of the fetal stomach. We hypothesized that because stomach filling and emptying is a dynamic process, measurement of stomach dimensions might be subject to error due to changes in stomach volume over relatively short periods of time. We measured stomach anteroposterior, transverse, and longitudinal dimensions at the beginning and end of a twenty minute period in 39 fetuses. To provide a standard for comparison, the same individual also serially measured biparietal diameter (BPD) twice at the same interval in 30 fetuses. The percent change between each of the paired serial measurements was then calculated and the mean percent changes compared between the stomach and BPD measurements: (mean ± SEM, Mann-Whitney-U test)

	Mean Percent Change	Significance Compared to BPD
Longitudinal	13.5 ± 2.0	p < 0.0001
Anteroposterior	17.7 ± 2.6	p < 0.0001
Transverse	15.1 ± 1.7	p < 0.0001
Volume	35.2 ± 4.7	p < 0.0001
BPD	1.2 ± 0.2	----

Because stomach measurements are subject to large variations in the same individual due to the dynamic nature of stomach dimensions and filling, we suggest that caution be exercised in the use of single measurements of stomach dimensions for the assessment of gestational age or the diagnosis of fetal abnormalities.

188 **DISTRIBUTION OF FETAL WEIGHT IN THE PRESENCE OF IDIOPATHIC POLYHYDRAMNIOS.** Asrat T, Thomas S, Towers CV, Nageotte MP, Major CA, Women's Memorial Hospital, Long Beach, CA, University of California, Irvine, CA.

We conducted a study to investigate the relationship of idiopathic polyhydramnios diagnosed in the third trimester and the incidence of fetal macrosomia. Between 9/88 and 12/90, 1550 patients had over 5000 serial amniotic fluid volume determinations. Of these, 157 were diagnosed with polyhydramnios, defined as an AFI of ≥20cm. Patients with diabetes, multiple gestations and congenital anomalies were excluded, resulting in 94 study patients with idiopathic polyhydramnios. The birthweight distribution of these infants according to the California growth curves is outlined below.

Distribution of Birthweight

Percentile	N(%)
<10th	17(7.5)
10th-50th	33(35.1)
51st-89th	44(46.8)
>90th	10(10.6)
TOTAL	94(100)

CONCLUSION: Only 10 infants, 10.6%, had birthweights >90th percentile, which reflects the normal distribution in California. The birthweight of infants born to mothers with idiopathic polyhydramnios is normally distributed. Unlike, in pregnancies complicated by diabetes, idiopathic polyhydramnios does not seem to correlate with fetal macrosomia.

189 RECOGNITION OF THE LARGE FOR GESTATIONAL AGE (LGA) FETUS USING GESTATIONAL AGE INSENSITIVE PARAMETERS. Joseph M. Miller, Jr., LSU Medical Center, New Orleans, LA.

Accelerated abdominal circumference (AC) growth occurs in the LGA fetus of diabetics and may allow improved recognition. The utility of the AC growth rate (AGR) and the ratio of the femur length (FL) to AC were evaluated in 35 diabetic and 52 nondiabetic patients, scanned after the 31st week on ≥2 occasions at least 2 weeks apart. The initial and final scans were analyzed. Birthweight (BW) tables of Brenner defined the median BW and LGA (>90%). AGR correlated with LGA status in diabetics but not in nondiabetics. FL/AC from the last study was strongly associated with LGA status in both groups. Both AGR and FL/AC correlated with relative BW (RBW) = BW÷median BW for GA, r=.408 and −.675, respectively, and may explain why these indices work better for larger LGA newborns of diabetics (RBW=1.37±.17) than nondiabetics (RBW=1.25±.08), p=.03. FL/AC may be more useful than AGR, particularly in diabetics

		Diabetics			Nondiabetics		
		LGA	NonLGA	p	LGA	NonLGA	p
AGR	≥1.2	10	4	.004	5	6	.100
cm/wk	<1.2	4	17		7	34	
FL/AC	<.21	13	4	.000	7	5	.003
	≥.21	1	17		5	35	

190 TRANSVERSE CEREBELLAR DIAMETER/ABDOMINAL CIRCUMFERENCE RATIO IN PREGNANCY: A NOMOGRAM W. Meyer,[X] D. Gauthier,[X] S. Warsof, A. Bieniarz University of Illinois at Chicago, Chicago, IL

In fetal growth disturbances, cerebellar growth has been shown to remain constant while abdominal circumference may vary considerably. To determine whether a relationship exists between fetal transverse cerebellar diameter (TCD) and abdominal circumference (AC), 138 patients with well dated pregnancies between 14-42 weeks were evaluated in a cross-sectional study. All pregnancies were normal, with no maternal or fetal factors which are associated with abnormal fetal growth. The TCD, AC and TCD/AC ratio were calculated for each patient and correlated to gestational age with linear regression analysis. RESULTS. Excellent correlation exists between TCD and gestational age (r=0.97) as well as TCD and AC (r=0.98). TCD/AC was normally distributed with a mean of 13.65 +/- 0.88%, (median=13.64%, mode=13.61%). The 5th and 95th percentiles were 12.27 and 15.28% respectively. The TCD/AC ratio remained constant throughout pregnancy when compared to gestational age (r=0.03). CONCLUSION: THE TCD/AC RATIO IS A STABLE FETAL BIOMETRIC PARAMETER WHICH IS INDEPENDENT OF GESTATIONAL AGE. THIS RATIO MAY BE USEFUL IN THE PRENATAL DETECTION OF SOMATIC FETAL GROWTH ABNORMALITIES.

191 FETUSES WITH DOWN'S SYNDROME HAVE DISPROPORTIONATELY SHORTENED FRONTAL LOBE DIMENSIONS ON ULTRASOUND. Bahado-Singh R, Wyse L,* Dorr MA,* Copel JA, and Hobbins JC. Department of OB/GYN, Yale University School of Medicine, New Haven, CT.

Shortened occipital frontal diameter (due to short frontal lobe) occurs in Down syndrome (DS) postnatally. We assessed frontal lobe size in mid-trimester DS fetuses. Frontal lobe length (FLL) and frontal lobe-cavum septum pellucidum (FLL-CSP) were measured from inner table to anterior and posterior aspect of cavum, respectively. Fronto-thalamic distance (FTD) from inner table to posterior thalamus and FTD/BPD were obtained. Nomograms were generated for 125 normals (15-21 weeks) and compared to 19 DS fetuses. FTD and FTD/BPD proved the most useful parameters. When expressed as multiples of the median to eliminate variation due to gestational age, significant shortening in mean FTD in DS fetuses compared to normals ($p<0.0019$) and FTD/BPD ($p<0.0177$) was seen. In the DS group, 32% had FTD <10th percentile. If an observed-to-expected FTD ratio of 0.84 is used as a screening test for DS, sensitivity 21.1%, specificity 95.2%, and positive predictive value 0.6 would be obtained in a population with 1:250 risk of DS. **Conclusion: Frontal lobe dimension is significantly shortened in DS fetuses. Prospective evaluation of this finding is planned.**

192 **AN EVALUATION OF RESIDENT USE OF LABOR AND DELIVERY ULTRASOUND: VALUE AND LIABILITY.** L. Coultrip, C. Ludowese[X], L. Hawkins[X], V. Lupo. Hennepin Medical Center, Minneapolis, MN.

In this ongoing study, ultrasound (US) use by obstetric residents assigned to Labor and Delivery is prospectively monitored to determine the usefulness and limitations of US performed by second year residents without formal US training. Of 1225 patients evaluated on L&D for acute problems and 480 service deliveries during a four month interval, 191 US examinations have been documented. Indications included amniocentesis (15%), placentation (13%), EFW (10%) and other (15%). The most common indication for a scan is dating (47%) in the absence of prenatal care. 55% of these patients presented at 28 weeks or less. 95% of GA estimates were deemed accurate when confirmed by subsequent scan by trained technicians or newborn exam. Using BPD/AC, 19% of EFWs fell within 5% and 48% within 10% of fetal delivery weight within 48 hours of scan (N=30) compared to 27% and 58% respectively for FL/AC. Missed diagnoses included a term twin gestation and a gastroschisis. In an indigent population presenting with erratic prenatal care, L&D scanning affords an opportunity to accurately date the pregnancy in a population in which 35% would otherwise be poorly dated.

193 OBSERVER VARIABILITY IN SONOGRAPHIC ASSESSMENT OF CERVICAL LENGTH

W. R. Mulla[X], S. Eife[X], G.M. Jacobson[X] J. Ludmir Department of Obstetrics and Gynecology, University of Pennsylvania Medical Center, Philadelphia, PA

Ultrasound evaluation of the cervix has been proposed as an objective means of assessing cervical change during gestation. Several studies have tried to correlate sonographic changes in cervical length with the risk of cervical incompetence and preterm labor. The present study was designed to test the variablity of cervical sonographic measurements by independent observers. Thirteen patients in the first trimester were evaluated by two clinicians who each performed two measurements of cervical length determined with a 7.5 mHz vaginal probe. The length of the cervix was measured from internal os to external os. For each enrolled patient, there was no significant difference in cervical length measurement when assessed by the same observer. For observer A, the mean ± SD for the two cervical length measurements were 2.67 ± 0.59 and 2.76 ± 0.56 cm (p = 0.23). For observer B, these measurements were 2.58 ± 0.56 vs 2.59 ± 0.54 cm (p = 0.91). The mean differences in cervical length / patient for observers A and B were 1.69 ± 1.6 cm and 4.15 ± 2.5 cm, respectively. Although mean cervical length was consistent for the same observer, there was a significant interobserver difference noted for each patient (2.71 ± 0.57 vs 2.59 ± 0.54 cm, p=0.001). We conclude that there is a significant difference beween examiners when measuring cervical length with vaginal ultrasound. Measurements were consistent, however, when performed by the same observer. If sonogrqaphic evaluation is to be used as an objective way of assessing cervical length in pregnancy, serial measurements must be performed by the same individual.

194 THE CONSEQUENCE OF ULTRASOUND DETECTION OF LATE SECOND AND THIRD TRIMESTER, MILD TO MODERATELY SEVERE FETAL URINARY TRACT DILATATIONS.

Ignatia B. Van den Veyver, M.D.[X], Jozef S. Venderheyden, M.D.[X], Luc A. Meeuwis, M.D.[X], Christine T. Vandeputte, M.D.[X], and Julien M. Norga, M.D.[X]; Depts. of Ob/Gyn and Ped.; St. Augustinushospital; Wilrijk, Belgium.

30 - 50% of the anomalies detected by routine antenatal ultrasound (US) originate in the fetal urinary tract (FUT). The interpretation, management, and outcome of these is still uncertain. **Purpose:** To investigate the frequency of FUT dilatations during the late second and third trimester; to correlate antenatal US with postnatal findings; to establish a followup protocol. **Materials and Methods:** 3 US/pregnancy were performed in 2000 patients with an Aloka 256 and a 650 SSD real-time US scanner (3.5 MHz). Dilatations were classified as mild (pelvis only), moderate (dilated calyces), or severe (↓ renal cortex). Antenatal followup: conservative when unilateral with normal amniotic fluid; delivery when bilateral with ↓ amniotic fluid and fetal lung maturity. Neonatal followup: US scan after 72 hours, urine culture in first week. Followup at 3 months when mild or normal. IVP, voiding cystography, and treatment when abnormal. **Results:** FUT dilatation in 1.45% (29/2000 pts); mild-65.5%; moderate-24.1%; severe-10.3%. Of the mild cases, 50% were normal at birth; 68.4% at 3 months; 20.6% of children had surgery done before 1 year of age or before symptoms occurred. **Conclusions:** Dilatation of the FUT is common on antenatal US; if mild limited followup is required. Early treatmert or surgery before symptoms can be offered after antenatal diagnosis.

195 SONOGRAPHIC RENAL PELVIS SIZE IN NORMAL AND DOWN SYNDROME FETUSES.

Kirk JS, Uckele JE[X], McNeil L[X], Rice M[X], Riggs T[X], Comstock CH, and Lee W. Div. of Fetal Imaging, Dept. OB-GYN and Dept. Pediatrics, William Beaumont Hospital, Royal Oak, MI.

Objectives: 1) To determine the size of renal pelves in normal fetuses throughout gestation. 2) To determine if renal pelvis size in Down syndrome fetuses differed from normal fetuses. Methods: From 9/1/90 to 6/14/91, an antero-posterior diameter of at least one renal pelvis was measured prospectively in fetuses when the fetal bladder was not distended. Only babies born at our hospital to mothers with a history of regular menses were included in the normal group. All newborn charts and karyotype results were reviewed for this group. There were 604 normal fetuses after anomalies and abnormal karyotypes were excluded. During the study period, 9 fetuses with Down syndrome had renal pelves measured. Retrospective review of videotaped scans of Down syndrome fetuses from the last 5 years added 25 Down syndrome fetuses with adequate views for measurement (total = 35). Results: In the normal fetuses, the renal pelvis diameter increased linearly with gestational age ($y = 0.01x + 2.78$, $r = 0.435$). Using the 95th percentile level as the upper limit of normal, abnormally full renal pelves occur at $\geq$ 4 mm for < 17 weeks, $\geq$ 5 mm for 17 to 30 6/7 weeks, and $\geq$ 6 mm for 31 weeks and over. Only 4 of the 35 Down syndrome fetuses had at least one abnormal renal pelvis diameter (binomial distribution p = 0.27) Conclusion: Renal pelvis size in Down syndrome fetuses did not differ significantly from normal fetuses.

196 **AURICULAR MID-CALVARIUM MEASUREMENT: THE ANTENATAL DIAGNOSIS OF LOW SET EARS**

Mark T Cullen MD, Jaqueline Green RDMS*, Luis Sanchez-Ramos MD, John C. Hobbins MD. University of Florida, Jacksonville, FL. and Yale University, New Haven,CT.

Low set ears is a congenital anomaly that can be associated with genetic syndromes and aneuploidy. Prenatal identification would assist in antenatal counseling and permit the option of karyotype analysis. We present data on the ultrasound evaluation and antenatal identification of low set ears. The study was prospective and cross sectional. Two hundred and sixty five well dated patients were referred for ultrasound examinations throughout pregnancy. Patients were examined once. After a thorough anatomic survey, an auricular to mid-cranial (AMC) measurement was obtained. This measurement was made on a coronal plane of the head at the level the thallamus, from the mid calvarium to the inferior insertion of the external ear. A nomogram was generated from the 265 well dated normal pregnancies with 95% confidence intervals. Follow up examination of the newborn was accomplished in all cases. There was a strong correlation between gestational age and the AMC (R=.94). There were 5 fetuses with low set ears that underwent ultrasound examination and had an AMC measurement, 4 were predicted prenatally. Low set ears were diagnosed in all three trimesters. The earliest diagnosis was made at 12 week. **Conclusion**: Low set ears can be diagnosed with ultrasound.

197 **ADVERSE FETAL OUTCOME ASSOCIATED WITH VARIX OF THE FETAL INTRAABDOMINAL UMBILICAL VEIN.** DP Reisner, BS Mahony,[X] JP McGahan,[X] DA Nyberg,[X] Swedish Hosp. Med. Ctr., Seattle WA and Univ. California-Davis, Sacramento CA

Varix of the fetal intraabdominal umbilical vein (FIUV) is a rare finding of uncertain etiology. We followed 11 fetuses with FIUV varix detected with prenatal ultrasound (US). US indications included elevated MSAFP (N=5), family history of congenital abnormalities (N=2), vaginal bleeding (N=1), abdominal mass on outside US (N=1), size/dates discrepancy (N=1), and preterm labor (N=1). Maternal age ranged from 21-35 years. One fetus, born to a 35-year-old, had Trisomy-21. Seven of 11 fetuses were males. One pregnancy is ongoing.

- IUFD (1 w/ Trisomy-21) 4/10 (40%)
- Abnormal karyotype (4 not tested) 1/7 (14%)
- Elevated MSAFP (4 not tested) 5/7 (71%)

CLINICAL OUTCOMES (N=11)

- 2nd trimester dx w/ IUFD at 27-30 wks 4/6
- 3rd trimester dx w/ survival (1 premature w/ hydrops) 4/4
- Ongoing pregnancy 1

One neonate had IUGR. Three macerated fetuses precluded accurate weights. Three of 4 fetuses with IUFD underwent autopsy, which did not reveal cause of death. Second trimester detection of FIUV varix may be associated with increased fetal morbidity and mortality and warrants close fetal surveillance.

198 IMPROVEMENT OF UMBILICAL ARTERY DIASTOLIC FLOW PREDICTS BETTER NEONATAL OUTCOME. JG Bell[X], A Ludormirsky,[X] J Bottalico[X], S Weiner, Pennsylvania Hospital, Philadelphia, PA

Fetuses that show absent end diastolic flow in the umbilical artery have a high risk of developing IUGR and oligohydramnios, have increased stillborn rates, and have significant perinatal and neonatal morbidity and mortality. Using doppler flow measurement as a clinical parameter for delivery timing is still very controversial. 60 pregnancies with a diagnosis of absent diastolic flow were studied. Fetuses were followed by traditional well being testing(BPP,NST,fetal movement assessment) and delivery decisions based on these parameters or worsening maternal condition. In 11 of 60 cases(18%), diastolic flow improved as the pregnancy progressed and gestation was prolonged with improved outcome. Results:

	Improvement	No Improvement
Oligohydramnios	3/11(27%)	21/49(43%)
IUGR by US(< 10%)	5/11(45%)	29/49(59%)
Dx to Delivery (days)	49(range 9-121)	11(range 0-57)
Stillborn	1/11(9%)	6/49(12%)
Gest. at Deliv(wks)	32.3(range28-37.6)	29.3(range 21-35)
Avg. Birthwt.(gms)	1418(range499-2400)	964(range280-1879)
Neonatal Death	1/11(9%)	12/49(25%)
Avg.# days in nursery	34(range 5-86)	69(range 25-186)
Survivors	9/11(82%)	30/49(61%)

Conclusion: The data emphasize the possibility of umbilical artery diastolic flow improvement in a group of fetuses that seemed to be in a decompensated state.

199 FETAL DESCENDING AORTA (DA) DOPPLER IN RESPONSE TO MATERNAL INGESTION OF LOW DOSE ASPIRIN (ASA). J.C. Veille, R. Hanson, L. Henderson, M. Swain, M. Sivakoff, Dept. of Ob/Gyn, Bowman Gray School of Medicine, Winston-Salem, NC and Case Western Reserve University, Cleveland, OH.

The effect(s) of chronic maternal ingestion of low dose ASA (40-80 mg) on the fetal DA blood flow (DAF) has not been documented. Pulsed Doppler was used to study DAF in fetuses exposed to ASA and compared to a control group. This was done at 3 different gestational periods: Groups (GRP) I = 12=23; II = 24-32; III = 33-41 weeks. A total of 230 studies were done throughout gestation. Six Doppler waveform were analyzed and averaged. The size of the DA was determined during systole, using a frame grabber. Results are reported as X ± SD. ANOVA was used to determine significance.

GRP	$DAPFV_C$	$DAPFV_{ASA}$	$DATVI_N$	$DATVI_{ASA}$
I	45.0 ± 2	46.2 ± 3	5.6 ± 0.3	6.1 ± 0.6
II	59.0 ± 3	58.5 ± 2	7.8 ± 0.4	7.3 ± 0.4
III	63.4 ± 3	56.5 ± 5	7.8 ± 0.4	7.2 ± 0.6

GRP	$DA"SV"_N$	$DA"SV"_{ASA}$	$DA"O"_N$	$DA"O"_{ASA}$
I	0.47 ± .08	0.35 ± .07	58.4 ± 8.6	57.4 ± 12.2
II	1.21 ± .11	1.03 ± .09	166.4 ± 16.7	143.6 ± 11.9
III	1.97 ± .19	1.89 ± .36	259.0 ± 26.1	274.5 ± 50.2
p	0.0000	0.0000	0.0000	0.0000

Legend: DAPFV = Descending aorta peak flow velocity (cm/sec); DATVI = descending aorta time velocity integral; DASV = descending aorta "stroke volume" (ml); DAO = Descending aorta output (ml/min); C = Control; ASA = Aspirin. Results: (1) No significant differences were found in PFV and TVI with advancing GA and among the "C" and "ASA" group. (2) Both the "SV" and "O" significantly increased with GA. No difference in the "C" and "ASA" groups were found. Conclusions: Maternal ingestion of daily low dose **ASA DOES NOT** significantly affect DA flow velocity and output. (Supported by NIH Grant HL38296).

200 **EFFECT OF LOW DOSE ASPIRIN (ASA) ON HUMAN FETAL RENAL BLOOD FLOW (FRBF).** J.C. Veille, R. Hanson, L. Henderson, M. Swain, Dept. of Ob/Gyn, Bowman Gray School of Medicine, Winston-Salem, NC

Low dose ASA has been used to prevent certain obstetrical complications. The effect of ASA on the FRBF has not yet been studied. FRBF was determined using pulsed Doppler in two groups of patients. One group of patients was used as a control group, the other group was taking 40-80 mg of ASA daily from the 12th week onward. Analysis was done at two different gestational (i.e. ≤28 weeks and >29 weeks) age) to determine any effect of maturity on FRBF in the control and in the ASA groups. A total of 143 studies were done (94 in control and 49 in ASA group). Three to six waveforms/study were analyzed and averaged. Results are expressed as X and SD. ANOVA test for repeated measurements was used to detect statistical significance.

Groups	I (≤28 wks)	p	II (≥29 wks)	p
S/D ASA	7.33±3.1	NS	6.83±1.1	NS
S/D Control	8.02±2.2		5.88±2.5	
PFV ASA	33.65±9.6	NS	36.25±9.7*	<0.02
PFV Control	29.50±10.2		24.49±10.4	
TVI ASA	5.23±2.0	NS	6.27±2.4*	<0.02
TVI Control	5.01±1.8		4.29±1.6	

(Legends: S/D=systolic/diastolic ratio; PFV=peak flow velocity (cm/sec); TVI=time velocity integral; ASA=aspirin) Results: 1) The S/D waveform was not different between the two groups at the both gestational ages; 2) In the "early" gestational age group no difference was found in PFV and TVI between the two groups; 3) In the "more advanced" gestational age, PFV and TVI were significantly greater in the ASA group when compared to control. Conclusions: ASA was found to significantly affect the human fetal renal vascular bed at or after the 29th week. This may be through a direct or an indirect effect of a prolonged maternal ingestion of ASA on this vascular bed or other vascular beds like the ductus, the aorta, the ventricles or the systemic vasculature. (Supported by NIH Grant HL38296).

201 **FETAL INTRACARDIAL EFFECT OF MATERNAL INGESTION OF LOW DOSE ASPIRIN (ASA).** J.C. Veille, R. Hanson, M. Sivakoff*, M. Swain, L. Henderson, Dept. of Ob/Gyn, Bowman Gray School of Medicine, Winston-Salem, NC and CWRU, Cleveland, OH*.

Chronic maternal ingestion of low dose ASA may have significant effects on fetal intracardial blood flow velocity (IBFV). Even though it has been assumed that no or minimal effects occur in the fetus, data are lacking. IBFV using pulsed Doppler was assessed at 3 different gestational age (GA) periods: Group (GRP) I = 12-23; II = 24-32; III = 33-41 weeks) in fetuses exposed to ASA. Fetuses not exposed to ASA were used for control (C). A total of 230 studies (gge; 51 ASA) were done. Results are as X ± SEM. An ANOVA was used to assess any differences between each GRP.

GRP	$TVTVI_C$	$TVTVI_{ASA}$	$MVTVI_C$	$MVTVI_{ASA}$
I	4.4 ± 0.2	3.9 ± 0.3	4.9 ± 1.2	3.7 ± 0.2*
II	6.1 ± 0.2	5.9 ± 0.3	6.5 ± 0.9	5.5 ± 0.4*
III	7.1 ± 0.2	8.1 ± 0.5	6.1 ± 0.2	5.9 ± 0.5
p	< 0.000	< 0.0000	NS	.002

GRP	$TVPFV_C$	$TVPFV_{ASA}$	$MVPFV_C$	$MVPFV_{ASA}$
I	41.5 ± 2	37.4 ± 2	36.9 ± 1*	33.9 ± 1*
II	50.7 ± 2	45.7 ± 2	46.9 ± 12*	42.6 ± 8*
III	56.6 ± 1	60.3 ± 3	46.7 ± 1	43.5 ± 4
p	< 0.0000	< 0.000	0.00	.0000

Legend: TVTVI = Tricuspid valve time velocity integral; MV = Mitral valve; PFV = Peak flow velocity (cm/sec); C = control; ASA = Aspirin. Results: (1) PFV and TVI across the tricuspid valve ↑ significantly with advanced GA in both the C and ASA. No difference within the groups was found. (2) MV TVI did not significantly ↑ with GA in the C GRP. In the ASA, TVI significantly ↑ during the 2nd GA period. No difference was documented, however, within each GA group. (3) MVPFV significantly ↑ in the C and ASA GRPS during the 1st to 2nd GA period. Conclusions: Even though major changes were seen in intracardial blood flow with advancing GA, NO DIFFERENCE was documented between the C and ASA GRPS. (Supported by NIH Grant HL38296).

202 **LOW MIDDLE CEREBRAL ARTERY (MCA) RESISTANCE INDEX OF POURCELOT (RI) PREDICTS NEONATAL MORBIDITY IN POST-TERM PREGNANCIES.** J. Shyken, S. Lieberman[x], A. Kivikoski[x], J. Smeltzer, Dept. OB/GYN, Washington Univ., St. Louis, MO

Uterine and umbilical artery velocimetry has not proven useful in management of prolonged pregnancies. There is little information regarding the value of MCA Doppler for this purpose. Forty-seven well-dated pregnancies at ≥41 weeks gestational age were prospectively studied to define the relationship between fetal cerebrovascular resistance as measured by MCA-RI, umbilical artery pH, and occurrence of abnormal pregnancy outcomes. Two groups were identified: those with normal outcomes and those with neonatal morbidity (having two of the following: umbilical artery pH <7.2, low 1 minute or 5 minute Apgar score, or neonatal intensive care unit admission). Eight of 47 infants had significant neonatal morbidity. The normals differed from the abnormals only by mean MCA values (0.74 ± .01 versus 0.64 ± .03, t=2.98, p<.005) and gestational age in weeks (41.8 ± .08 versus 42.3 ± 0.1, t=-2.58, p<.02). Gestational age and MCA-RI together clearly delineated those with neonatal-morbidity from others by discriminant analysis. Cutoff values for MCA-RI and their corresponding systolic to diastolic ratios (S/D) for each gestational age were calculated (using the formula RI = 0.14(gestational age) - 5.16) to obtain 100% sensitivity.

Weeks Gestation	RI	S/D
41	≤.58	2.38
42	≤.72	3.57
43	≤.86	7.14

For these cutoff values, sensitivity was 100%, specificity 74.4%, and positive predictive value of 44.4%. Further, MCA-RI predicted umbilical artery pH (R^2=0.22, p=.03). CONCLUSION: MCA Doppler indices are helpful in the management of post-dates pregnancies, and low RI values as indicated portend neonatal morbidity.

203 **UTERINE ARTERY DOPPLER VELOCIMETRY, PLACENTAL PATHOLOGY AND PERINATAL OUTCOME.** E. Ferrazzi [x], G.P. Bulfamante [x], A. Barbera [x], A. Pavesi [x], and G. Pardi. Dept. Ob/Gyn, Dept. Pathology, San Paolo Biomedical Science Institute, University of Milan, Italy.

The placental morphology was analyzed in 21 pregnancies with abnormal longitudinal uterine doppler S/D ratio (abn. S/D) and in 15 pregnancies with normal uterine S/D ratio (nor. S/D). Nine patients with abn. S/D developed pregnancy induced hypertension (PIH). All fetuses with abn. S/D were growth retarded in utero (IUGR). 3 fetuses only with nor. S/D were IUGR (see Table-top). In the normal pregnancy-nor. S/D group, only 8% of the placentas showed haematoma and 17% had trophoblastic hischemic lesions. IUGR fetuses with nor. S/D showed similar normal placentas. In the IUGR group with abn. S/D, placentas showed similar lesions to those observed in IUGR-PIH group with abn. S/D.: large infarcts (41% vs.55%), abruptio placenta (8% vs 22%), placental hematoma (25% vs 22%) and trophoblastic hischemic changes (83% vs 100%). Table-body shows the perinatal results in the 4 groups:

PREGNANCY	NORMAL	IUGR	IUGR	IUGR - PIH
UTERINE S/D	NOR.	NOR.	ABN.	ABN.
N. CASES	12	3	12	9
ABN.UMBILICAL PI	-	-	7	7
FETAL DISTRESS	-	-	5	3
P.N. DEATH	-	-	1	2
DELIVERY WEEK	38(2)	39(1)	33(3)	29(2)
CESAREAN SECT.	-	-	12	7
NEWBORN WEIGHT	3195(456)	2323(230)	1581(545)	896(376).

IUGR with abn. S/D are at greater risk of placental lesions and related abnormal outcome.

204 **THE PERINATAL SIGNIFICANCE OF ABSENT END DIASTOLIC FLOW IN DISCORDANT TWINS.** E. Baker,[X] J. Crowley,[X] K. H-Wilkes,[X] M. D'Alton, Dept. of MFM, St. Margaret's Hospital, Tufts University, Boston, MA

Over two years 50 pairs of twins demonstrated discordant fetal growth by ultrasound with intrapair estimated fetal weight difference of at least 20%. All sets had serial growth scans and umbilical artery Doppler studies. Of the 50 pairs 37 had normal Dopplers. 13 pairs demonstrated absent end diastolic flow (AEDF) in the smaller twin (4 with dichorionic and 9 with monochorionic placentation.) AEDF did not dictate delivery; however, intensive fetal surveillance with daily NST's AND BPP's were suggested by the perinatal team. The average gestational age at delivery was comparable between the groups with and without AEDF (33.0 wks. vs 33.8 wks.) There was no significant difference between discordancy at delivery in the group with AEDF (26% ± 13%) and the groups with normal Doppler studies (25% ± 9%.) The overall perinatal survival was 94/100 (94%.) There were 6 perinatal deaths (4 IUFD's and 2 neonatal deaths) in the twins with AEDF compared with no deaths in the group of discordant twins with normal Doppler flow (p<0.001.) An additional 2 cases demonstrated multicystic encephalomalacia and seizures in the neonatal period. No serious neonatal morbidity occurred in the group with normal Doppler flow. In conclusion AEDF identifies a subset of discordant twins who are at significant risk for perinatal death and adverse neonatal outcome.

205 **COLOR AND SPECTRAL DOPPLER FLOW MAPPING OF THE HUMAN PLACENTA** *S Rotmensch, M Liberati,* JS Luo,* Y Gollin,* JC Hobbins. Dept OB/GYN, Yale University*

Color Doppler flow equipment allows for visualization of arterial, venous and capillary flow in trophoblast and placenta' bed. We investigated morphologic, and blood flow characteristics of subplacental spiral arteries and intravillous fetal arteries in subsets of 74 normal (NL) and 13 IUGR pregnancies between 18 and 41 weeks gestation. Fetal vessel counts were standardized on a 2 cm^2 ultrasound screen area (SA). *In vivo* and histopathologic findings of placental tissue and placental bed biopsies were correlated in 2 cases. **Results:** 1.Mean intravillous vessel count was not different between normal and IUGR placentas. However, in one severely distressed IUGR fetus no intravillous flow could be detected with maximal gain settings. 2.Pulsatility index (PI) decreases in fetal circulation from umbilical artery (UA) towards central placenta (CP) ($p<0.001$) and apparently continues to decrease towards peripheral placenta (PP). Measurements in scanning planes parallel to blood flow suggest that this gradient is due to relatively increased diastolic flow in the PP. PI of intravillous arteries appeared to be higher in IUGR placentas ($p=0.06$, $n=13$). However, forward diastolic flow was observed in intravillous arteries even when flow in the UA was absent or reversed. 3. In one case of severe IUGR, the usually prominent decidual vascular turbulence was remarkably diminished, and correlated with absent "physiologic change" on placental bed biopsy. Mean PI of subplacental spiral arteries was 0.46 ± 0.14 between 20-30 wks gestation. 4. Pulsatile maternal blood flow into 2/3 of placental mass thickness was observed, contrary to the Ramsey theory. **Conclusions:** Color Doppler flow mapping of the placenta allows for *in vivo* investigation of hemodynamic aspects and might be a useful adjunct in the assessment of utero-placental function.

206 UMBILICAL ARTERY VELOCITY DECELERATION TIME IN FETUSES WITH ABSENT END-DIASTOLIC VELOCITIES. JH Indik,[X] KL Reed, Arizona Health Sciences Center, Tucson, AZ

Fetuses with absent end-diastolic velocities in the umbilical artery (AEDV) and umbilical venous pulsations have a worse outcome than fetuses with AEDV without umbilical venous pulsations. To quantify the association between umbilical arterial and venous velocities, we examined umbilical artery velocity deceleration time (time from peak velocity to time of estimated zero-line intercept of the deceleration slope) and divided by the time of the cardiac cycle in 21 fetuses with AEDV. Percent deceleration time in 11 fetuses with umbilical venous pulsations was decreased (0.47±0.12%) compared with 10 fetuses without umbilical venous pulsations (0.58±0.08%, $p<0.05$). The decreased percent deceleration time in the fetal umbilical artery may be due to increased afterload in the placental and fetal venous vasculature, with a mismatch between volume flow and vascular compliance. These results are further evidence of the interrelationship of umbilical arterial and umbilical venous velocities, since umbilical venous pulsations are associated with changes in umbilical arterial velocities. In addition, a subgroup with decreased percent deceleration time and increased morbidity is identifiable in fetuses with absent end-diastolic velocities in the umbilical artery.

207 USE OF DOPPLER IN THE MANAGEMENT OF HYPERTENSIVE DISORDERS IN PREGNANCY

E.P.Schneider M.D., H.Schulman M.D., G.Farmakides M.D., I.Martine[X]
Dept.Ob/Gyn Winthrop University Hospital Mineola, New York

Although there are many studies on the management of hypertension during pregnancy,there are no standards which analyze how management effects decision making for: usage of drugs, tests, allowing or inducing labor,and the frequency of cesarean section. In this study we present a 2 year experience from a community teaching hospital in which Doppler velocimetry formed the basis for the management of pregnant women with hypertension. From 1/1/89 through 12/31/90, 134 hypertensive patients were evaluated with uterine and umbilical Doppler velocimetry, and results are as follows:

Doppler	Both Normal	Abnormal Uterine	Abnormal Umbilical	Both Abnormal
Maternal Fetal Parameters				
#Of Pts	104	13	12	5
Mean Age(yrs)	30±5	30±6	28±6	34±4*

*p<0.05 **p<0.01 ***p<0.001

A Doppler classification of hypertension in pregnancy identifies 4 groups of patients with varying clinical outcomes. The classification distinguishes women who can be managed expectantly from those who have increasing fetal risk. We offer this study as a beginning effort for others to analyze the effect of various management plans on the need for prenatal testing, medications hospitalization, inductions of labor and cesarean sections.

208 MIDDLE CEREBRAL ARTERY BLOOD FLOW VELOCITY IN PREGNANCIES WITH EXTREMELY ABNORMAL UMBILICAL ARTERY S/D RATIO

J. Forouzan, Z-Y Tian[X], C. Lindenbaum[X], P. Samuels
University of Pennsylvania Medical Center
Philadelphia, PA

Management, specifically the timing of delivery, of patients with extremely abnormal umbilical artery S/D ratio remains controversial. Six patients with extremely abnormal umbilical artery S/D ratio (defined as S/D > 99th percentile and/or absent end diastolic velocity) were diagnosed during a 3 years period. All patients had risk factors requiring conventional antenatal surveillance. Middle cerebral artery (MCA) flow velocimetry was performed regularly starting from the time of diagnosis of abnormal umbilical artery flow (24-28 weeks of gestation) until the time of delivery. The physicians managing the pregnancy were blinded to the MCA flow velocity measurements. Upon first measurement, all MCA flow velocities were abnormal (<mean - 2SD). All patients delivered small for gestational age infants with a neonatal mortality rate of 33%. All six patients delivered prior to 35 weeks of gestation because of deteriorating antepartum fetal testing. Analysis of MCA flow velocity revealed that all of the waveforms converted to normal on an average of 4 days prior to worsening of conventional antepartum fetal testing necessitating delivery. The umbilical artery S/D ratios remained extremely abnormal despite normalization of MCA flows. **Conclusions:** In patients with abnormal umbilical S/D ratios, abormal MCA flow velocities may predict eventual poor outcome earlier than conventional testing. Abnormal MCA flow velocity, however, did not indicate a need for immediate delivery. In fact, a return of MCA flow velocity to normal was a harbinger of impending fetal jeopardy. The role of MCA flow velocity measurement in optimally timing the delivery of the at risk fetus requires further investigation.

209 CLINICAL SIGNIFICANCE OF MEASURING THE UMBILICAL ARTERY S/D RATIO AT THE PLACENTAL AND FETAL CORD INSERTION SITES

I. Forouzan, P. Samuels, S. Eife[X], A.W. Cohen
University of Pennsylvania Medical Center, Philadelphia, PA

Umbilical artery S/D ratios vary at different sites along the umbilical artery. We studied a group of fifty high risk pregnancies in the third trimester. We analyzed the ability of the umbilical artery S/D ratio, performed within 7 days of delivery, to predict the likelihood of poor pregnancy outcome among these patients. Poor outcome was defined as small -for- gestational age infants, the presence of meconium at delivery, fetal distress in labor requiring cesarean section, or 5 minute Apgar scores < 7. Twelve patients, (24%) had abnormal S/D ratios near the abdominal end of the umbilical cord. Abnormal S/D ratios were seen in 9 (18%), and 4 (8%) patients at the mid cord segments and placental insertion sites, respectively. All those with an abnormal S/D ratio at placental end of the cord also had an abnormal S/D ratio at the mid cord segment and abdominal insertion site. This, however, was not true for patients who had abnormal measurements at the mid cord or abdominal end of the cord. Poor outcome occurred in 11 patients (22%). An abnormal S/D ratio (> mean + 2SD) at the placental insertion site had a better predictive value (40%) than did abnormal values at the mid cord and abdominal end of the cord (28% and 20% respectively). **Conclusion:** In our study, the ability to use Doppler blood flow studies to predict poor pregnancy outcome is less than reported in the obstetric literature. Our success in predicting adverse outcomes, however, was improved by measuring the umbilical artery S/D ratio at the placental insertion site.

210 TRICUSPID REGURGITATION: A METHOD OF MONITORING PATIENTS TREATED WITH INDOMETHACIN.

R.L. Rosemond, F.H. Boehm, G. Moreau,* H. Karmo*. Dept. of OB/GYN, Vanderbilt Univ. Medical Center, Nashville, TN.

Doppler ultrasound (U/S) has been used to detect fetal ductus arteriosus constriction in up to 50% of patients treated with Indomethacin. This technique is difficult to perform and results are not entirely reproducible. In this study, we propose an alternate method of monitoring patients on Indocin. Significant ductal constriction will lead to tricuspid valve regurgitation (TR). Using Doppler U/S to detect TR, 30 normal control patients were studied to determine the typical velocity waveform that occurs across the tricuspid valve. The upper limit of normal for regurgitant flow was determined to be .6 m/sec. 45 patients in the same gestational age range who were treated with Indocin (50 mg suppository load, 25 mg PO q 6) for preterm labor were studied using the same technique. Length of therapy was variable, but all patients had at least one study performed per 72 hour interval. Indocin was discontinued if there was significant regurgitant flow or the amniotic fluid index became ≤ 5 cm. Results: There were 2 cases (4.4%) of TR detected and 4 cases (8.8%) of oligohydramnios (oligo). Both cases of TR resolved within 24 hours and 3 of 4 cases of oligo resolved with 72 hours. The fourth case with oligo delivered within 24 hours of stopping Indocin. There were 31 neonatal intensive care unit admissions. There were no instances of persistent fetal circulation or intraventricular hemorrhage. One infant developed mild necrotizing enterocolitis at 30 days of life and one infant developed transient renal tubular dysfunction. The etiology of the renal failure was thought to be related to either gentamycin or Indocin toxicity. Neither of these cases was from the group that developed TR or oligo. We conclude that patients treated with Indomethacin can be safely and easily monitored by observing for the development of TR or oligo and that the incidence of clinically significant ductal constriction may be less than originally reported.

211 **COMPARISON OF THE DOPPLER WAVEFORM CHARACTERISTICS OF THE PROXIMAL VERSUS DISTAL UTERINE ARTERY USING COLOR FLOW MAPPING.**

R. Allen,[X] L. Castro, D. Ogunyemi,[X] K. Roll,[X] L. Platt, Cedars-Sinai and King-Drew Medical Centers, UCLA School of Medicine, Los Angeles, Ca.

Analyses of Doppler ultrasound flow velocity waveforms (FVWs) have been used to investigate the uteroplacental circulation. Previous studies suggest that uterine artery FVWs vary significantly with the sampling site. **Purpose:** To determine whether the location along the uterine artery alters the doppler FVWs and to assess whether observed differences are influenced by gestational age (GA). **Methods:** 27 subjects from 18 to 40 weeks GA had studies performed. 15 subjects had repeated studies at 4 week intervals. The proximal and distal UA were identified with color flow mapping. Pulsed Doppler was then used to obtain the FVWs. The mean S/D ratio and RI were calculated from at least 3 waveforms. The data were analyzed using repeated measures analysis of covariance with and without GA as the covariate and the subject as a random factor for repeated measures.

Results: n= number of studies

ANCOVA* For RI and S/D Proximal VS. Distal

	n	mean diff. (SEM)	p-value
S/D placental	50	0.30 (0.06)	.0001
S/D non-placental	51	0.50 (0.21)	.021
RI placental	50	0.09 (0.02)	.0001
RI non-placental	51	0.07 (0.02)	.0001

*Analysis of covariance without gestational age in the model.

Gestational age was not an important covariate in any of the analyses. The changes between proximal and distal RI and S/D ratios were not significantly different between placental and non-placental sides. **Conclusions:** The S/D ratio and RI decline significantly along the course of the UA and this decline is not influenced by GA. This decline may reflect a decrease in resistance to flow as the uterine vessels near the placenta. Supported by UCTRDRP Grant#1KT96

212 EFFECT OF SAMPLING SITE ON UMBILICAL DOPPLER INDICES IN INTRAUTERINE GROWTH RETARDATION (IUGR)

A. Skoll, S. Sonesson[X], G. Tessyler[X], P. Bonnin,[X] J.-C. Fouron[X]. Fetal Cardiology Unit, University of Montreal, Montreal, Quebec.

Previously, we confirmed that the S/D ratio, pulsatility index (PI), and resistance index (RI) are higher in the abdominal than placental end of the umbilical artery in normal pregnancy, and that this difference disappears at the end of gestation (International Perinatal Doppler Society, 1991). We hypothesize that this is due to a relative increase in fetal circulatory volume compared to placental volume late in gestation. Therefore, we sought to determine whether this pattern holds true for growth retarded fetuses. Systolic and diastolic velocities were measured at the abdominal (A) and placental (P) ends of the cord of 28 fetuses 28 - 40 weeks gestation with severe IUGR (birthweight < 3rd percentile for GA). The mean A-P difference in all indices remained significant even at the end of gestation. (Table 1) This suggests: 1) that when monitoring these high risk fetuses with doppler studies, sample site should be controlled for in serial examinations, and 2) that the disappearance of the A-P difference in normal fetuses may result from increased fetal blood volume relative to placental volume late in gestation.

Table 1 Mean A-P difference in indices (>36 wks)

	Δ S/D	Δ PI	ΔRI
Normals	0.29±.6†	0.05±.17†	0.03±.07†
IUGR	1.17±.99*	0.33±0.2*	0.10±.08*

† = NS

213 LOW PLACENTAL RESISTANCE IS ASSOCIATED WITH FETAL MACROSOMIA. AL Diket[X], HA Gabert and JM Miller, Jr., LSU Medical Center New Orleans, LA

We evaluated the relationship of umbilical artery Doppler velocimetry and increased fetal growth. 153 patients who delivered ≥38 weeks were studied with continuous wave Doppler within 2 weeks of delivery. Large for gestational age (LGA) fetuses were compared to appropriate for gestational age fetuses (AGA). Repetitive measurements of the systolic to diastolic ratio (S/D), pulsatility index (PI) and resistance index (RI) were averaged. Gestational age at time of study and delivery was not different between the two groups. S/D, PI and RI were significantly less in the LGA group.

	Weight(g)	S/D	PI	RI
LGA	4212±212	2.20±.25	.82±.14	.54±.05
AGA	3207±356	2.46±.37	.95±.20	.58±.05
p	.0001	.0001	.0001	.0001

Individual evaluation of each of the 3 measurements found that sensitivity and specificity were poor.

S/D	LGA	AGA	PI	LGA	AGA	RI	LGA	AGA
≤2.00	9	5	≤.75	11	10	≤.50	10	7
>2.00	30	109	>.75	28	104	>.50	29	107

While low values are poorly predictive of LGA status, the decreased resistance observed may identify one mechanism of macrosomia.

214 AMNIOTIC FLUID GLUCOSE CONCENTRATIONS ARE REDUCED IN TERM PARTURITION AND IN CYTOLOGIC AMNIONITIS. R. Romero, M. Famirez,[X] W. Sepulveda,[X] F. Brandt,[X] R. Gonzalez,[X] E. Behnke,[X] M. Mazor, Depts. of Ob/Gyn; Yale Univ. School of Medicine, New Haven, CT; Wayne State Univ., Detroit, MI

Amniotic fluid glucose (AF-G) determinations have been proposed as a sensitive method for the diagnosis of intraamniotic infection (AJOG 1990;163:968 and AJOG 1991;164:818). Recent observations, however, indicate that labor per se may decrease AF-G concentrations and thus limit the utility of this test (SGI 1991, Abs. #84). This study was designed to examine the effect of term labor and cytologic amnionitis on AF-G levels. Materials and Methods: AF was retrieved from 365 women divided into four groups: group 1, term patients not in labor (n = 101); group 2, term patients in active labor with an AF white blood cell count (AF-WBC) of <50 cells/mm^3 (n = 184); group 3, term patients in active labor with an AF-WBC of >50 cells/mm^3 (n = 30); group 4, women in the midtrimester of pregnancy undergoing genetic amniocentesis (n = 50). Glucose determinations were performed by the glucose-oxicase method. Patients at term had simultaneous plasma glucose determinations. Results: 1) Women in active labor had significantly lower AF-G than women at term not in labor (median = 8.9 mg/dL, range = 3.8-38.8 vs. median 13.5 mg/dL, range 4.8-33.8; p <0.0001). 2) Women in active labor with an AF-WBC >50 cells/mm^3 had a significantly lower AF-G than those with an AF-WBC <50 cells/mm^3 (median = 9.4 mg/dL, range = 3.8-38.8; p <0.0001). 3) There were no significant differences in maternal plasma glucose concentrations among the three study groups (p = 0.57). 4) Patients in the midtrimester of pregnancy had a significantly higher AF-G concentration than patients at term (median = 43.1 mg/dL, range = 26.5-62.8 vs. median = 13.5 mg/dL, range = 4.8-33.8; p <0.05). Conclusions: 1) Normal AF-G concentrations decrease with gestational age. 2) The cut-off of 14 mg/dL proposed for the diagnosis of intraamniotic infection in preterm labor cannot be used at term because at least 50% of normal women had an AF-G concentration below this level. 3) Term labor is associated with a reduction in AF-G concentration. 4) Patients with cytologic amnionitis had the lowest AF-G concentration observed in this study.

215 EXTRACORPOREAL PERFUSION OF HUMAN UTERI: A SYSTEM TO STUDY THE ELECTROMECHANICAL EVENTS OF MYOMETRIAL CONTRACTILITY. C. Bulletl,[X] G. Bazzochl,[X] R. Romero, R.A. Prefetto,[X] P. Mimmi,[X] G.A. Lanfranchi,[X] C. Flamigni, Depts. of Ob/Gyn, Yale University School of Medicine, New Haven, CT and The University of Bologna, Bologna, Italy

Studies of the physiology and pharmacology of human uterine contractility are essential for understanding the mechanisms involved in term and preterm labor. Previous experimental approaches to the study of myometrial contractility have been based upon either myometrial strips or animal models. Studies based upon myometrial strips are non-physiologic because the myometrium is removed from paracrine control mechanisms. Extrapolation of results of animal studies to the human is always open to question. We have designed a new experimental system that uses extracorporeal perfusion of human uteri to study the electromechanical events of uterine contractility. Materials and Methods: Uteri were obtained (n = 10) after total abdominal hysterectomy. Uterine arteries were cannulated and connected to an extracorporeal perfusion machine specially designed for uterine perfusion. This system used a servomechanism to maintain perfusion pressure within physiological range (120 mm Hg +/- 10 mm Hg), temperature (37°C) and humidity (99%). The perfusion medium was Krebs-Ringer HCO3, 2% dextrose, pH = 7.4. Electrical activity was recorded by bipolar intramyometrial electrodes, and mechanical activity was recorded with an intraluminal fluid-filled open catheter connected to a Beckman type 4-237 transducer. To validate this system, we perfused the uterus with oxytocin and recorded electromechanical events. Results: Functional studies of human contractility could be carried out for at least 24 hours after establishment of the preparation. Oxytocin perfusion was associated with an increase in electrical activity (spike potentials/30 minutes, percent duration of rhythmic spike activity and frequency of rhythmic spike activity) (p <0.01) and also in the frequency of contractions per 10-minute window (p <0.01). Conclusion: A novel experimental paradigm for the study of human uterine contractility has been developed. This system can be used to examine the effect of uterotonins and tocolytic agents before administration to humans.

216 AMNIOTIC FLUID INTERLEUKIN-6 AND PROSTAGLANDIN E_2 ARE INCREASED IN TERM HUMAN PARTURITION. M. Mazor, R. Romero, D. Kleinman,[X] A. Wiznitzer,[X] M. Glezerman,[X] Departments of Obstetrics and Gynecology, Soroka Medical Center, Ben-Gurion University, Israel and Yale University School of Medicine, New Haven, CT

Cytokines have been implicated in the mechanisms responsible for preterm human parturition in the setting of infection. It is unclear, however, if cytokines may also play a role in term labor. Interleukin-6 (IL-6) is a cytokine produced by a variety of immune and nonimmune cells in response to several infectious and noninfectious stimuli. Recently IL-6 has been shown to stimulate prostaglandin (PG) production by human amnion and decidua (Eur J Pharmacol 1991;192:189). The purpose of this study was to examine whether there is a correlation between amniotic fluid (AF) concentrations of IL-6 and PGE_2. Materials and Methods: AF was collected from 19 women at term not in labor and 32 women in active spontaneous labor. IL-6 was measured with a radioimmunoassay (RIA) validated for AF and PGE_2 with an RIA previously described (J Pharmacol 1983;35:576). Results: Women in active labor had significantly higher AF concentrations of IL-6 than women not in labor (median = 2.58 ng/ml, range = 0.2-8.83 vs. median = 0.37 ng/ml, range = 0.1-2.05, respectively; p <0.001, Mann-Whitney U test). Similarly AF PGE_2 concentrations were significantly higher in women in active labor than in those not in labor (median = 6.46 ng/ml, range = 1.16-23.05 vs. median = 0.21 ng/ml, range = 0.07-0.68, respectively; p <0.001). A strong correlation between AF IL-6 and PGE2 was found (Spearman correlation, r = 0.89; p <0.001). Conclusion: Term human parturition is associated with a significant increase in AF of both IL-6 and PGE_2.

217 **A COMPARISON OF INTRAVAGINAL PROSTAGLANDIN E_2 AS A GEL OR CONTROLLED RELEASE PESSARY FOR CERVICAL RIPENING AND INITIATION OF LABOR.** C. Smith, A. Miller, M. Stancil, W. Rayburn. Dept of OB/GYN, Univ of Nebraska College of Medicine, Omaha, NE.

Intravaginal application of prostaglandin E_2 (PGE_2) in a low-dose preparation is helpful to promote cervical ripening and initiate labor. The purpose of this one-year investigation was to compare the safety and efficacy of PGE_2 administered either sequentially as a 2.5 mg gel (n=79) or as a single application of a controlled release 10 mg pessary (n=82). The groups were similar in maternal age, race, gestational age, initial Bishop score, and indication for induction. Cesarean section for a failed induction occurred in equal proportion between the two groups. A change to a Bishop score ≥ 8 occurred more often in the pessary than gel group at 6 hours (29, 35.4% versus 12, 15.2%, p = 0.003) and at 12 hours (55, 67.1% versus 38, 47.5%, p = 0.012) postdosing. Labor ensued without need for oxytocin more often in the pessary than gel group (68, 82.9% versus 40, 50.6%, P < .0005). Multiple dosings of the gel were required in 49 (62.1%) cases. Uterine hyperstimulation occurred with slightly greater frequency in those patients receiving the pessary than the gel (7, 8.5 % versus 1, 1.3% , P = 0.078), but this difference was not statistically different and removal was accomplished only with the pessary. We conclude that intravaginal PGE_2 is better delivered as a controlled release pessary than as a gel, because it is a singly applied, easily removable preparation which produces greater cervical change and often initiates labor without need for oxytocin.

218 **NEONATAL OUTCOME IN PROLONGED 2ND STAGE OF LABOR.** E. Xenakis,* O. Langer, N. Field,* A. Samueloff,* L. Ridgway, M. Berkus Dept. OB/GYN, Univ. Texas HSC at San Antonio, Texas.

It is commonly held that a 2nd stage of labor exceeding 2 hours is associated with increased morbidity. More recent data have challenged this concept. In order to investigate the relationship between length of 2nd stage and fetal outcome, 1670 consecutive women were studied. Adverse neonatal outcome was defined as: level III NICU admission with respiratory support and/or hypotonia, IVH, sepsis, convulsions or neonatal death. The study revealed that in 92% of the cases, fetal heart rate (FHR) characteristics could not predict adverse outcome. Only in 8% of cases was abnormal FHR associated with adverse outcome. The relationship between the length of 2nd stage (both nulliparas and multiparas) and abnormal outcome is shown below:

N	Duration of 2nd Stage (min)	Adverse Neonatal Outcome	Cord pH <7.20	Apgar at 5min <7
760	0-29	3.3%	10.3%	0.4%
224	30-59	1.3%	19.3%	0.4%
90	60-89	5.6%	26.7%	3.3%
37	90-119	10.8%	16.2%	---
45	120-179	4.0%	22.0%	-----
24	180+	20.8%	26.1%	16.7%

p < .0001

Further analysis (stepwise multiple regression) showed that 30% of the variance (prolonged 2nd stage) is explained by: length of 1st stage of labor; station at entry in 2nd stage; birth weight; and analgesia. Our data indicate a significant increase in the deleterious effects of prolonged 2nd stage on the fetus.

219 USE OF AN INSUFFLATABLE ABDOMINAL GIRDLE TO SHORTEN THE SECOND STAGE OF LABOR M.Y. Cai,* S.F. Zhao* (Sponsor: R. Petrie) Depts. OB/GYN. Peking Union Medical College, Beijing & Lishan Hospital, Liaoning, China

Prospectively 160 consecutive normal term nulliparas were randomized into study and control groups (80 each). During the second stage of labor, the abdominal girdle was insufflated to a basal pressure of 30-60 torr, during contractions the girdle pressure was increased and maintained at a general pressure of 150-200 torr, and with the appearance of 2-3 cm diameter of scalp at the introitus, the girdle was further insufflated to a high pressure of 300 -350 torr. Control patients were managed identically except without girdle. The mean ages were 26.2 (control) and 26.6 (study). The mean durations of second stage labor were 40'23"(S) and 59'59"(C) P<0.01. The mean durations from appearance of fetal head at the vulva to complete delivery were 11'56"(S) and 20'56"(C) P<0.01. Vacuum extraction was necessary in 15/80 instances(C) and 5/80(S). The mean 1 minute Apgar scores were 9.98(S) and 9.88(S) P>0.05. Funic (A&V) respiratory blood gas values were within normal ranges as were maternal vital signs and respiratory blood gas analyses P>0.05. There were no differences in the instances of abnormal FHR patterns or presence of meconium between the two groups. The results of this study indicate that this technique is simple, safe and easy to use as well as an effective procedure for both shortening second stage labor and reducing the need for vaginal operative delivery safely for mother and newborn.

220 **INTRAAMNIOTIC 15 METHYL PROSTAGLANDIN F2 ALPHA VERSUS INTRAVAGINAL PROSTAGLANDIN E2 FOR SECOND TRIMESTER LABOR INDUCTION**

B. Campbell, R. Newman, D. Eller, S. Cox, P. Roussis, Med Univ of S.C., Charleston, S.C., University of Kentucky, Lexington, KY

Second trimester abortion is frequently complicated by significant morbidity. Although instrumental dilatation and evacuation is touted to be the safest method of second trimester abortion, many physicians lack the experience to perform this procedure confidently. This has led to the common use of prostaglandins as abortifacients. Unfortunately, frequent systemic side effects and a high incidence of incomplete abortion requiring surgical intravention are common complications. In an attempt to minimize these risks, we compared patients undergoing labor induction with vaginal prostaglandin E2 (Group A, N = 20) and intraamniotic 15 Methyl prostaglandin F2 alpha (Group B, N = 20). Group A received vaginal 20 mg PGE_2 suppositories every 3 to 4 hours. Group B received 2.5 mg 15MPGF_2 alpha intraamniotically under ultrasound guidance. Group A successfully delivered by 24 hours in 90% and by 36 hours in 100% of cases. Seven patients in Group A had an incomplete abortion requiring surgical intervention. Group B had 95% and 100% of patients delivered within 24 and 36 hours respectively and only 1 patient had an incomplete abortion. Significant gastrointestinal side effects were noted in 65% of Group A and 5% of Group B. (P < 0.001).

Table	Group A (N = 20)	Group B (N = 20)	P
Nullip/Multip	11/9	11/9	NS
Gest. Age	19.0±2.6 wks	18.0±2.5 wks	NS
Time to delivery	16.0±5.1 hrs	12.7±6.2 hrs	NS
Delivery of placenta	69.3±47.8 min	15.9±31.9 min	<.001
Side effects: GI	13 (65%)	1 (5%)	<.001
Fever.	6 (30%)	0	<.01
Incomplete Ab	7 (35%)	1 (5%)	<.01
Est. blood loss	230 cc	120 cc	NS

This study confirms the efficacy of intraamniotic 15 Methyl PGF_2 alpha for second trimester labor induction compared to intravaginal PGE_2 suppositories with significantly fewer systemic side effects and fewer cases requiring surgical intervention.

221 **Withdrawn at authors' request.**

222 EFFECT OF TIME INTERVAL BETWEEN TWIN DELIVERY ON OUTCOME. T. Feng,* R. Swindle,* Dept. Gyn/Ob, Johns Hopkins University School of Medicine, Baltimore, MD 21205

It has been recommended that the interval between delivery of twins should preferably be within 15 minutes (min) and not more than 30 min. The purpose of this study is to evaluate the effect of delivery interval on the outcome of the 2nd twin. All twin deliveries from 1981 to 1987 were reviewed for the following criteria: 1) infants weighed >1500 gram or were ≥34 weeks by Dubowitz score, 2) the first twin was delivered vaginally. Obstetric data obtained by chart review included mode of delivery, presentation of 2nd twin, interval between delivery and 5 min Apgar score. In addition, all infants with a 5 min Apgar score ≤7 had a chart review. Time intervals were divided into 4 categories ≤15 min, 16-30 min, 31-60 min and >60 min. These groups were later collapsed during analysis. The results were analyzed using Fisher's exact test to compare groups and a p-value <0.05 was considered significant. **Conclusion:** An interval >60 min between twin deliveries did not have an adverse effect on outcome as judged by Apgar score, length of stay, or birth trauma. The largest incidence of cesarean section (C/S) (50%) occurred in the 31-60 min time interval which may represent adherence to older recommendations regarding the "safe" interval between twin deliveries. Additional data will be presented.

	INTERVAL IN MINUTES				P VALUE	
EVENT	≤15	16-30	31-60	>60	≤30 vs >30	≤60vs>60
Total	59	33	16	11	--	--
Breech del. of 2nd twin	26	3	0	1	.0075	.1793*
C/S for 2nd twin	1	7	8	2	.0009	.5212*
2nd twin with Apgar <7	2	1	0	1	.6481*	.3251*

*Not significant by Fishers Exact Test

223 SERUM α_1- ANTI-TRYPSIN: A MARKER FOR LABOR.

P.C. Leppert, S.Y. Yu[x], Dept. Ob/Gyn, Univ. Rochester, Rochester, NY

The association between labor status and an acute phase protein, α_1-anti-trypsin, also called α_1-anti-protease (API) was examined. Sera were obtained from 229 women on admission to the labor floor. Labor status was determined by Friedman curves. Concentrations of API were assayed by radial immunodiffusion using a monospecific antibody.

Results:

α_1-anti-protease in mg/dl

	membranes intact	ROM	combined
no labor	(N= 49) 236±6*	(N=11) 257±16	(N=60) 243±6*
latent phase	(N= 66) 255±7	(N=47) 252±9	(N=113) 258±5
active labor	(N=33) 259±11	(N=23) 269 ± 10**	(N=56) 259±7

* p = <.01 ** p = <.005

Gestational age, hypertension and diabetes had no obvious impact on our findings. The exact mechanism causing API elevation is speculative. However, we suggest that API may prove useful as a biochemical marker for labor, especially when membranes are intact.

224 **IS PRETERM LABOR AN INFLAMMATORY PROCESS? AMNIOTIC FLUID cICAM-1 LEVELS ARE ELEVATED IN PRETERM LABOR.** CM Salafia[x],CA Vogel[x], J Pezzullo[x], M Lentner[x], E Mainolfi [x], JP Burns[x], G Foye, P Swift [x], LSilberman[x] R Rothlein[x] Depts. Lab. Med. and Ob/Gyn, Danbury Hospital, CT, Boehringer Ingelheim Corp,CT,TRC, Rhode Island Hospital, RI.

Acute intrauterine infection and histologic markers of chronic inflammation of placental villi or implantation site have been linked to preterm birth. Acute infection is thought to initiate labor via cytokine induction of prostanoids. Cytokines in amniotic fluid (AF) in cases of preterm birth without histologic acute infection have not been detected. cICAM-1 is a molecule produced in the early stages of inflammatory responses, serum levels of which are increased in liver and cardiac transplant patients undergoing allograft rejection. We assayed cICAM-1 levels [cICAM-1] by ELISA in 40 AF samples obtained at amniocentesis at 16-17 weeks for maternal age/anxiety, and compared them to 20 AF samples obtained by amniocentesis for evaluation of maturity or at cesarean section (C/S) with delivery at 32 -36 weeks, and 18 AF samples obtained at term C/S delivery. Log-transformed data are presented as mean +/- SE. Mean [cICAM-1] in **midtrimester** samples was **36.8 pg/ml +/- 8.** Mean [cICAM-1] in **preterm births** was **419.5 pg/ml +/- 65.7 (T=5.28, p<0.05)**, and significantly elevated over that of **term samples** (mean [cICAM-1]=**173.3 pg/ml +/- 32.7 , T= 3.16, p<0.05).** 11 of 20 patients delivering preterm presented in spontaneous labor; mean [cICAM-1] was 598.8 pg/ml +/- 37 v. 347.2 pg/ml +/- 67 in 9 patients delivering without labor by C/S (p<0.05). AF [cICAM-1] in preterm and term cases was not associated with presence or severity of histologic acute intrauterine infection (p>.10). These data suggest that preterm labor is an inflammatory process and that chronic inflammation may contribute to otherwise idiopathic preterm labor. Also, disease processes which necessitate premature delivery of the fetus may also involve chronic intrauterine inflammation.

225 **PRESSURE WAVE CHARACTERISTICS OF THE UPPER AND LOWER UTERINE SEGMENT IN ARRESTED LABOR.** F.Margono,* A.Karimi,* E.Prakash* and H.Minkoff.Dept.Ob/Gyn,State University of New York, Brooklyn,NY

Most methods for the measurement of uterine contractions during labor involve the use of an intrauterine pressure transducer (IPT). Using a single IPT Seitchik found no difference in the pressure wafe form characteristics of patients with successful or failed first stage of labor, either before or after oxytocin. Caldeyro Barcia stated that the intensity of the contraction diminishes from the top to bottom of the uterus in normal labor with the upper segment of the uterus contracting more strongly than the lower. It is possible that in cases of failed 1st stage of labor the lower segment of the uterus contracts more strongly than the upper. This phenomen would not be detectable with single IPT. To investigate this possibility two IPTs were inserted into the upper and lower segments of the uterus of laboring patients with cervical dilatation of at least 4 cm who were failing to progress. All patients had a single term vertex fetus, and EFW <4000 g. There were 3 primiparas and 5 multiparas. The location of the IPT tips was confirmed by ultrasound, both intrauterine pressure wave patterns were recorded simultaneously. Management of labor was based upon the pattern of the upper segment and labor progress. 3 patients underwent cesarean section for failure to progress. Prelimenary analysis of the intrauterine pressure wave forms (table 1) showed that those who underwent cesarean section had higher intrauterine pressures in the lower segment than the upper segment. The remaining patients showed greater pressures in the upper segment. Oxytocin increased intrauterine pressure in both upper and lower segments but did not change the gradient between segments. If these data are confirmed, pressure gradients may be used to gauge the likelihood of success of pitocin.

Table 1: Active Pressure Integral pre and post oxytocin

	(Pre) Upper	Lower	(Post) Upper	Lower
NSVD	2.79±0.33	2.17±0.45	3.19±0.49	2.47±0.45
CS	2.24±0.25	2.84±0.65	3.22±0.36	3.80±0.32

226 **PREGNANCY AFTER CESAREAN SECTION: RESULTS FROM A SINGLE CENTER.** Steven A. Friedman, MD,* Clare L. Cammarano, MD,* Russell K. Laros, MD. Department of Obstetrics, Gynecology and Reproductive Sciences, University of California, San Francisco (UCSF), San Francisco, California

We conducted a retrospective review of the UCSF Perinatal Database to determine whether an attempted trial of labor (TOL) after previous cesarean section is more desirable than an elective repeat cesarean section (ECS). Inclusion criteria were previous cesarean section, birth weight ≥750 g, and delivery at UCSF between 1 June 1976 and 31 December 1990. A total of 589 patients (including 8 with twin gestations) met these criteria. Three hundred six (52%) had an ECS and 283 (48%) had a TOL, of whom 177 (63%) delivered vaginally. The two groups were similar in age, parity, gestational age, and birth weight. Results are expressed as means±SD. Significance is defined as P<.05.

	TOL (SVD & CS)	ECS	P Value
Endometritis (%)	3.9	5.9	NS
Hospital stay (d)	3.5±2.2	5.5±3.1	<.0005
Δ Hematocrit (vol %)	-4.9±4.5	-3.2±3.3	<.0005
Transfusion (%)	2.5	1.6	NS
5-min Apgar ≤6 (%)	4.5	2.6	NS
Umbilical artery pH	7.25±0.08	7.26±0.07	NS
Neonatal intensive care (%)	7.7	8.1	NS

There were no maternal deaths nor uterine ruptures. Although statistically significant, the greater fall in hematocrit in the TOL group is clinically unimportant. These data support the American College of Obstetricians and Gynecologists' recommendation that a woman with a single previous cesarean section "be counseled and encouraged to attempt labor in her current pregnancy."

227 DILAPAN PLUS PROSTAGLANDIN E_2 VAGINAL GEL FOR CERVICAL RIPENING. Andrew Chao, David Plourd[X], Mai-Anh Doan[X]. Dept. Ob/Gyn, Santa Clara Valley Medical Center, San Jose, CA

We compared Dilapan dilators plus prostaglandin E_2 (PGE_2) gel to PGE_2 alone. Third-trimester induction patients with Bishop scores <5 were randomly assigned. Group 1 (n=25) received 1-6 dilators (median, 5) plus 3 mg PGE_2 gel. Group 2 (n=37) received gel alone. Dilators were removed in 4 hours. One or two more PGE_2 doses were applied at 4-hour intervals if the Bishop score was still <5; then oxytocin was begun. Parity, gestational age, and initial Bishop scores were comparable. Group 1 had a greater increment of Bishop score at 4 hours (median 3, range 0-11 vs. median 1, range 0-9; $p < 0.05$). However, the insertion-to-complete-dilatation intervals did not differ significantly (1267 min ± 638 SD vs. 1240 ± 549), nor did cesarean rates. Furthermore, the amnionitis/endometritis rate was higher in Group 1 (44% vs. 8%). This trial failed to justify the combined use of Dilapan and PGE_2.

228 **MORPHOMETRIC CORRELATES OF CEPHALOPELVIC DISPROPORTION.** R.N. Pollack[X], L. Goldstone[X], MY. Divon. Dept Ob/Gyn, The Albert Einstein College of Medicine, Bronx, NY.

The significant contribution of labor abnormalities to the increasing number of cesarean sections has focused interest on the diagnosis and management of these conditions. Morphometric factors associated with cephalopelvic disproportion (CPD) have reportedly included maternal height, weight and shoe size, as well as fetal macrosomia and macrocephaly. A simple antenatal predictor of CPD which integrates both maternal as well as fetal morphometric parameters has yet to be described. Purpose: To ascertain if the ratio of maternal height to fetal size is altered in pregnancies complicated by CPD. Method: 60 patients delivered by cesarean section (c/s) for active phase labor disorders and 138 matched controls who had spontaneous vaginal deliveries were compared. Morphometric parameters studied included maternal height, maternal weight, maternal body mass index (BMI) and symphyseal fundal height (SFH). A parameter which relates fetal size to maternal height was defined as the Maternal-Fetal Ratio [MFR = Maternal Ht (cms) + Symphyseal Fundal Ht (cms)]. Results: A significant correlation between the presence of an abnormal MFR (defined as MFR < 4.00) and delivery by cesarean section for active phase labor disorders was observed ($p < 0.000001$). The odds ratio (OR) of a patient with an abnormal MFR having a cesarean section for an active phase labor abnormality was 5.08 (95% CI = 2.6 - 10.0). As previously observed short maternal stature was also associated with an increased rate of c/s for active phase labor disorders. The OR of a patient < 160 cms. tall having a c/s for an active phase labor abnormalities was 2.21 (95% CI = 1.17 - 4.17). Maternal weight and BMI were not significantly correlated with delivery by c/s for labor abnormality. Conclusion: Of the various parameters studied, an abnormal MFR was most significantly correlated with delivery by c/s for active phase labor disorders. Prospective evaluation of the maternal fetal ratio in the prediction of CPD may be indicated.

229 **PROLONGED LABOR (>12 H) IS ASSOCIATED WITH A SIGNIFICANT DECREASE IN UMBILICAL ARTERY pH.** GM Morton[x], T C-S Foster[x], GJ Valenzuela. Dept Ob & Gyn SBCMC and Loma Linda Univ., California.

Prolonged labor (>12 h) has been described as having a detrimental effect on fetal outcome; however, in many of these studies the characteristics of the population have been poorly described. We report here on the influence of duration of labor on umbilical cord pH. 1110 women delivered at term were studied. All were without fetal or maternal complications, had normal electronic fetal monitoring strips, and delivered spontaneously. Cord blood gases were determined within 20 minutes of delivery. Fetal umbilical arterial and venous pH's were averaged on patients with durations of labor of <4, 4-8, 8-12, 12-16, and >16 hours. A progressive decline in arterial, but not venous, pH was noted; Apgar scores did not differ among the groups. The frequency of arterial pH<7.2 increased from 8.0% at 4 h to 18% at >16 h; arterial pH of <7.1 occurred in 2.6% of those delivering after 16 hours, which was also significantly different from the other four groups. We conclude that increasing duration of labor is associated with a fall in umbilical artery pH, although the number of infants with true acidosis is very low.

230 **PROLONGED SECOND STAGE AND PERINATAL OUTCOME: A CASE CONTROL STUDY.**

Luis Sanchez-Ramos, M.D., Patricia Schroeder, M.D.[X], Donna Briones, R.N.[X] University of Florida, Jacksonville, FL.

A prolonged second stage of labor i.e; greater than 2 hours, has been regarded as dangerous for the parturient and her infant. However, recent studies have challenged this conclusion. The purpose of this study was to evaluate the effects of a prolonged second stage of labor on perinatal and maternal outcome. From September 1990 to June 1991 during which time 4523 patients delivered at our institution, patients with prolonged second stage were diagnosed and identified by L&D personnel. For each study case, two controls were chosen for comparison. After discharge the charts (mothers and infants) were reviewed with particular emphasis on perinatal and maternal complications. A total of 271 patients were evaluated (71 study patients and 140 controls). Both groups were similar except for the duration of the second stage. The study patients had a significantly higher rate of cesarean delivery and at delivery the birthweight was greater. However, the incidence of operative vaginal deliveries was similar in both groups. No differences were noted in Apgar scores, cord gas values, or median length of NICU stay. Maternal complications were similar in both groups. We feel that the data does not support an arbitrary shortening of the second stage in the presence of a reassuring fetal heart rate and normal descent of the presenting part.

231 PRIOR CESAREAN BIRTH: RISK FACTORS ASSOCIATED WITH UTERINE RUPTURE.

Anna S Leung MD,* Richard M Farmer MD, Eleanor K Leung MD,* Richard H Paul MD. University of Southern California, Los Angeles, California

Trial of labor (TOL) after previous cesarean section (C/S) is actively advocated. The risk of uterine rupture is a major concern as one undertook TOL. Delayed diagnosis of uterine rupture could be catastrophic. A uterine rupture was defined as a uterine wall defect requiring emergency laparotomy or operative intervention for fetal distress or acute maternal bleeding with an estimated blood loss of greater than one liter. A case control study was conducted to possibly identify the risk factors associated with uterine rupture. The cases consisted of 33 patients who had undergone TOL with uterine rupture between 1987-1989. 33 women with prior C/S during the same period were randomly selected as controls.

	cases	controls	P value
age	27.4	28	N.S.
parity	1.9	2.1	N.S.
No. previous C/S	1.3	1.1	N.S.
No. vaginal birth after C/S	0.2	0.5	0.045
birth weight (grams)	3516	3554	N.S.
gestational age (weeks)	40.4	40.0	N.S.
No. with amnionitis	7	2	N.S.
total duration of labor (hours)	15.8	10.7	0.036
duration latent phase (hours)	10.6	6.6	N.S.
duration active phase (hours)	6.5	4.7	N.S.
duration second stage (hours)	2.0	1.3	N.S.
No. with protracted labor (PL)	18	4	0.000
No. on oxytocin	25	19	N.S.
No. with epidural anesthesia (EP)	15	13	N.S.
No. on oxytocin with PL	16	4	0.003
No. with EP and PL	10	3	N.S.
No. on oxytocin with EP and PL	9	3	N.S.

In conclusion, patients with uterine rupture had protracted and longer duration of labor. The use of oxytocin or epidural anesthesia alone did not seem to be associated with uterine rupture. However, patients on oxytocin with protracted labor had higher incidence of uterine rupture. Patients who were undergoing TOL with oxytocin usage should be definitively evaluated for protraction and arrest disorders.

232 **THE PHYSIOLOGY OF SQUATTING DURING LABOUR**

J Gardosi[x], Perinatal Research & Monitoring Unit, Queens Medical Centre, Nottingham, England

Squatting was the normal birthing posture in many cultures but on modern labour wards, women are rarely able to adopt this position. With the development of the Birth Cushion, squatting has become a viable option for the management of second stage and delivery. This obstetric device is made of a U-shaped soft foam wedge which the mother sinks into while pulling on side handles during the bearing down efforts. A previously reported randomised controlled trial of 427 women in their first labour showed that this posture, as compared to a semi-recumbent position, results in significantly shorter second stages (median 31 vs 45 min), fewer forceps deliveries (9 vs 16 %), fewer perineal tears but more labial tears, and no difference in blood loss. Further investigation into the physiological effects of this posture during second stage reveals that it affects all three obstetric 'P's of labour: *1. The Powers* are increased as bearing-down is easier, more efficient and better coordinated; this results in an increase in the voluntary component of intrauterine pressure during contractions. *2. The Passenger* is able to contribute more of his weight, as a continued downward force acting during as well as between contractions. *3. The Passages:* Previous, unconfirmed Xray studies have suggested that the pelvic outlet increases in upright postures. The effect of squatting on the bispinous diameter was investigated with vaginal ultrasound pelvimetry (n=13), using a Kretztechnik Combison 300 Panoramascanner with 230 degree vaginal probe. This showed a mean increase of 4.1 mm (semi-recumbent 107.2 mm, SD 4.6; squatting 111.3 mm, SD 7.0; paired t-test 3.989, p=0.002). Squatting has proven clinical as well as physiological advantages which help to explain the popularity that this birthing position has had throughout ancient history.

233 CHORIOAMNIONITIS: A HARBINGER OF DYSTOCIA. A.J. Satin,* M.C. Maberry,* K.J. Leveno, M.L. Sherman,* D.M. Kline,* Dept. Ob/Gyn, Univ. Texas Southwestern Med. Ctr., Dallas, Texas

The impact of chorioamnionitis on the course of labor is controversial. Some clinicians believe chorioamnionitis has stimulatory effects while others suspect inhibitory influences. 266 pregnancies with chorioamnionitis and requiring labor stimulation with oxytocin were matched for age, race, parity, gestational age, oxytocin dosage regimen, cervical dilatation at initiation of oxytocin, and time from rupture of membranes to initiation of labor stimulation.

RESULTS:

OUTCOME	CHORIO-AMNIONITIS BEFORE OXYTOCIN N=69	CASE MATCHED CONTROLS N=69	P	CHORIO-AMNIONITIS AFTER OXYTOCIN N=197	CASE MATCHED CONTROLS N=197	P
C/S (%) Dystocia	6 (9)	6 (9)	NS	78 (40)	20 (10)	<.0001
Fetal Distress	4 (6)	2 (3)	NS	9 (5)	8 (4)	NS
Oxytocin to Delivery Hours, Mean (SE)	4.3 (.2)	5.6 (.4)	.04	12.6 (.4)	7.9 (.4)	<.0001

Conclusions: The impact of chorioamnionitis on the course of labor can be divided into two clinical presentations. Primary chorioamnionitis diagnosed upon admission may enhance labor stimulation and does not increase the risk for cesarean section. However, secondary chorioamnionitis diagnosed after initiation of oxytocin may be a sign of abnormal labor since it is associated with a marked increase in abdominal delivery for dystocia.

234 THE PEDIATRIC GRAVIDA: MATERNAL OUTCOME TB Jones, HM Wolfe, MP Dombrowski, NE Roumayah[x], and SF Bottoms. Wayne State Univ., Hutzel Hospital, Detroit, MI.

Adolescent pregnancy has been associated with increased risk for obstetrical complications such as preeclampsia, operative delivery, low birth weight, and neonatal morbidity and mortality. Little is known, however, regarding the intrapartum course of the pediatric gravida (age ≤14). We compared the labors of 412 pediatric gravidas to 13,222 nulligravidas aged 20-25 delivering from 1983-1990. Odds ratios and 95% confidence intervals are tabulated below.

	Age≤14	Age 20-25	Odds	C.I.
Preeclampsia	7.2%	3.3%	2.3	1.5-3.3
1° Cesarean	14.0%	13.3%	1.0	0.8-1.4
Forceps	5.5%	3.9%	1.4	0.9-2.2
Vacuum	3.9%	0.8%	4.6	2.7-7.9
Episiotomy	64.3%	38.6%	2.8	2.3-3.5
3° or 4° Lac.	20.3%	6.9%	3.4	2.7-4.3

Pediatric gravidas had longer second stage labor (31±31 mins.) than the older group (24±31 mins., $p<0.01$). There was no significant difference in first stage of labor, route of breech delivery, use of classical uterine incisions, or estimated blood loss. Other than increased use of local, anesthesia administration was similar in the two groups. We conclude that pediatric gravidas 1) are more than twice as likely to have preeclampsia, 2) are more likely to undergo operative delivery, but only by the vaginal route, and 3) suffer significant perineal lacerations despite more frequent use of episiotomy.

235 COMPUTERIZED COLPOSCOPY AND CONSERVATIVE MANAGEMENT OF CERVICAL INTRAEPITHELIAL NEOPLASIA IN PREGNANCY

Magdy S. Mikhail[x], Irwin R. Merkatz, Akolisa Anyaegbunam, Seymour L Romney[x]. Albert Einstein College of Medicine, Bronx, New York.

Cervical punch biopsies in pregnancy can be associated with excessive bleeding and may induce prostaglandin release which may precipitate premature labor. Objective sequential monitoring of cervical intraepithelial neoplasia (CIN) lesions by a noninvasive technique, to ensure that the lesion is not progressing, may obviate the need for a biopsy. Computerized colposcopy allows for image processing and storage, contrast and edge enhancement, the detection of subtle changes and computer assisted quantification of lesions. Thus, lesion size changes can be objectively demonstrated and monitored. Seventeen pregnant patients with abnormal Pap smears and a fully visualized squamo-columnar junction were serially monitored during their pregnancies using computerized colposcopy. All patients had baseline computer-assisted measurements of their cervical lesions and a repeat measurement at monthly intervals. The mean age of the patients was 27 and the mean size of the lesion was 59 mm^2. During the period of observation 17.7 % of colposcopically visualized lesions increased in size, 11.8 % remained unchanged, 41.1 % decreased in size, and 29.4 % disappeared completely. In patients with an increase in lesion size (n=3) a biopsy was performed which revealed CIN III but no microinvasion. No biopsy was needed in patients whose lesions remained unchanged (n=2), demonstrated a decrease in size (n=7) or disappeared (n=5). Thus cervical biopsy during pregnancy was avoided in 82.3% of cases. At postpartum follow up, all patients had colposcopically directed punch biopsies. Only those patients with an increase in lesion size revealed high grade CIN. This confirms previous observations that lesion size correlate with CIN grade. The ability to sequentially quantitate CIN lesions during pregnancy, using computerized colposcopy, provides an objective noninvasive mode to evaluate progression/regression. Computerized colposcopy has the potential to replace subjective colposcopic evaluation with objective computer assessment and may have a role in the conservative management of CIN in pregnancy.

236 CLINICAL FUNCTIONS OF A MULTI-SITE COMPUTERIZED OBSTETRICAL ULTRASOUND DATABASE. JE Deaver and K Johnson[x]. UTHSC at Houston, Dept Ob, Gyn and Repro Sci, and Comprehensive Informatics for Perinatal Health (CIPHI), Citrus Heights, CA.

Typical obstetrical ultrasound software programs perform data collection and transformation, display gestational age-related plots, and create reports having numerical tables in addition to descriptors merged with static phrases. These databases often have a narrow focus on ultrasound procedures at one site rather than on patient care at many sites. We designed and will demonstrate a computerized ultrasound record accessible from multiple sites designed to integrate ultrasound data with patient-oriented functions. The system is a module of the Athena OMS (CIPHI) computerized prenatal record, uses SQLBase database server (Gupta Technologies), and runs under the Windows 3.0 (Microsoft) graphical user interface on IBM-compatible computers. The resulting software aids in risk assessment (dating, fetal growth restriction, post-dates), allows users to create clinical protocols which, for quality assurance, can be reconciled with orders, and provides reminders concerning diagnoses, risk assessment, data errors, and protocol compliance. Ease of use is accomplished by selection of graphical objects rather than by key entry of commands. In addition to the traditional functions of ultrasound data collection and reporting, the system we describe enhances the clinical utility of ultrasound data.

237 INTERNETWORK COMPUTING FOR PERINATAL RESEARCH: A PROTOTYPE SYSTEM. L.C. Chik,* V. Salari,* R.J. Sokol, Dept. Ob/Gyn, Wayne State Univ./Hutzel Hosp., Detroit, MI

Perinatal computing has increased in breadth and complexity. Typically, applications are mounted on multiple platforms, from pc's to mainframes, limiting access. Thus, for example, in our department, most perinatal computing has been performed on a multi-user minicomputer, leading to excruciatingly slow response times at high load periods, such as the day before the SPO abstract deadline. A plethora of pc's and Macintoshes, as well as 2 Sun workstations, is also available. It would be desirable if a faculty member could execute a stepwise multiple regression, using a program stored in a network host in the perinatal database lab under a network file system (NFS) with the input data file in her study directory. Results could be sent immediately to her colleague at another host computer. Such an information processing scenario was foreseen a decade ago when DARPA (Defence Advanced Research Projects Agency) supported the development of TCP/IP (Transmission Control Protocol/Internet Protocol) in Ethernet networks for heterogeneous computers. With a contemporary NFS, we have implemented up-to-date internetwork capacity with a departmental database and a research host computer serving a consortium of investigators and mixed personal computers. This has resolved serious conflicts between acute heavy research demand and daily clinical database operations. As a benchmark, a Sun workstation can be accessed from multiple sites to perform large statistical analyses at > 20x the previous speed of the minicomputer, now used primarily for clinical database operation. Likewise, we can utilize network resources from different computers to enter a patient dataset in the ultrasound laboratory, generate a report on the database host and combine an alphanumeric report with a gray scale ultrasound image on the departmental letter head for a referring physician. Internetwork technology has great potential for clinical application for functional quality assurance and decision support.

238 PERI: A COMPUTER INFORMATION SYSTEM FOR THE PRACTICE OF PERINATAL MEDICINE. Robert N. Wolfson, M.D./Ph.D., Damon Stafford[x], President, Memorial Hospital, Colorado Springs, CO, and LewMin Inc., Albuquerque, NM

Perinatal medicine is characterized by a broad range of services that may include perinatal consultation, genetic consultation, antepartum testing, diagnostic ultrasound, prematurity prevention and specialized procedures such as amniocentesis, CVS and PUBS. In any one pregnancy patients may utilize only one or perhaps all of the services offered. The purpose of this project was to develop a computerized uniform chart for tracking, scheduling and reporting of services. PERI is the result of a joint effort of a Perinatal Unit and software developer to achieve a computer information system designed for Perinatal Medicine. Using a multi-user/multi-tasking computer system, PERI has customized data entry to achieve perinatal, genetic and prematurity prevention consultation as well as progress notes and other annotations. NST monitor data is obtained in realtime to produce a report including a compressed graphical presentation of the NST as well as other interpretive data. Ultrasound reports are derived from concurrent data entry during examination and yield tabular and graphical presentation of the findings along with interpretive dialogue and clinical management considerations. Preliminary experience with PERI suggests that it fulfills the diverse needs of the Perinatal practice. The challenge, benefits and obstacles of developing new computer software will be presented.

239 AN AUTOMATED OBSTETRICAL DATABASE THAT DOES MORE. J. P. VanDorsten, T.C.C. Peng, P. Dilzer[x], Medical College of Virginia-Virginia Commonwealth University, Richmond, VA.

Since October, 1990 the Division of Maternal-Fetal Medicine has successfully integrated into the Hospital Information System's (HIS) main frame computer an automated obstetrical database which generates ultrasound reports, antepartum testing reports, admission history and physicals, labor and delivery summaries, discharge summaries, and birth certificates. The advantages of this user interactive system are as follows: 1. on-line entry utilizing light pens and menus at one of 350 terminals, 2. step-wise entry by physicians and nurses to minimize entry time (≤ 5 minutes for any one data set), 3. immediate availability of data at any terminal, 4. legible, timely, and accurate reports, and 5. elimination of redundant data entry by healthcare providers. In this computerized obstetrical database, many additional tasks are expedited: 1. monthly quality assurance reports using ACOG obstetrical indicators, 2. maintenance of housestaff experience logs as required by the Residency Review Committee, 3. maintenance of patient lists for attending physicians as required by the ABOG, 4. ad hoc reports, queries, and clinical research, and 5. documentation of utilization of labor and delivery services and referral patterns. In summary, this automated database fulfills many non-traditional roles that improve the quality and efficiency of health care.

240 PATIENT LIST SOFTWARE FOR CANDIDATES TAKING THE ORAL EXAM IN MATERNAL-FETAL MEDICINE
C. Stedman and A.G. Robichaux III, Dept. Ob/Gyn, Ochsner Clinic, New Orleans, LA

Although software exists to compile case lists for the general oral examination in obstetrics and gynecology, no application is offered nationally for the maternal-fetal medicine (MFM) case list. As of 1990 the composition of the MFM summary form changed dramatically from that required for the general exam, and a tallying of 48 patient subgroups is now mandated. We wish to report a FileMaker Pro® (Claris, Santa Clara, CA) template capable of generating the obstetrical, gynecologic, and summary forms specific for the MFM lists. This program functions with Macintosh SE, SE/30, IIcx, IICi, IIfx, IIsi, Classic, or LC models. System software may be 6.05, 6.07, or the recently introduced system 7.0. We have created a work sheet that allows tabulation of all required data so the physician is spared subsequently recalling the chart from medical records. The typical work sheet requires just 2-3 minutes to complete. Modules are available in either black/white or color; users may choose data entry screens customized for either 13", 16", or 19" monitors. Buttons and macros allow easy report generation by a laser printer. Cases in which the physician acted solely as a consultant for inpatients are listed separately as requested by the American Board of Obstetrics and Gynecology.

241 FETAL IMAGING WORKSTATION. W. Lee*, C.H. Comstock*, J.S. Kirk, Div of Fetal Imaging, William Beaumont Hospital, Royal Oak, MI; Wayne State University *

An interactive fetal imaging computer workstation has been established (William Beaumont Hospital Research Institute, March of Dimes Birth Defects Foundation, Apple Computer) to examine various ways that images and sophisticated computer graphics can be used to interactively teach physicians about the prenatal diagnosis of birth defects. Main features include: 1) fetal ultrasound image and animation library; 2) medical image archival system; 3) data-base categorization and image search capabilities; 4) interactive multimedia tutorials; and 5) in-house slide production. This system uses a Macintosh IIfx computer with a 19 inch Supermac monitor. Ultrasound images are typically captured from videotape (Nuvista card, FORA color encoder, FORA time-based corrector) or photographs (Sharp JX-600 scanner). Correlative autopsy specimens are either digitized from standard photographs or by an electronic still camera system (Sony ProMavica). These images are postprocessed through Adobe Photoshop and digitally archived onto optical disk. Processed images can be placed onto hard disk, laserdisc (Panasonic TQ-3031F), or CD-ROM for inclusion into a variety of educational tutorials via Macromind Director. A Supercard application provides clinical database organization and search capabilities for up to 108,000 images on a 12-inch laserdisc. We are currently in the process of developing interactive multimedia software interfaces for the fetal imaging library. Photorealistic 3-D animation software will be eventually used to simulate normal and abnormal fetal heart development. Our works-in-progress demonstration will show potential uses for this visually-based information management system.

242 CUSTOMISED ANTENATAL GROWTH CHARTS

J Gardosi[x], A Chang[x], B Kalyan[x], EM Symonds[x]
Perinatal Research & Monitoring Unit, Dept Ob/Gyn
Queens Medical Centre, Nottingham, England

A new antenatal chart was developed which can be 'customised' to each mother's individual characteristics and used to assess birth centiles of her previous babies, as well as fundal height measurements and ultrasound - estimated fetal weights during the ongoing pregnancy. Multiple regression and variance analysis was performed on computerised data from 4179 pregnancies with ultrasound-confirmed dates. This showed that in addition to gestation and sex, the maternal booking weight, height, ethnic group and parity were significant, independent determinants of birthweight in our population. Correction factors were calculated and entered into a computer programme which uses this database to generate a personalised growth chart with corrected centile curves. This can be printed out at the beginning of pregnancy and added to the notes. Such adjustment of normal limits resulted, in our retrospective sample, in a reduction of false-positive and false-negative diagnoses of 'SGA' (small for gestational age; <10th centile) by 28% and 24% , and 'LGA' (large for gestational age; >90th centile) by 22% and 26%, respectively. We suggest that the relevant physiological variables which act as determinants of birthweight in a particular maternity population need to be better recognised in clinical practice. Prospective analysis is planned, and we hypothesize that such 'customisation' of growth assessment will reduce unnecessary investigations, interventions and patient anxiety and lead to better allocation of existing resources.

243 A COMPREHENSIVE PERINATAL DATABASE PROGRAM. P. Urso,[X] J.A. López-Zeno,[X] B. Nies,[X] S. Bathgate,[X] J. Grossman. Dept. of OB-GYN, The George Washington University Medical School. Washington, D.C.

Using a relational database program (OMNIS) we have designed a comprehensive perinatal database. It is capable of storing all the information that is requested in the ACOG Prenatal Forms This includes all data from prenatal visits, including laboratory test results. In addition, it is capable of storing and generating fetal surveillance reports, like NST. CST or BPP. Calculations of gestational age and fetal weight are incorporated into the ultrasound reports generated by this database. Upon admission to labor and delivery, all outpatient information is available in a computer terminal. The physician's admission, delivery and discharge notes can be computer generated with the information collected during labor and delivery. Nursing notes and birth certificates are also incorporated into the database. Our system provides a single, unified data resource capable of meeting both research and quality assurance needs. At our institution, the peer review process is currently conducted with information primarily obtained from this database, which conforms to the JCAH obstetrical standards. It also generates resident's experience forms and attending's case list for the ABOG. We are currently integrating the obstetrical anesthesia and neonatal data into this program. This program can be utilized in the Macintosh or the IBM operative systems. A demonstration of the Macintosh version will be given at the SPO meeting.

Poster Session III

Friday, February 7, 1992
10:00 a.m.-12:30 p.m.

Grand Salons I-IV

CATEGORIES	POSTER NOS.
Genetics and Teratology	244-285
Fetal Therapy	286-293
Prematurity	294-329
Placental Physiology	330-343

244 **SIMILARITY OF TWINS TO SINGLETON MSAFP RATIO BY RACE: NO NEED TO ESTABLISH SPECIFIC MULTIFETAL TABLES.**

A Drugan,x JE O'Brien, R Gambino, MP Johnson,* MI Evans, Depts Ob/Gyn, Hutzel HospitalWayne State U, Detroit, M , Rambam Medical Center, Haifa, Israel, and MetPath Inc., Teterboro, NJ

MSAFP values in 535 twin gestations were grouped according to week of gestation (15-20 wks) and race. MSAFP (MIU/ml) in blacks was higher than in whites (p<.01).

	White Pregnancies				Black Pregnancies			
GA	No.	Twins	Single	Ratio	No.	Twins	Single	Ratio
15	81	56.8	26.1	2.17	19	56.3	25.8	2.18
16	170	60.6	28.3	2.14	33	77.6	30.8	2.52
17	101	69.9	32.3	2.16	25	83.4	33.2	2.51
18	50	74.7	38.0	1.97	18	85.1	45.1	1.96
19	16	83.2	43.1	1.93	6	88.0	48.1	1.83
20	10	107.5	44.4	2.42	6	96.5	56.7	1.70
Total	428			2.13	107			2.10

Using race specific cutoffs of 4.5 MOM, 3.7% of whites and 4.7% of blacks were considered high, which is comparable to findings in singletons. These differences would not have been found in a non-adjusted mixed race database. "Low" results (1.0 MOM for age-matched singletons) were seen in 7.2% of whites and 5.6% of blacks, comparable to singleton pregnancies. Using race-specific databases, the interracial differences in frequency of either "high" or "low" results was not significant. We conclude: 1) different databases should be used in black and white twin pregnancies, 2) "High" (>4.5 MOM) and "low" (<1 MOM) cutoff values derived from the large databank of singleton pregnancies seem to be adequate for interpretation of MSAFP results in twins, obviating the need to build specific median curves for multifetal gestations.

245 FETAL CHOROID PLEXUS CYSTS: THE SMALL OR TRANSIENT CYST IS NOT NECESSARILY BENIGN. V. Klein, M. Perpignano, H. Cohen, F. Mandel, J. Streltzhoff, F. Chervenak, Depts. Ob/Gyn, Radiology and Research, North Shore Univ. Hosp. and NY Hosp., Cornell Univ. Med. College, NY

Analysis of 3770 obstetrical patients having prenatal sonograms between 14 and 32 wks. gestation revealed that 87(2.3%) were found to have fetal choroid plexus cysts. Eighty-three patients underwent amniocentesis, six(7.2%) had abnormal karyotypes. Four cases had the commonly associated chromosomal abnormality, trisomy 18. Two cases had a karyotype not usually associated with choroid plexus cysts, mosaic Turner's and trisomy 21. Of the six abnormal karyotypes, one had a 4 mm unilateral cyst, and 3 had bilateral cysts of 3-5 mm; two had larger cysts. In only one case with a 16 mm cyst had any associated structural abnormalities been detected sonographically. In the two cases of trisomy 18 that were not terminated and in the fetuses with trisomy 21 and mosaic Turner, cysts resolved between 23-26 wks. Our data suggests that fetal karyotyping should be considered in all fetuses with choroid plexus cysts, irregardless of laterality, size or spontaneous resolution prior to birth.

246 IDENTIFICATION OF TURNER SYNDROME WITH FETAL HYDROPS IN MULTIPLE MARKER SCREENING FOR DOWN SYNDROME D N Saller Jr[1], M G Blitzer[2x], S Schwartz[2x] & J A Canick[1x] [1]Brown Univ./Women & Infants Hosp. Prov.,RI & [2]Div. of Human Genetics, Univ. of Md. at Baltimore, MD

We previously reported the identification of non-immune fetal hydrops, some cases of which had Turner syndrome, in multiple marker screening for Down syndrome (which is based on age, low alpha-fetoprotein [AFP], low unconjugated estriol [uE3] & elevated human chorionic gonadotropin [hCG]). These cases were detected because of consistently low uE3 & markedly elevated hCG. In order to investigate the levels of uE3, hCG, & AFP associated with Turner syndrome, we identified 15 cases of 45,X karyotypes (7 with hydrops and 8 without) for which a second trimester maternal serum sample was available. The AFP levels were reduced in both groups (median MoM=0.81, range=0.39-1.59), although 4 of these cases had been referred for low AFP (possibly biasing the AFP levels). The uE3 levels were substantially reduced in both groups (median MoM=0.48, range=0.12-1.45). The hCG levels had a bimodal distribution with no overlap (rank sum test, p=0.001), in which all 7 hydropic pregnancies had markedly elevated levels (median MoM=3.84, range=1.80-5.77) and all 8 non-hydropic pregnancies had low levels (median MoM=0.52, range=0.21-0.76). All of the 7 hydropic cases would have been identified as screen positive for increased Down syndrome risk while none of the 8 non-hydropic cases would have been so identified. These findings indicate that the morpholologic defect of hydrops fetalis, rather than the 45,X karyotype itself, is responsible for the high risk pattern in multiple marker screening for Down syndrome. Non-hydropic 45,X pregnancies have relatively low AFP, uE3 & hCG, and are unlikely to be identified as high risk for Down syndrome. They may, however, be detected as high risk for Trisomy 18 (in which all 3 markers are consistently low).

247 PRENATAL ALCOHOL EXPOSURE AND NEUROBEHAVIORAL FUNCTION IN INFANCY: EVIDENCE FOR THRESHOLD AND DIFFERENTIAL VULNERABILITY. J.L. Jacobson,* S.W. Jacobson,* R.J. Sokol, S.S. Martier,* J.W. Ager,* Depts Ob/Gyn and Psychology and Fetal Alcohol Research Center, Wayne State Univ., Detroit, MI

The relation of prenatal alcohol exposure to anatomic alcohol-related birth defects (arbd) has been characterized in our studies as exhibiting a threshold and differential fetal vulnerability. Though relations of prenatal exposure to neurobehavioral abnormality have been reported, threshold effects and differential vulnerability have not been systematically sought. In a prospectively studied disadvantaged inner city black sample (n=389), periconceptional and antepartum fetal alcohol exposure was estimated from repeated maternal reports and the Bayley scales of infant development administered to offspring at age 1 year by examiners blinded to prenatal history. Consistent with previous studies, after control for potential confounders, higher levels of drinking at conception and during pregnancy were associated with poorer performance on the Bayley with no evidence of threshold. However, when 1 standard deviation below the sample mean was used as the criterion for poor performance, no effect was detectable below 14 oz of absolute alcohol per week (AA/W) (28 standard drinks/w) periconceptionally or 3.5 oz AA/W (7 drinks/w) during pregnancy. Using this criterion, neurobehavioral function was notably impaired in 30% of the higher exposed offspring, but not in the remaining 70%. These results suggest that, as with anatomic arbd, relationships of prenatal alcohol exposure to neurobehavioral abnormality may be characterized by a threshold above which there are marked individual differences in vulnerability to the effects of prenatal alcohol exposure.

248 ANEUPLOIDY IN SECOND TRIMESTER OLIGOHYDRAMNIOS
J. Manley M.D[X], L. Vought, M.S.[X], Stuart Weiner, M.D. Dept. of Maternal - Fetal Medicine, Pennsylvania Hospital, Philadelphia, PA
The diagnosis of oligohydramnios was made in 49 pregnancies in the second trimester between January, 1989 and August, 1991. In all patients, the diagnosis of membrane rupture and suspected twin-twin transfusion was ruled out. Oligohydramnios was suspected subjectively by the examiner, and the amniotic fluid index fell more than one standard deviation below the mean for gestational age. The mean AFI was 3.6. A genetic procedure was offered in all cases, and karyotype was obtained in 46 (94%). One patient declined and cultures failed to grow in two patients.
Aneuploidy was diagnosed in 11 (24%). There were four cases of triploidy, one XYY, two of autosomal trisomy, and four unbalanced translocations. Aneuploid fetuses had a mean AFI of 3.3 (range 0-6) and a mean gestational age at diagnosis of 20.7 weeks. Although ultrasound showed associated abnormalities (growth retardation, elevated head to body ratio, etc). in all but one fetus, the constellation of findings in each case was not specific for the type of aneuploidy. In addition some fetuses with structural abnormalities had normal karyotypes. Of those with normal karytotypes, 37% selectively terminated the pregnancy before viability. The mean AFI in this group was 3.7, and the mean gestational age was 21.2 weeks. Twelve of forty six (26%) survived; all had normal karyotypes, ten had normal ultrasound examinations, one had evidence of distal urinary tract obstruction, and one had multiple, large placental lucencies. the mean AFI was 5.3 and the mean gestational age at diagnosis was 22.5 weeks. This series suggests that not all cases of second trimester oligohydramnios are associated with poor outcome. However, the high incidence of aneuploidy suggests that a procedure for determining fetal karyotype should be offered to provide additional information for management of pregnancy.

249 **EARLY ALTERATIONS IN GAMMA AMINOBUTYRIC ACID (GABA) LEVELS IN FETAL ALCOHOL EXPOSED MICE.** C.S. Zajac[X]. Dept. of Ob/Gyn, Wayne State Univ., Detroit, MI.
Children with alcohol related birth defects (ARBD) exhibit sensory and behavioral deficits which may be associated with an inability to integrate and respond appropriately to external stimuli. There is also considerable behavioral evidence of developmental delay in central nervous system development in these children. The superior colliculus is a sensory integrative area of the brain which plays a major role in coordinating reflex responses to visual, auditory, vestibular and somesthetic input. Altered levels of the inhibitory neurotransmitter gamma aminobutyric acid (GABA) in the superior colliculus may contribute to the attentional and behavioral problems of children with (ARBD). Alterations in the developmental expression of GABA by prenatal alcohol exposure may affect an individual's capacity for dealing with excessive afferent input to the brain. Such individuals would be unable to screen out excess sensory stimuli and would exhibit sensory and behavioral deficits such as attention deficits. Using a fluorometric microassay of lyophilized brain tissues, levels of GABA were determined in the superior colliculus of Swiss Webster mouse fetuses (gestation day 15) which had been exposed prenatally to 3g/kg ethanol/day by gastric intubation. A nutritional control group was intubated with maltose dextrin solution isocaloric to the alcohol. Significantly higher levels of GABA were found in the superior colliculus of gestation day (GD) 15 mouse fetuses exposed to alcohol in utero when compared with control animals. Previous studies have shown increased neuronal nuclear density (i.e. increased number of neurons) in the same area of the brain in GD 18 mice. Since neurons are overproduced in normal development, and then decrease in number as normal synaptogenesis occurs, it is hypothesized that the increased level of GABA at GD 15 may reflect developmental delay as well. This may provide insight into possible pharmacologic amelioration of some of the problems of the fetal alcohol exposed child. (Supported by grant P50 AA07606 from NIAAA).

250 **EAR LENGTH IN SECOND TRIMESTER ANEUPLOID FETUSES.** Luanna Lettieri, John F. Rodis, James F.X. Egan, Anthony Vintzileos, Lori Feeney[X], Patricia Dellaripa[X], University of Connecticut Health Center, Farmington, CT
Abnormally small ears have been noted to be one of the most consistent clinical findings in patients with Down syndrome and other aneuploid conditions. We undertook a study to test the hypothesis that abnormally short ears are of diagnostic value in detecting second trimester aneuploid fetuses by ultrasound. We prospectively studied 326 consecutive patients undergoing ultrasound examination for genetic amniocentesis from 14-22 weeks gestation with singleton pregnancies from January - July 1991. The standard fetal biometry measurements were obtained, including ear length (from helix to the tip of the lobe). Of these patients, 87% (283) had ear measurements obtained and a nomogram for ear length by gestational age was compiled. The ear lengths of the remaining 13% (43) were not obtained due to unfavorable fetal position. The relationship between the ear length and gestational age was linear ($R=.7$, $p<.001$). Scattergrams were developed and regression analyses were used to establish the 5th, 10th, 20th, 50th, 80th, 90th and 95th percentile lines. Six fetuses were found to have a chromosomal abnormality: 4 had trisomy 21, one had trisomy 18 and one was a mosaic trisomy 21. All six aneuploid fetuses had ear lengths $\leq$ 20%ile for gestational age for a sensitivity of 100%. The specificity, positive and negative predictive values were 71% (196/277), 7% (6/87) and 100% (196/196), respectively. Using a cutoff of $\leq$ 10%ile for gestational age, the sensitivity was 67% (4/6) with a specificity of 82% (226/277). The positive and negative predictive values were 7% (4/55) and 99% (226/228), respectively. The trisomy 18 fetus had an ear length below the 1% for gestational age. We suggest that fetal ear length may be useful in sonographically identifying aneuploid fetuses in the second trimester.

251 **CONTINUUM OF GENOMICALLY ALTERED GROWTH IN MONOSOMY, DISOMY, & TRISOMY 21: OBSERVATIONS FROM THE FIRST PRENATALLY DIAGNOSED MONOSOMY 21.** Mark Paul Johnson[X], Philip Arbit[X], John Lusak[X], Faisal Qureshi[X], Nelson B. Isada, Peter G. Pryde[X], Mark I. Evans, Depts. OB/GYN & Pathology, Hutzel Hospital/Wayne State University, Detroit, MI.
We have previously investigated the differental patterns of organ-specific intrauterine growth retardation in trisomies 18, 21, and monosomy X. We showed that IUGR patterns are chromosome specific and established gravimetric indices for the major organ systems. Utilizing this approach, we have examined the first case of prenatally diagnosed monosomy 21, and observations raise the possibility of a numerically influenced growth potential for chromosome 21. Direct necropsy measurements of body and visceral weights from the 22 wks. gestation monosomy 21 fetus were compared to expected weights based on power equation body-wt. indices.

Organ	Monosomy 21	Disomy 21	Trisomy 21
adrenal	3.3 gms	1.25 gms	0.48 gms
brain	60.0	44.05	42.40
heart	3.5	2.09	1.36
kidney	10.0	2.42	1.45
liver	macerated	15.41	15.45
lung	4.80	4.45	3.96
thymus	macerated	0.46	0.06
body wt.	295.00	(460.00)	283.30

Overall body weight was decreased isecondary to the presence of caudal regression sequence with markedly shortened lower limbs. However, organ weights were much higher than expected which implies a more rapid growth rate in this fetus. When the three groups are compared, there appears to be a numeric-specific growth potential continuum, inversly based on the number of chromosome 21s present. Therefirem normal growth may be dependent on a disomic 21 state, while growth is depressed in trisomic states and accelerated in monosomic states. We believe this is the first demonstration of a possible relationship of chromosome number to fetal growth rates, and implies the presence of fetal growth regulatory systems associated with chromosome 21.

252 **ACE INHIBITOR FETOPATHY.** Peter G Pryde,* Clark E Nugent, Aileen B Sedman,* Mason Barr Jr.* Depts of Ob/Gyn, Pathology, and Pediatrics, University of Michigan Medical Center, Ann Arbor, MI and Dept Ob/Gyn, Division of Repro Genetics, Hutzel Hospital/Wayne State U, Detroit, MI.

The ACE-inhibitors (AI) are widely prescribed and effective antihypertensives, but are not without risk in pregnant women. Profound fetal toxicity has been reported in several animal models. Adverse human-fetal outcomes have also been reported. We describe a pattern of anomalies and physiologic alteration which can be termed AI fetopathy and report three additional infants in which this peculiar pattern is manifest (table).

Case	Maternal disease, medication	Gestation,mode of delivery, birth wt (%-ile)	Oligo	Neonatal hypoten-sion, anuria	Other
#1	26 y/o, 8 yr SLE, chronic HTN, on captopril	33 wk, fetal distress, induction, vaginal breech, 1440 g male (< 2.5%-ile)	severe	profound unremitting	Potters features, IUGR, PH, HC, RTD, death @ 14 hrs.
#2	15 y/o, 10 yrs HTN, on lisinopril	32 wks, fetal distress, cesarean section, 1480 g male (< 2.5%-ile)	severe	profound (improved only after dialysis)	IUGR, HC, RTD and ATN, persistant renal insuffiency, on dialysis, now 15 mo of age.
#3	30 y/o, 9 yrs chronic HTN, on enalopril	32 wks, fetal distress, cesarean section, 980 g male (< 2.5%-ile)	severe	profound (improved on dialysis)	IUGR, HC, short limbs, RTD, death @ 9 de of life (renal failure)

These cases combined with those previously reported indicate that AIs are fetotoxic. The peculiar pathophysiologic pattern cannot be ascribed to the underlying materna disease or other medications. AI fetopathy is characterized by fetal hypotension, anuria-oligohydramnios, growth-restriction (IUGR), hypocalvaria (HC), renal tubular dysplasia (RTD), and in the most severe cases pulmonary hypoplasia (PH). In surviving neonates profound hypotension and anuria are observed which are recalcitrant to volume replacement and pressor therapy. The hypotension resolves only after dialysing off the otherwise renally secreted drug. Although present data do not allow inference of frequency of AI fetopathy in exposed pregnancies, these drugs should be viewed as human fetotoxins and considered only as a last resort for use during pregnancy.

253 **FAMILIAL OMPHALOCELE (FO): CONSIDERATIONS IN GENETIC COUNSELING.** PG Pryde,* NB Isada, MP Johnson*, MI Evans, Dept OB/GYN, Hutzel Hosp/Wayne State Univ, Detroit, MI

Isolated, nonsyndromic omphalocele is generally regarded as a sporadic malformation. Recurrence risks (RR) are considered negligible. Our observations on a patient in whom five consecutive pregnancies (by 2 separate nonconsanguenous partners) were complicated by FO (see table) suggests a need to alter the standard counseling for RR. Neither the patient nor her partners had history of relatives affected by omphalocele although the patients brother and his son had very large umbilical hernias requiring surgical repair. Some cases of familial isolated omphalocele have been reported. Most pedigrees are suggestive of a vertical mode of transmision although there are a few cases with only a single generation involved. In no previously reported case was a complete generation, and so many members affected. It is problematic to speculate as to the genetic mechanism operating in this family.

Preg.#	Karyotype	Delivery	Outcome
1	not done	25 wks SVD	680 g F, omph, death @ 24 h
2	46,xx	16 wks SAb	ultrasound confirmation omph prior to Ab
3	not done	29 wks labor, classical CS	1500g M, omph, repair, death @ 5 mo
4	not done	30 wks labor, LTCS (repeat)	1590 g M, omph, repair, death@ 24h
5	46,xx	30+ wks labor,LTCS (repeat	1650 g F, omph, repair, death@ 24 h

Abbreviations: omph= isolated omphalocele, M= male, F= female, SAb= spontaneous abortion, LTCS= low transverse cesarean section, SVD= spontaneous vaginal delivery

Because the defect occurred with two separate fathers a monogenic autosomal recessive mechanism is unlikely. However, the finding of a large umbilical hernia in the patient's brother and his son, makes an autosomal dominant mechanism with variable expressivity a tenable explanation. A polygenic-multifactorial mechanism which might be suggested as an alternative explanation is not satisfying in light of the 100% transmission through 5 siblings. With present data and diagnostic limitations the true mechanism operating cannot be elucidated. Undoubtedly it is largely genetic. These cases emphasize omphalocele heterogeneity and caution in counseling RR.

254 **DETERMINANTS FOR PARENTAL DECISION TO ABORT (DTA) OR CONTINUE FOR NON-ANEUPLOID ULTRASOUND DETECTED ABNORMALTIES.** PG Pryde,* AE Odgers,* NB Isada, MP Johnson, MI Evans. Dept OB/GYN, Reprod. Genetics, Hutzel Hospital/Wayne State U, Detroit, MI.

Decision to abort an otherwise wanted pregnancy because of fetal anomalies is complex. This study evaluates DTA after finding malformations on ultrasound in the karyotypically normal fetus. All pregnancies managed on our service complicated by ultrasound abnormalities from 4/90-8/91 were included (n=262). Cases with associated karyotypic abnormalities (KA) were excluded (n=35) as were cases in which a diagnosis was made after the legal gestational age (GA) limit for abortion (24 wks, n=65). The remaining 159 cases were stratified into prognosis groups of severe, uncertain, and mild. Data were analyzed using ANOVA with decision to continue (C) or terminate (T) as the dependent variable. **Results:** Mothers age, gravity, parity, and gestational age at diagnosis were not significantly different between groups. Severity of the ultrasound abnormality was strongly correlated with DTA (p=.0001).

	Mild	Uncertain	Severe	Totals
T	2.8%	11.1%	65.6%	30.2%
C	97.1%	88.9%	34..4%	69.8%
Total	100%	100%	100%	100%

Conclusions: 1. In non-aneuploid pregnancies with ultrasound diagnosis of fetal abnormality, the major predictor of DTA is severity of prognosis. 2. Contrary to previous assertions by other authors, but in agreement with our previous study in KA fetuses, the GA at the time of diagnosis is not an important variable in DTA. 3. Contrary to widely held opinion, most parents having fetuses with significant anomalies which carry uncertain prognoses opted to continue pregnancy. This was particularly true for defects potentially correctable by in-utero intervention (eg. bladder shunt, data not shown).

255 **ANTENATAL DIAGNOSIS USING AMPLIFICATION OF FETAL DNA FROM MATERNAL BLOOD.**

C. Chambers[x], A. Eyre[x], K. Ward, Dept Ob/Gyn, University of Utah School of Medicine, Salt Lake City, UT

To determine the practicality of testing fetal cells present in the maternal circulation for genetic diagnosis, a model testing for the Y chromosome was selected. 50 maternal blood samples were obtained from gestations ranging from 6 weeks to term. DNA was extracted from the samples. The polymerase chain reaction was used to search for Y-specific sequences (of fetal origin) using either nested primers (Lo et al, *Lancet* 1990) which detect a single copy region or primers to Y alphoid repeats (Witt et al., *Hum Genet* 1989). Results were compared to the neonatal sex recorded at delivery . Sensitivity (ability to correctly identify male fetuses) was 80-100%, increasing with each successive trimester of pregnancy. Specificity varied from 20-92% depending on the primer set and the assay conditions. False positives occurred predominantly with samples from multiparous patients who had previously delivered a male child. This model suggests that amplification of paternal specific markers from maternal blood could reduce the need for invasive diagnostic procedures in order to perform DNA testing, especially in nulliparous gestations.

256 **ASSESSMENT OF THE INFLUENCE OF CHERNOBYL ON BIRTH DEFECTS AND ABORTION RATES IN AUSTRIA.**

[X]M.C.H. Haeusler, [X]A. Berghold, [X]M. Schaffer, [X]W. Schoell.
Dept. of OB/GYN, Karl-Franzens University & Joanneum Research, Graz, Austria

The teratogenic potential of low dose radiation is difficult to determine. The purpose of this study was to assess whether measured radioactive fallout (predominantly I^{131} or Cs^{137}) following the Chernobyl disaster in April 1986 altered the rate, pattern or regional distribution of birth defects (BD) or abortion rates in southern Austria. The Styrian malformation register (SMR) was set up as a population-based regional multi-source system whereas the existing government register still relies on one source and therefore provides poor ascertainment especially in cases of internal defects (overall BD rates: 2.3% vs 1%). Over a period of 5 years (1985-89) the SMR monitored 66,740 total births. 64 sources provided data on 1695 cases of BD, of which 1617 were suitable for analysis. All cases were analysed in terms of their calculated conception date and coded (ICD9) and divided into 3 main groups, based on their vulnerable phase of embryogenesis: Group I (n=157): cyclopy, NTD, esophageal atresia, etc. Group II (n=630): CHD, facial clefting, diaphragmatic hernia, syndactyly, etc. Group III (n=133): de novo chromosomal anomalies. In group III the vulnerable time of spermato- and oogenesis was considered. To study possible regional clustering, the pre- and post-Chernobyl rates were plotted in 17 subdistricts. No significant changes in incidence or regional distribution of BD were observed, but a baseline BD rate has been established for future surveillance.

To study other possible effects of the disaster, the overall abortion rate and the counselling frequency at termination clinics for periods of 1.5 years before and after the event were compared. All Styrian pathology departments provided data on 7775 abortions (16% of 48,017 total births). The abortion rate and the counselling frequency was not been altered significantly following the disaster.

257 **UNEXPLAINED ELEVATED SECOND TRIMESTER MATERNAL SERUM ALPHA FETOPROTEIN: A MARKER FOR LOW BIRTH WEIGHT.**

M. Maberry,[X], R. Stettler[X], K. Moore[X], B. Dowdy[X], R. Putnam[X], K. Leveno, L. Gilstrap, Dept Ob/Gyn, University of Texas Southwestern Medical Center, Dallas, Texas.

The association between elevated maternal serum alpha fetoprotein (MSAFP) values and fetal anomalies, multiple gestations and intrauterine demises has been well described. However, the significance of unexplained elevated MSAFP values remains unclear as does the appropriate subsequent pregnancy management for these women. The purpose of our study was to prospectively follow those women with unexplained elevated MSAFP values throughout their pregnancies. From the beginning of our MSAFP screening program in March 1988 until February 1991, 12,530 women in our single center, indigent population underwent MSAFP sampling between 15 and 19 weeks of gestation. Of these women, 259 had elevated MSAFP values (greater than or equal to 2.5 MoM). 51 women (19%) had unexplained elevated MSAFP values after repeat blood sampling and high resolution ultrasound, with or without amniocentesis for amniotic fluid AFP, acetylcholinesterase, and fetal karyotype. These women were subsequently followed with frequent clinic visits and serial ultrasound examinations for fetal growth. There were two spontaneous abortions and 49 live born infants, 13 (27%) of which were low birth weight (less than 2500 grams). This differs significantly from the rate in our general obstetric population (10%, $P<0.001$) during this time. We conclude that in our population, unexplained elevated MSAFP values are associated with an increased incidence of low birth weight infants, the cause of which remains unclear.

258 ABNORMAL SECOND TRIMESTER ULTRASOUNDS ARE ASSOCIATED WITH KARYOTYPIC ABNORMALITIES.

MP Dombrowski, SM Berry, NB Isada, MI Evans, Dept of Ob/Gyn, Hutzel Hosp./Wayne State Univ., Detroit MI

Anecdotally, it is evident that fetal aneuploidy is associated with abnormalities of amniotic fluid volume (AFV) and fetal structural anomalies, however, the risks have not been determined. We reviewed prospectively collected data from 2822 second trimester ultrasounds and karyotypes in a high-risk, referral population. Abnormal AFVs were diagnosed by subjective and objective criteria. The index-risk sample included gravidas <35y with structurally normal fetuses and normal AFV. Odds ratios and 95% confidence limits (CL) for abnormal karyotypes among structurally normal fetuses with abnormal AFV are listed below:

Decreased AFV	4 of 63	5.0 (CL 1.7 to 15.2)
Oligohydramnios	0 of 28	
Decreased + Oligo	4 of 91	3.4 (CL 1.1 to 10.2)
Increased AFV	3 of 26	9.7 (CL 2.7 to 35.0)
Polyhydramnios	1 of 17	4.6 (CL 0.6 to 36.8)
Increased + Poly	4 of 43	7.6 (CL 2.5 to 23.4)

The risk of abnormal karyotype was greater among all cases of abnormal AFV (8 of 134) than age >35y (16 of 1027); 4.0 (CL 1.7 to 9.6). Structurally abnormal fetuses with normal AFV were at markedly increased risk for abnormal karyotypes (16 of 116); 11.9 (CL 5.9 to 23.7). We conclude: 1) 2nd trimester abnormalities of AFV, whether increased or decreased, have a significantly increased risk of abnormal karyotypes, 2) such patients should be offered karyotypes, 3) structural anomalies, even with NAFV, are associated with a markedly increased risk of abnormal karyotype.

259 **AMNIOTIC FLUID ACETYLCHOLINESTERASE (ACHE) IS FOUND WITH GASTROSCHISIS BUT NOT OMPHALOCELE.**

AA Saleh, NB Isada, MP Johnson[X], RJ Sokol, MP Dombrowski, MI Evans, Center for Fetal Diagnosis & Therapy, Dept Ob/Gyn, Wayne State University/Hutzel Hospital, Detroit, MI

Amniotic fluid ACHE has been used to assist in the evaluation of neural tube defects. It has also been detected in ventral wall defects. We examined amniotic fluid ACHE in 24 pregnancies, 16 complicated by gastroschisis and 8 by omphalocele. One omphalocele was ruptured antenatally and was excluded. In 22 out of 23 cases, a normal karyotype was found; one omphalocele had trisomy 13. ACHE was measured by polyacrylamide gel electrophoresis as previously reported and results reported as positive, suspicious, or negative. Results shown below were analyzed by chi-square.

ACHE	Omphalocele	Gastroschisis
Positive	0	12
Negative	7	0
Suspicious	0	4

$\chi^2=.0001$

All omphaloceles were negative for ACHE, while all gastroschises were positive or suspicious. We conclude that a positive or suspicious ACHE is highly associated with gastroschisis or a ruptured omphalocele, but not with an intact omphalocele. Such findings are consistent with the differing origins of the defects and may be used in the differential diagnosis.

260 **SIGNIFICANCE OF AMNIOTIC FLUID PLATELET FACTOR 4 AND BETA-THROMBOGLOBULIN IN GENETIC AMNIOCENTESIS.** AA Saleh, NB Isada, MP Johnson, MI Evans, T Ozawa, MP Dombrowski, M Treadwell, EF Mammen, Dept Ob/Gyn, and Center for Fetal Diagnosis and Therapy, Hutzel HospitalWayne State University, Detroit, MI.

Platelet factor 4 (PF4) and betathromboglobulin (BTG), unique markers of irreversible platelet activation, have not been evaluated in amniotic fluid. While PF4 is mainly cleared by endothelium and to a lesser extent by kidneys, BTG is only cleared by kidneys. Therefore, amniotic fluid PF4 and BTG levels may reflect fetal platelet activation, endothelial and/or renal function. We measured PF4 and BTG by ELISA in amniotic fluid from 78 patients with normal α-fetoprotein (AFP) and 24 with high AFP (anencephaly 5, gastroschisis 5, fetal demise 8, cystic hygroma 1, placental hematoma 1, hydrocephalus 4). All pregnancies ranged from 15-20 weeks gestation. Results are shown below (mean ± SD). Mann-Whitney U test was used.

AFP:	Normal (n-78)	Abnormal (n=24)	Significance
Gestation (wks)	17.5 ± 1.7	18 ± 1.7	N.S.
PF4 (IU/ml)	1.3 ± 2.3	4.6 ± 10	p<0.001
BTG (IU/ml)	18.2 ± 13.8	30 ± 26.5	p<0.001

PF4 and BTG correlated significantly with AFP (expressed as MOM) only in the abnormal group (p<C.05, p<0.0001 respectively). We conclude 1) amniotic fluid PF4 and BTG are measurable in second trimester amniotic fluid, 2) are elevated in malformations where structural defects allow direct access to amniotic fluid or diffusion across simple membranes, and 3) may reflect underlying fetal pathology which activates platelets.

261 **FREQUENCY OF CONFINED PLACENTAL MOSAICISM IN PREGNANCIES WITH INTRAUTERINE GROWTH RETARDATION.** L. Wilkins-Haug, M.F. Greene, D.J. Roberts[X], C.C. Morton[X], Depts of Ob/Gyn and Pathology, Brigham and Women's Hospital, Harvard Medical School

Confined placental mosaicism (CPM) occurs in conjunction with a karyotypically normal fetus in 2-3% of chorionic villus samples. An increased rate of intrauterine growth retardation (IUGR) has been reported in these pregnancies. Among third trimester pregnancies complicated by IUGR, however, the frequency and clinical characteristics of CPM are unknown. We report karyotype analyses of amnion, chorion, villi and cord blood from 12 pregnancies with IUGR (birth weight <10%). In two cases, mosaicism was detected in all placental lines: 46,XX/48,XX,+17,+21 (55%/45%) and 46,XX/92,XXXX (66%/34%). The aneuploid line was confirmed in uncultured amnion preparations utilizing fluorescent in situ hybridization with an alpha satellite probe specific to chromosome 17. In a third case, a 46,XX/92,XXXX (75%/25%) mosaicism was confined to the amnion. In all cases, cord blood karyotypes were normal. Comparison of the ultrasound findings, perinatal complications and placental pathology from these cases provides a preliminary clinical description of the IUGR fetus with placental mosaicism. We conclude that CPM occurs with greater frequency among pregnancies with IUGR. Attempts to identify additional cases and to delineate further the associated clinical characteristics are ongoing.

262 THE EFFECTS OF ETHANOL ON LINOLEIC ACID INCORPORATION AND METABOLISM BY HUMAN PLACENTAL TISSUE IN VITRO. E. Kirk,[X] P. Ogburn, R. Holman,[X] J. Miles,[X] Dept. OB/GYN & Internal Medicine, Mayo Clinic & Hormel Institute, Rochester & Austin, MN

The teratogenic effects of ethanol (ETOH) may involve alterations in essential fatty acid metabolism. To study this, [1-^{14}C] linoleic acid (LA) was added to human placental tissue in DMEM media (n=7) exposed to 95% oxygen at 37° in a shaking incubator with varying concentrations of alcohol from 0-200 mg/dL. Samples of tissue and media were removed and analyzed at intervals over 24 hrs. We found significant uptake of LA into placental tissue (47.8% + 4.8% p<.01) at 12 hrs. ETOH did not significantly affect this uptake. After 12 hrs. incubation the conversion of LA to intermediate fatty acids leading to arachidonic acid decreased by more than 40% at even the lowest ETOH concentrations. This decrease was significant (p<.05) at ETOH concentrations of 100 & 200 mg/dL. Our work supports evidence of deranged LA metabolism secondary to ETOH in placental tissue in vitro.

263 **FREE BETA HCG IN DOWN SYNDROME SCREENING.** J. Larsen, K. Garver,[X] S. Frank,[X] J. Macri,[X] Dept. OB/GYN, George Washington Univ. Med. Ctr., Washington, D.C., Dept. Medical Genetics, Western Pennsylvania Hosp., Pittsburgh, PA, NTD Laboratories, Inc., Carle Place, NY.

Recent reports have demonstrated enhanced detection efficiency in Down syndrome screening using Free Beta hCG, especially in early weeks of gestation (<17 weeks). We have collaborated in a blind study using samples collected at a single center and maintained at -20°C. AFP and Free Beta were measured in a single laboratory utilizing in-house ELISA technology. Patient-specific risks were calculated using linear multivariate discriminant analysis. The normative data set for both MSAFP and Free Beta was established on 2,900 pregnancy samples, all of which were: under 35 years of age, between gestational weeks 14-22, non-diabetic, singleton, white pregnancies. The blind study set consisted of 50 patient samples, 42 of which were normal outcomes and 8 confirmed cases of trisomy 21. The blind study set consisted of 12 patients at or above 35 and 38 patients under 35 years of age. Nine cases fell below 17 weeks of gestation and 41 at or above. Of the 8 cases of Down syndrome, 6 (75%) demonstrated significantly increased risk and were thus correctly identified. In 4 cases where pregnancy outcome was normal, biochemical results indicated an increased risk for Down syndrome. In 3 of these cases, maternal age was greater than 35. We conclude that this is further confirmation of the usefulness of Free Beta hCG as a marker in Down syndrome screening.

264 EMBRYOSCOPIC OBSERVATIONS OF THE YOLK SAC

Mark T. Cullen MD, John Whetham M.D, EA Reece MD, Luis Sanchez-Ramos M.D University of Florida , Jacksonville and Yale University, New Haven,CT.

Abnormalities of the secondary yolk sac have been associated with fetal malformations and death. To evaluate the appearance of the secondary yolk sac in normal and abnormal pregnancies, transcervical embryoscopy was performed on 220 pregnant women prior to termination of pregnancy. Gestational ages ranged from 7-13 menstrual weeks. The embryoscopic technique has previously been reported. Transvaginal ultrasound was performed prior to the termination. There were 8 fetal anomalies diagnosed by ultrasound that were included in the study, 4 of which had an aneuploidy. The where 4 additional aneuploid fetuses without an anomaly that underwent examination. The normal appearance of the secondary yolk sac in the first trimester is that of a highly vascular sphere, attached to the vitelline vessels. There were 3 yolk sac abnormalities noted in this study. An enlarged poorly vascular yolk sac was seen in a hydropic fetus at 9 weeks with an unbalanced translocation. In 2 cases where the fetus appeared normal a bilobed yolk sac was seen. **Conclusion**: Yolk sac abnormalities occur in normal and abnormal conceptuses and are not associated with most fetal anomalies.

265 THE USE OF NUCHAL SKIN FOLD MEASUREMENT IN SCREENING FOR CHROMOSOME ABNORMALITIES IN A HIGH RISK POPULATION

WJ Watson, RC Miller, NC Chescheir, MK Menard, WF Hansen, VL Katz. Dept. OB/GYN, UNC School of Medicine, Chapel Hill, NC.

The nuchal skin fold measurement is abnormal in more than 50% of fetuses with Down syndrome, but is not well investigated in other chromosome abnormalities. We prospectively measured the nuchal skin fold prior to amniocentesis in 800 fetuses at risk for chromosome abnormalities. The measurment could not be obtained because of fetal position or maternal obesity in 6.9%. Nuchal thickness was increased (>5mm) in 2.4% of normal fetuses. Thirty two abnormal karyotypes were identified, 7 of which were balanced familial translocations or inversions. A sonographic abnormality, nuchal thickness (NT) and/or dysmorphology (D), was found in 48% of the significant abnormal karyotypes. The positive predictive value of isolated fetal nuchal skin thickness for a significant abnormal karyotype was 12%.

Karyotype	N	D	NT	D+NT
Trisomy 21	9	1	3	2
Trisomy 18	3	2	0	1
Sex	7	0	0	0
Structural	5	2	0	0
Triploidy	1	0	0	1
Familial	7	0	0	0

Conclusion: High resolution ultrasound may identify nearly 50% of fetuses with significant chromosome abnormalities. Nuchal skin measurement does not appear to help identify fetuses with abnormal karyotypes other than Down syndrome.

266 HOW MUCH IS TOO MUCH NUCHAL MEMBRANE IN THE FIRST TRIMESTER?

Anthony Johnson, Patti Morgan[X], Shauna Heeger[X], Kimberly A. Klush[X], Ronald J. Wapner, Jefferson Medical College, Philadelphia, PA.

Given the strong association between aneuploidy and cystic hygroma in the first trimester we sought to determine if a similar relationship exists between fetal karyotype and the depth of the nuchal membrane thickness (NMT). In a prospective series of 827 consecutive viable singleton pregnancies with a risk of fetal aneuploidy ≥ a maternal age of 35 years, an attempt was made to obtain the NMT prior to chorionic villous sampling (CVS) performed at 9-12 weeks gestation. NMT was measured transabdominally with the fetus in the sagittal plane using the maximum distance from the outer cervical spine to the inner margin of the skin. Fetal position permitted NMT measurements in 242 cases (29.2%). Cytogenetic results were available in all cases, with 24 (2.9%) abnormalities identified. In normal fetuses with NMT measurements there were 230 normal results and 12 (5%) aneuploids. Excluding NMT findings, all fetuses included in the analysis were felt to be anatomically normal at the time of CVS. Linear regression failed to demonstrate a clinically significant difference in NMT range between 9 and 12 weeks in the normal fetuses, $r^2 = 0.032$.

NMT (mm)	≥2.0	≥2.5	≥3.0
sensitivity	81.8%	81.8%	63.6%
specificity	78.3%	90.4%	97%
+PPV	15.3%	29%	50%
-PPV	98.9%	98.9%	98.2%

Logistic regression confirmed a strong relation between NMT and fetal aneuploidy such that for each 1mm increase in NMT the relative risk of an affected fetus was increased by 4.67 (95% CI: 2.29-9.48, p<0.0001) We conclude that the presence of fetal NMT ≥ 2.0 mm in a first trimester pregnancy with a risk of fetal aneuploidy ≥ a maternal age of 35 years is highly predictive of a cytogenetic abnormality and warrants genetic counseling and possible prenatal diagnosis.

267 PRENATAL ALCOHOL EXPOSURE REDUCES AMNIOTIC FLUID LEVELS OF α-FETOPROTEIN IN RATS.

J. Hannigan[X], C. Flood[X], J. DiCerbo[X], G. Mizejewski[X]. Fetal Alcohol Research Center, Dept. of Ob/Gyn, Wayne State University School of Medicine, Detroit, MI and Wadsworth Laboratories, New York State Department of Health, Albany, NY.

Disruption of humoral neuro-regulatory factors is one possible mechanism of alcohol teratogenesis. In a study of pregnant alcoholics, Halmesmaki, et al (1987) predicted fetal alcohol syndrome (FAS) in 59% of cases, using maternal serum α-fetoprotein (AFP) as a marker. We tested the impact of prenatal alcohol on amniotic fluid AFP levels in rats. Alcohol (12.5 g/kg/day) was fed to dams from gestation day 6 to 20, when amniotic fluid was collected. Alcohol concentrations on this day were 120 mg/dl in maternal blood and 159 mg/dl in amniotic fluid. The alcohol-exposed litters had significantly lower amniotic fluid AFP levels than control groups. Alcohol-exposed fetuses weighed less and had larger placentae than control litters. Within the alcohol-exposed litters, there was a small negative correlation between amniotic fluid AFP and alcohol levels. Finally, alcohol-induced reductions in amniotic fluid levels of AFP were greater in male than in female fetuses. The results suggest that prenatal alcohol exposure reduces amniotic fluid AFP levels in a dose-dependent manner. Decreased availability of α-fetoprotein may contribute to alcohol-induced alterations in fetal maturation. SUPPORTED IN PART BY RSD AWARD No. 00111 FROM NIAAA.

268 **FETAL INTRACARDIAC KCL WITH SECOND TRIMESTER PREGNANCY TERMINATION: A METHOD TO AVOID THE HOPELESS RESUSCITATION OF THE NONVIABLE, ABNORMAL ABORTUS.** NB Isada, JC Fletcher, MP Johnson, WB Blessed, MI Evans. Division of Reproductive Genetics, Dept Ob/Gyn, Hutzel Hosp/WSU, Detroit, Mi and The Center for Biomedical Ethics, Dept Medicine, U Virginia, Charlottesville, Va.

Genetic and obstetric ultrasound services often reveal anomalous fetuses which, after counseling, parents choose to terminate. However, an increasing number of centers will not perform pregnancy terminations after 20 wks, in part because of the chance of obtaining a "live born" neonate. In a few cases, 2nd trimester abortion has resulted in the birth of a neonate with signs of life, even with utilization of intraamniotic urea. Pediatricians are put in an impossible position and may feel obligated to attempt full resuscitative efforts. Because this has happened in our institution, we have introduced fetal intracardiac potassium chloride (KCl) as a routine adjunctive procedure based on our experience with this method in multifetal pregnancy reductions. Under ultrasound guidance, a 22-gauge needle is directed into the fetal cardiac chambers. Proper placement is verified by blood return. Three to five cc of KCl (2 meq/ml) is instilled. Cessation of cardiac motion is verified with M-mode scanning. This approach was successful in causing rapid fetal cardiac arrest in 14 out of 15 cases. A decision to use intracardiac KCl avoids some of the ethical and legal quagmires that arise when the abnormal abortus-newborn has signs of life, and can be readily introduced into programs where invasive perinatal procedures are performed.

269 **NEUROTOXIC EFFECTS OF LEAD ON HYPOTHALAMIC DOPAMINERGIC NEURONS.** S. Ramin, W. Kedzierski,[X] J. Porter,[X] Dept. Ob/Gyn, Univ. Texas Southwestern Med. Ctr., Dallas, [X]

We investigated the neurotoxic effects of lead in primary cultures of hypothalamic cells from 18 to 22 day gestation Long-Evans rat fetuses. Two week old cell cultures were treated with various levels of lead nitrate for 24 h. Then, the medium was collected, acidified, and assayed for dopamine (DA) and dihydroxyphenylalanine (DOPA) by HPLC with electro-chemical detection. DOPA secretion is summarized below:

Lead	DOPA (pmol/well/24 h)		
Conc.	18 Days	20 Days	22 Days
Control	17.2±1.5	32.4±1.9	36.2±2.7
$1x10^{-10}M$	8.5±0.4	15.7±1.0	30.7±0.9
$1x10^{-9}M$	9.3±0.3	25.3±1.5	31.8±0.6
$1x10^{-8}M$	10.6±0.6	22.6±0.8	30.2±1.0
$1x10^{-7}M$	10.0±0.3	22.7±0.6	36.8±3.0
$1x10^{-6}M$	10.7±0.4	24.8±1.2	36.5±2.2
$1x10^{-5}M$	10.1±1.0	28.8±0.7	38.9±0.6
$1x10^{-4}M$	19.3±0.7	39.1±1.7	50.1±1.1
$1x10^{-3}M$	22.8±0.4	42.9±1.0	54.4±2.4

n=3-5

DA secretion follows the same pattern. At low levels of lead, DOPA and DA secretion are inhibited, whereas at high levels DOPA and DA secretion are stimulated. However, the inhibition with lead is more pronounced on cells from younger fetuses than it is from older fetuses. Conversely, the stimulation with lead is more pronounced on cells from older fetuses than it is from younger fetuses. The same pattern is seen with long term (two weeks) exposure of cultured cells to lead nitrate. These data suggest that the neurotoxic effects of lead may depend in part on the age of the fetus at the time of exposure.

270 **METHAMPHETAMINE USE DURING PREGNANCY IN A LARGE URBAN POPULATION.** S.M. Ramin, M.D., B.B. Little, Ph.D.,[-] K.J. Trimmer, M.D., D.I. Standard, B.S.,[+] C.A. Blakely, Ph.D.,[+] & L.M. Snell, M.P.H.[+] Depts. of Ob/Gyn & Fam. Prac. & Comm. Med., The Univ. of Texas Southwestern Med. Ctr., Dallas, Tx., PPRL, Texas A & M, College Station, Tx.

A paucity of information exists on effects of methamphetamine (MA) use during pregnancy and fetal outcome. Umbilical cord blood was collected from 863 consecutive births at two large urban public hospitals serving a primarily indigent population. Radioimmunoassay was used to test for the presence of MA. Medical record information was linked to serological analyses. Patients positive for other drugs (opiates, cocaine, alcohol, toluene) were excluded. Results are summarized below.

	MA (n=48)		Control (n=519)		
	Mean	SE	Mean	SE	P
Birth weight (gm)	3173	69	3327	18	0.03
Birth length (cm)	49.4	0.4	49.3	0.1	NS
Head circumference (cm)	33.7	0.3	33.8	0.1	NS
Apgar: 1 minute	8.4	0.1	8.6	0.1	NS
5 minute	8.8	0.1	8.9	0.1	NS
EGA (weeks)	38.6	0.3	38.8	0.1	NS
	N	%	N	%	
Major anomalies	2	4	27	4	NS
Minor anomalies	1	2	42	6	NS

These results are similar to those previously published for MA use during pregnancy by self-reported history. Although a reduction in birth weight was found in the MA group, the frequency of congenital anomalies was not increased compared to the control group.

271 **APPLICATION OF MOLECULAR CYTOGENETICS TO UNCULTURED FIRST TRIMESTER CHORIONIC VILLI.** K. Blakemore, G. Prabhakar,* G. Stetten,* R. Giraldez,* F. Marcus,* W. Chen.* The Johns Hopkins University School of Medicine, Baltimore, MD.

The clinical utility of fluorescent chromosome-specific centromere probes has been shown on interphase amniocytes and blood cells. We describe a method for use of these DNA probes on interphase nuclei from a solid tissue, chorionic villi. "Direct" preparations of uncultured villus cells were made by the method of Simoni et al. (1983), with and without 24 hr incubation, Colcemid exposure, and heat drying of slides. Fluorescence in situ hybridization was performed by the method of Pinkel et al. (1986) with minor modification. 20 ng of biotinylated probe DYZ3, DXZ1 or D9Z1 (ONCOR, Inc.) was added to a hybridization mixture (60% formamide/2X SSC), 10 μl of which was applied to each slide followed by heat denaturation (80°C for 5 min). Slides were incubated overnight at 42°C, and washed (60% formamide/2X SSC at room temp). The probe was detected with FITC conjugated avidin. Preparations were counterstained with propidium iodide (0.4 μg/ml) and examined using a Zeiss epifluoresce microscope. A clearer signal was obtained when slides were air dried. Omitting the 24 hr incubation and Colcemid exposure of the villi did not alter signal quality. Three cases illustrate the utility of this method: Case 1, at risk for the fragile X syndrome, to rapidly determine fetal sex; Case 2, a blighted ovum in a patient with two previous conceptuses, to demonstrate yet another recurrence; and Case 3, in which mosaicism for trisomy 9 was found on routine cytogenetic analysis of cultured villi, to examine the proportion of abnormal cells in direct villus metephases and interphase nuclei. Fluorescence in situ hybridization is a valuable new tool for rapid identification of fetal sex chromosomes and specific trisomies in prenatal diagnosis. First trimester results are possible using cell preparations made from chorionic villus tissue.

272 **ELEVATED MSAFP, PLACENTAL ABNORMALITIES, AND PRETERM DELIVERY.** **MA Williams,[X] DE Hickok, R Zingheim,[X] DA Luthy, J Kimmelman,[X] DA Nyberg,[X] BS Mahony,[X] Swedish Hosp. Med. Ctr. and University of Washington, Seattle WA**

Unexplained elevated MSAFP in the midtrimester is associated with placental abnormalities and adverse pregnancy outcomes. We assessed the association between unexplained elevated MSAFP and placental abnormalities in relation to infant outcomes in a hospital-based cohort study. Women with elevated MSAFP (N=188) had 4 times the risk of delivering a preterm infant than women with normal MSAFP (N=202)(95% CI 2.1-8.0).

GROUPS	N	% Preterm	RR (95%CI)
Normal MSAFP, Normal placenta	184	4.9	1.0
Elevated MSAFP only	149	17.5	3.6 (1.7-7.4)
Elevated MSAFP, Abnormal placenta	33	33.3	6.8 (3.1-15.2)

Women with both elevated MSAFP and abnormal placental findings were 6.8 times more likely to deliver a preterm infant than women with normal MSAFP levels and sonograms (95%CI 3.1-15.2). Elevated MSAFP was associated with a shortening of mean gestation length by 1.4 weeks (95%CI 0.6-2.0). A joint history of elevated MSAFP and placental abnormalities was associated with a greater decrease in the mean gestation by 2.8 weeks (95%CI 1.8-3.9). These findings suggest that elevated MSAFP and placental abnormalities are associated with particularly poor outcome. Careful examination for placental abnormalities should be a part of the evaluation of elevated MSAFP.

273 **ALPHAFETOPROTEIN IN DIABETIC PREGNANCY-A REASSESSMENT.** Tessie Tharakan*,Laxmi Baxi,Douglas Kramer*,Rosamond Anderson*,College of Physicians & Surgeons,Columbia University & Columbia Presbyterian Medical Center,New York,NY

We correlated glycosylated hemoglobin (HbA1) with Maternal Serum Alphafetoprotein (MSAFP) corrected for gestational age,race and maternal weight in 90, and amniotic fluid AFP (AFAFP) in 30, diabetic pregnancies.

Patient Groups	Time of HbA1 meas.	n	Corr.Coef. HbA1:MSAFP	P
1	in first 12 wks	22	0.06	ns
2	within 0-6 wks. before MSAFP	42	0.11	ns
3	within 6 wks after MSAFP	34	0.18	ns

There was no reduction in MSAFP with increasing HbA1 values. Even in patients with HbA1 exceeding 9 gm% (n=9) mean MSAFP was 0.84MOM(SD± 0.29) as compared to 0.85MOM(SD±0.23) in those with HbA1 from 5 to 8.9 gm%. It has been hypothesised that poor glycemic control may lead to decreased production of AFP by the yolk sac and /or the fetal liver. If so we would expect decreased AFAFP. We measured AFAFP in 30 pregnancies with HbA1 from 4.5 to 16% early in pregnancy, and under 7.5% (except 2 patients) at the time of amniocentesis. AFAFP values even in patients with HbA1 ⩾9%(n=3) were within normal limits. Thus,given these limited data, it appears that degree of control of blood sugar had no influence on fetal AFP production as indicated by AFAFP levels. If the levels of MSAFP in patients with poor glycemic control are low,this is probably not due to decreased fetal AFP production, but may perhaps be due to increased glycosylation of this protein causing increased catabolism. In conclusion,in this series of pregnancies with fairly well controlled diabetes,we observed normal values of AFAFP and MSAFP(mean 0.84 MOM) even when HbA1 exceeded 9%.

274 KARYOTYPE ANOMALIES IN FETUSES WITH URINARY TRACT ANOMALIES. S Sutherland*, J Iams, B Goodwin*, J Moore*, J Westman*, M Motley*, E Diss*, M Landon, R O'Shaughnessy, R Reiss, and S Gabbe. The Ohio State University Department of Obstetrics & Gynecology, and The Departments of Pediatrics and Cytogenetics Laboratory, Children's Hospital, Columbus, OH

The prevalence of abnormal karyotypes among fetuses with ultrasonographically detected urinary tract abnormalities is reported to range from 1 to 28%. The data available to guide clinical care is remarkably limited, however. We reviewed the clinical and ultrasound findings from 60 pregnancies in which a fetal urinary tract anomaly was detected antenatally. Among 33 in whom pre- or postnatal karyotype analysis was performed, there were five (15%) fetuses with abnormal karyotypes, two of whom had no extrarenal anomalies seen with ultrasound. Ten of 16 with uni- or bilateral cystic kidneys had a karyotype performed, and two had an abnormal karyotype: A fetus with trisomy 18 had oligohydramnios, a unilateral cystic kidney, and IUGR, and died *in utero*. One with 46, XX del (11)(q24.2) had absent amniotic fluid, bilateral renal cysts, and was aborted. Eight others with unilateral (6) or bilateral (2) cystic kidneys had normal karyotypes. Eight cases of megacystis were studied, and three of seven (43%) fetuses tested had abnormal karyotypes: one with a 46, XY/47,XXY karyotype and absent amniotic fluid was electively aborted; another with a cystic hygroma, megacystis, and normal fluid had an unbalanced translocation {46 XY, -12, +der(12) t(4;12)(q28;p13.3)}; a third with a balanced translocation [46,X,t(X:22)(q26;q11.1)mat] and oligohydramnios died in the neonatal period of pulmonary hypoplasia. Eleven of 19 fetuses (9 of 13 bilateral and 2 of 6 unilateral) with hydronephrosis had a karyotype done; all were normal. Eight of 17 with renal agenesis or dysplasia had studies done, and all were normal. Women presenting with a fetal renal anomaly should be offered antenatal chromosome studies.

275 SECOND TRIMESTER MSAFP IN INSULIN DEPENDENT DIABETICS. Sunderji S, M.D., Macri JN, Ph.D.[X] SUNY-Health Science Center at Syracuse, NY, NTD Labs at Carle Place, NY.

Attention has been drawn to the differing concentrations of maternal serum alpha-fetoprotein (MSAFP) in patients with insulin-dependent diabetes mellitus as compared to patients without this disease. We have evaluated this question in 132 insulin-dependent diabetic pregnancies. Our study confirms earlier findings that MSAFP concentrations in pregnant diabetic women are lower than non-diabetic women. However, our study fails to confirm earlier estimates of a 40% reduction. Our data indicates that the MSAFP concentration of pregnant insulin-dependent diabetics results in a 16% reduction compared to that observed in non-diabetic pregnant women.

It has been suggested that there is an inverse correlation between MSAFP and the degree of diabetic control during pregnancy as monitored by glycosylated hemoglobin. This has led some to recommend adjustment in MSAFP concentration in women whose diabetes has not been well controlled. Conversely, no correction should be made if diabetic control is satisfactory.

We studied the above association using glycated serum proteins which assesses average blood glucose levels over a 2-3 week period. The same maternal serum specimens from 132 insulin-dependent diabetic pregnancies that were assayed for MSAFP were also assayed for glycated serum proteins. A non-significant correlation of R = .10 was found (P = 0.27) for AFP vs. GSP. Our data suggest that the degree of control in maternal diabetes does not significantly influence or alter the level of MSAFP. The alteration in MSAFP observed in pregnant diabetic women may result from the underlying disease process rather than the level of blood glucose control.

We conclude that MSAFP concentrations in insulin-dependent patients should be increased by less than 20% rather than earlier recommended adjustments amounting to increase of as much as 66%.

276 **ANTENATAL DIAGNOSIS OF CONGENITAL FINNISH NEPROSIS:** A Ghidini*, M Alvarez, RL Berkowitz, G Silverberg*, E Ainbender*, CJ Lockwood. Mt Sinai School of Medicine, New York, NY and North Shore University Hospital, NY.

Congenital Finnish Nephrosis (CFN) is an autosomal recessive disorder requiring neonatal renal transplant for survival. The definitive diagnosis of CFN rests on electron microscopic evaluation of the epithelial foot processes and basal membrane of the glomeruli. The prenatal diagnosis can be suspected in the presence of a positive family history with an amniotic fluid (AF) alpha-fetoprotein (AFP) > 10 Standard Deviations (SD) accompanied by a negative AF acetylcholin-esterase (AchE), absent hemoglobin F (HbF) and unremarkable fetal sonographic examination (1). We have expanded this indications to a low-risk population where the diagnosis of CFN has been correctly suspected in 7 patients with a MSAFP > 2.5 Multiples of the Median based on an AF AFP > 10 SD associated with a normal ultrasound examination, negative AchE and absent HbF (see Table below). In case # 6 the diagnosis of CFN was further supported by the presence of an AF albumin concentration of 960 mg/dl (normal values < 400 mg/dl).

Case#	wks	AFAFP (SD)	AchE	HbF	Fetal Renal Pathology*
1	22	>100	neg	neg	CFN
2	18	90	neg	neg	CFN
3	19	11	neg	neg	CFN
4	18	10	neg	neg	CFN
5	17	15	neg	neg	CFN
6	20	113	neg	neg	CFN

* = confirmed by election microscopy

CONCLUSIONS: The diagnosis of CFN can be strongly suspected even in a low risk population by the presence of an AF AFP > 10 SD. An elevated AF albumin concentration may represent an additional marker for the diagnosis of CFN; however its precise significance awaits further study.

277 **ENHANCED DOWN SYNDROME SCREENING EFFICACY BY COMBINING MATERNAL SERUM AND FETAL BIOMETRIC MARKERS.** *S Rotmensch, M Liberati,* JS Luo,* T O'Connor,* MJ Mahoney,* JA Copel, JC Hobbins, A Baumgarten.* Depts OB/GYN, Genetics, and Lab Med, Yale University.*

Whether fetal sonographic biometry and maternal serum alphafetoprotein (MSAFP) are independent parameters, which in combination could enhance screening efficacy for Down syndrome (DS), has not been determined. We analyzed prospectively collected data on 1125 patients who had genetic amniocentesis for advanced maternal age between 15-21 gestational weeks. 27 DS fetuses were identified in this population. Regression equations relating BPD to humeral length (HL) and femoral length (FL) were used to calculate ratios of observed (O) to expected (E) length. A cutoff point of 0.88 O/E for HL and FL yielded sensitivities (Sn) of 25.9% and 14.8%, and specificities (Sp) of 95.1% and 95.1%, respectively. A MSAFP cutoff of 0.42 MoM yielded a 37.0% Sn, and 98.1% Sp. Logistic regression analysis confirmed that O/E ratios for HL and FL were independent of MSAFP as a predictor of DS. A combination of O/E for HL and MSAFP yielded 55.5% Sn and 93.8% Sp. Inclusion of both HL and FL O/E ratios did not improve sensitivity. Conclusions: MSAFP and fetal long bone biometry are independent predictors of DS fetuses, which in combination enhance screening efficacy.

278 **DOES SONOGRAPHIC DETERMINATION OF FETAL SEX ENHANCE SCREENING EFFICACY FOR DOWN SYNDROME?** *S. Rotmensch, M Liberati,* JS Luo,* T O'Connor,* MJ Mahoney,* JC Hobbins, A Baumgarten*, Depts OB/GYN, Genetics, and Lab Med, Yale Univ.*

Male fetuses produce 5-10% higher maternal serum alphafeto-protein concentrations (MSAFP-C) than female fetuses. Postnatal extremity length is also larger in males than in females. We examined midtrimester sonographic biometry in relation to fetal sex and analyzed it's utility for enhancement of DS screening efficacy in conjunction with sex-related MSAFP-C. The series included 565 male and 558 female fetuses (including 14 males and 13 females with Down syndrome [DS]) whose mothers had amniocentesis for advanced maternal age between 15-21 weeks gestation. Regression equations predicting humeral length (HL) from biparietal diameter (BPD) for males and females were different (P=0.0006). A 0.84 ratio for females and 0.88 ratio for males of observed (O) to expected (E) HL yielded sensitivities (Sn) of 15.4% and 30.7% and specificities (Sp) of 98.0% and 95.1%, respectively. Median MSAFP for male fetuses was 2% higher than in females. An MSAFP of 0.5 MoM for females and 0.52 MoM for males yielded a Sn of 30.8% and 71.4% and Sp of 96.4% and 93.6%, respectively. Logistic regression analysis confirmed independence of O/E HL and MSAFP as predictors of DS. Combination of these parameters yielded 46.1% Sn and 94.3% Sp for female DS fetuses, but no improvement of the 71.4% sensitivity for male DS fetuses. Sex specific DS screening would result in overall sensitivity of 58.3% (assuming 90% feasibility of sonographic sex assignment and 92% prediction accuracy), as compared to 55.5% without knowledge of sex. **Conclusions:** 1. Male and female fetuses display differential biometric features in midtrimester. 2. Fetal sex specific interpretation of DS screening results tends to improve sensitivity. This would be more apparent with a 5-10% difference in MSAFP-C, as reported from large series in the literature.

279 **PEPTIDE HETEROGENEITY OF HUMAN CHORIONIC GONADOTROPIN (hCG) AND ITS ß-SUBUNIT IN DOWN SYNDROME PREGNANCIES.** S Rotmensch, M Liberati,* A Kardana,* M Mahoney,* JC Hobbins, LA Cole. Depts OB/GYN and Genetics, Yale University

Maternal serum hCG and its free ß-subunit (ß-SU) are markers for midtrimester Down syndrome (DS) screening. hCG molecules, however, are heterogeneous and have discordant immunoreactivity which can correlate with missing peptide linkages ("nicking") in the ß-SU. The purpose of this study was: 1. to compare hCG and ß-SU peptide heterogeneity between normal and DS pregnancies; 2. to determine the effect of nicking on hCG and ß-SU screening assays for DS. Sera from 60 women with karyotypically normal (51) and DS (9) fetuses at 13-22 weeks gestation were examined by immunoenzymometric assays utilizing monoclonal antibodies specific for total (=intact and nicked) hCG and total ß-SU as well as intact hCG and intact free ß-SU. **Results:** The amount of intact hCG (as % of total hCG) was 83.4%± 5.8% in DS and 76.9±11.1 % (p=0.06) in karyotypically normal pregnancies. Accordingly, the percent of nicked hCG was not statistically different. However, the assay specific for total free ß-SU was significantly higher in DS (0.34 ±0.18 vs.0.24±0.08%, p=0.04). The assay specific for intact free ß-SU showed no difference between DS and normal pregnancies (0.15±0.09 vs. 0.16±0.09 % p=NS). Accordingly, Down syndrome pregnancies had a higher serum concentration of nicked free ß-SU (0.20±0.18% vs. 0.03 ±0.08%, p=0.04%). In individual Down syndrome cases 8 fold higher serum concentrations of ß-SU were detected by the total ß-SU assay, as compared to the ntact ß-SU assay. **Conclusions:** 1. Missing peptide linkages in the ß-sububit occur more frequently in maternal sera of DS pregnancies. 2.Immunoassays which do not recognize nicked ß-SU yield falsely lowered concentrations and should not be used for DS screening. 3.Whether differences in nicking can be utilized to enhance DS screening efficacy remains to be determined.

280 **COCAINE USE DURING PREGNANCY IN A LARGE URBAN POPULATION.** Bertis B. Little, M.A., Ph.D.,+ Kenneth J. Trimmer, M.D., Susan M. Ramin, M.D., Donna I. Standard, B.S.,+ Craig A. Blakely, Ph.D.,+ and Laura M. Snell, M.P.H.+ Depts. of Ob/Gyn and Family Practice and Community Medicine, The University of Texas Southwestern Medical Center, Dallas, Texas, Public Policy Research Laboratory, Texas A & M University College Station, Texas.

Umbilical cord blood collected at delivery from 97% of 890 consecutive births at two large public county hospitals was tested for a cocaine metabolite (benzoylecgonine) by radioimmunoassay (RIA). Medical record information was linked to serological analyses. Any patient positive for other drugs (methamphetamines, opiates, alcohol, toluene) was excluded. Infants whose cord blood was positive for the cocaine metabolite (n=126) had significantly (P<.01) reduced birth weight (by >200 grams), birth length (1.5 cm), and head circumference (1 cm) compared to seronegative controls. Frequencies of genitourinary and major congenital anomalies were significantly (P<.05) increased among drug-exposed infants (odds ratios = 3.4 and 2.4, respectively) compared to seronegative controls. None of the mothers gave a history of cocaine use during pregnancy but birth outcomes parallel those reported previously in this population based upon self-reported history or drug use. Screening for cocaine abuse should be considered when unexplained complications such as fetal growth retardation or congenital anomalies are clinically suspected.

281 RAPID CYTOGENETIC ASSESSMENT OF FETAL BLOOD SAMPLES. Richard P. Porreco, M.D., Beryl Harshbarger, CLSp(CG)*, Loris McGavran, Ph.D.*, Presbyterian/St. Luke's Medical Center, The Children's Hospital, Denver, Colorado 80203.

Abnormalities diagnosed by antenatal ultrasound frequently require cytogenetic analysis of the fetus. Occasionally the karyotype results may alter obstetric management. Eighteen patients had fetal blood sampling done for a variety of abnormalities diagnosed by antenatal assessment. These included hydrocephalus, oligohydramnios, intrauterine growth retardation, non-immune hydrops, duodenal atresia, polyhydramnios, and multiple anomalies. Four cytogenetic techniques were attempted in arriving at a fetal karyotype. These included a direct harvest of lymphocytes in the fetal blood sample, a 24 hour incubation of fetal lymphocytes without mitogen, and a 48 and 72 hour mitogen stimulated incubation followed by harvest and analysis. Six of the eighteen cases showed diagnostic cytogenetic abnormalities. One half of the cases had results reported within 30 hours of obtaining the specimen following analysis of unstimulated cultures, including three of the six abnormal results.

#	Gest.Age	Indication	Results	Time (da)
1	38 wks	Hydrocephalus	46,XY	2
2	20 wks	Hydrocephalus	47,XX,+21	2
3	36 wks	IUGR, anomalies	69,XXX	<1
4	24 wks	Oligohydramnios	46,XY	2
5	18 wks	Down syndrome in affected twin	47,XY,+21	2
6	24 wks	Fetal ascites, oligohydramnios	46 XY	<1
7	30 wks	Non-immune hydrops	No Growth	-
8	17 wks	Cystic hygromas, hydrops in twin	No Growth	-
9	35 wks	IUGR	47,XY,+21	<1
10	31 wks	IUGR	46,XX	<1
11	19 wks	Identical twins, hydrothorax	46,XX	3
12	18 wks	Non-immune hydrops	46,XY	1
13	26 wks	IUGR	46,XY	2
14	26 wks	Oligohydramnios	46,XX	<1
15	26 wks	Hydrocephalus	46,XX	1
16	36 wks	Multiple anomalies	47,XY,+18	2
17	25 wks	Duodenal atresia	46,XY,-13, +robt(13;21)	1
18	30 wks	Hydramnios	46,XX	1

Conclusion: Unstimulated lymphocyte cultures from fetal blood samples may provide rapid cytogenetic analysis and alter obstetric management.

282 BART'S HYDROPS FETALIS IS NOT UNIFORMLY FATAL. D. Jackson, R. Farmer, K. Murray, D. Bianchi, J. Akabutu, Dept. M-F Medicine and Pediatrics, U of Ca, Irvine, Harvard Med. School, U of Alberta, Canada.

Fetal non-immune hydrops secondary to homozygous alpha thalassemia (4 gene deletion, Bart's hydrops fetalis) is generally counseled as a uniformly fatal perinatal condition. Follow-up on three known survivors refute this counseling. The children are now ages 8, 7, and 3. All received aggressive neonatal resuscitation at birth including intubation and blood transfusions. Gestational age and mode of delivery were 32 weeks/C-section, 28 weeks/C-section, and 28 weeks/vaginal-breech delivery, respectively. Neonatal and infant characteristics are shown below.

Current Age	Hgb Electrophoresis (Bart\Portland\H)	NICU (Day's)	Ht. / Wt. Percentile		Motor/Neuro Devel.
8 y/o	80%\20%\0	48	10%	5%	Bilat.hearing aids/poor speech dev.
7 y/o	78%\19%\3%	73	10%	25%	Appropriate for age
3 y/o	93%\7%\0	64	10%	5%	Appropriate for age

All three children undergo monthly transfusion and chelation therapy.

Conclusions: The follow-up on three neonatal survivors with in utero Bart's hydrops fetalis refutes counseling of uniform mortality. For parents opting for prenatal diagnostics and pregnancy continuation, in utero transfusion/gene therapy may be a focus of future perinatal research efforts to augment neonatal management.

283 SERUM HUMAN CHORIONIC GONADOTROPIN (hCG) AS A MARKER FOR LOW BIRTHWEIGHT IN WOMEN WITH UNEXPLAINED ELEVATIONS IN MATERNAL SERUM ALPHA-FETOPROTEIN (MSAFP). Hurley TJ, Quirk, Jr. JG, Blacklaw M*, Walker G*, Miller C* and O'Brien TJ*. University of Arkansas for Medical Sciences, Little Rock, AR, Department of Ob/Gyn.

It has been previously reported that unexplained elevations in MSAFP obtained in the second trimester of pregnancy are associated with an increased incidence of adverse pregnancy outcomes including stillbirth and low birthweight (LBW). In an attempt to more precisely identify this high risk group, we evaluated the efficacy of serum hCG measurements in 82 women with MSAFP elevations (>2.5 multiples of the median), but without demonstrable fetal defects by level II ultrasound or amniocentesis. In these 82 women, the incidence of (LBW) (<2500g) (including fetal demise) was 23% (19) vs 5% (5) in a control group of 100 women with normal MSAFP's (p<.001). For the study we defined an abnormal hCG as (≥2.5 MoM or ≤0.5 MoM). The incidence of an abnormal hCG value in these 82 women was 24%. In this latter group 50% delivered infants of birthweight <2500 grams as compared to 14.5% of those with serum hCG within the normal range (p<.002). There was one still birth in each group. The test performed with a sensitivity of 52%, specificity of 85% and a positive predictive value of 50%. Therefore women with an abnormal hCG (≥2.5 MoM or ≤0.5 MoM) and an elevated MSAFP have a 1:2 chance of delivering a low birthweight infant as opposed to a 1:5 chance with an elevated MSAFP alone. Further work needs to be done on the utility of serum hCG and other biochemical markers as independent predictors of poor obstetrical outcome in women with unexplained elevated MSAFP's.

284 **FETAL CHOROID PLEXUS CYSTS: AN INDEPENDENT RISK FACTOR FOR CHROMOSOMAL ANOMALIES.**

Porto M, Murata Y, Warneke LA[X], Keegan, Jr KA.
University of California Irvine Medical Center, Orange CA.

This prospective, controlled study was designed to determine the inherent risk of fetal aneuploidy with sonographically detected choroid plexus cysts (CPC) in the 2nd trimester. 63 cases of CPC were detected in 3247 2nd trimester ultrasound examinations (1.9%). Our control group consisted of all patients who had an ultrasound examination and genetic amniocentesis, between 15 and 22 weeks gestation, by the same sonologist on the same day as a study subject with a CPC (N=211). The two groups were demographically similar in maternal age and indication for examination (primarily: maternal age, abnormal AFP, previous anomaly). Six chromosomally abnormal fetuses: Trisomy 18 (3), Down syndrome (2), and Klinefelter syndrome were found in the CPC group (6/63, 9.5%). One fetus with Trisomy 21 was encountered in the control group, (1/211, 0.5%) [$p < 0.002$]. There was no correlation between bilaterality and chromosomal anomalies. Of note, 5 of 21 (23.8%) fetuses with CPC greater than 5mm in diameter had aneuploidy, compared with only 1 of 42 (2.4%) chromosomal anomalies with smaller cysts ($p < 0.02$). Two fetuses with CPC and aneuploidy had no other sonographically detected anomalies despite targeted scans including echocardiography. We conclude that fetal CPC is an independent risk factor for chromosomal anomalies. Based on our data, all patients with CPC should receive genetic counseling and be offered prenatal karyotype analysis.

285 EARLY AMNIOCENTESIS - RELIABILITY AND SAFETY. A LONGITUDINAL FOLLOW-UP TO DELIVERY IN 400 CONSECUTIVE CASES. S. Iwanicki,[x] M. Pattinson[x], D. Cox[x], H. Pattinson[x], D. King[x], Alberta Hereditary Diseases Program, Calgary, AB, Canada

Since 1989, advanced maternal age (≥35 y at EDC) patients in our center have been given the option of early amniocentesis (EA, 9-14 weeks). Patients were counselled that local risk rates related to EA were unknown. The procedures followed a detailed ultrasound (US) assessment and the taps were performed under US guidance by an experienced obstetrician. Cell cultures were processed for chromosome preparations using the flask method when EA was performed ≤13 weeks, otherwise the in situ method was used. Results were monitored to determine the incidence of culture failure (CF). Patients were contacted 4 weeks post EA to assess for early complications and again 4-6 weeks post-partum to evaluate for late complications. There were no stillbirths or neonatal deaths. Results are summarized in the table below with the percentage for each gestational age.

Gestational age (wks)	9	10	11	12	13	14	TOTAL
No. of procedures	3	46	73	83	74	121	400
Culture failure	1(33)	6(13)	1(1.4)	0 (0)	1(1.4)	0 (0)	9(2.3)
Pseudomosaicism	0 (0)	0 (0)	0 (0)	0 (0)	4(5.4)	1(0.8)	5(1.3)
Leakage/Bleeding	0 (0)	2 (4)	2(2.7)	0 (0)	2(2.7)	1(0.8)	7(1.8)
Spontaneous Abortion	0 (0)	1(2.2)	0 (0)	2(2.4)	1(1.4)	2(1.7)	6(1.5)
Pregnancy termination	1(33)	0 (0)	0 (0)	0 (0)	2(2.7)	0 (0)	3(0.8)
Preterm delivery	0 (0)	0 (0)	1(1.3)	1(1.2)	2(2.7)	3*(2.5)	7(1.8)
Congenital anomalies	0 (0)	1(2.2)	1(1.3)	1(1.2)	2(2.7)	1(0.8)	6(1.5)
Lost to Follow-up	1(33)	1(2.2)	0 (0)	1(1.2)	1(1.4)	1(0.8)	5(1.3)

* Includes one following abdominal trauma and one twin pregnancy

Early experience showed that CF at <11 weeks was unacceptably frequent (14.3%). Procedures were then performed only at ≥11 weeks, with a CF rate of 0.6%. There were no more congenital abnormalities (2 club foot, 1 absent patellae, 1 cleft lip, 1 cleft palate and 1 congenital hip dysplasia) than would be expected. This study suggests that the risks and reliability associated with EA compare favourably to those previously reported with traditional amniocentesis.

286 OUTCOME OF ANTENATALLY DIAGNOSED CYSTIC ADENOMATOID MALFORMATIONS (CAM)

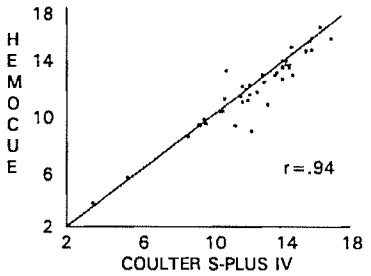
Jeffrey Kuller, Jerome Yankowitz[X], James Goldberg, Michael Harrison[X], Roy Filly[X], Peter Callen[X], Mitchell Golbus[X] Fetal Treatment Program Univ. Calif. Med. Ctr., San Fran., CA

We reviewed our experience with 21 cases of fetal CAM diagnosed antenatally. Seventeen of these patients elected to continue pregnancy. In 9 cases, non-immune hydrops fetalis (NIHF) did not develop and all these infants survived. In the remaining 8 cases, NIHF developed between 20-27 weeks. Fetal intervention was undertaken in 7 of the 8 cases. In the 1 case with NIHF in which intervention was not undertaken, the patient ruptured membranes at 33 menstrual weeks. The infant died of respiratory distress at 1 hour of life. In 3 cases, ultrasound guided needle aspiration of macrocystic lesions was performed. In one patient, preterm labor and delivery of a viable infant occurred 1 week later. In the other 2 fetuses, cystic fluid rapidly reaccumulated and cystoamniotic shunts were placed. In one patient, the catheter remained in place but the patient ruptured membranes 2 days later and delivered a previable fetus. In the other case, the catheter malfunctioned 2 days later and the patient underwent fetal surgery. In 5 patients, fetal surgery was performed (hysterotomy/resection of chest mass). Three infants survived and are doing well. One case is ongoing. The nonsurvivor died on day 2 of life with anasarca and severe respiratory compromise. The mother's course was complicated by severe preeclampsia ("mirror syndrome"). In cases where NIHF occurs early, fetal surgery may prove to be a viable therapeutic option.

287 **MANAGEMENT OF FETAL HEMOLYTIC DISEASE NOT REQUIRING ANTENATAL TRANSFUSION THERAPY.** C. Weiner, L. Estle[X], K. Wenstrom and S. Sipes. Dept. OB/GYN, Univ. Ia. College of Med., Iowa City, Ia. 52242

Direct evaluation of a fetal blood rather than an amniotic fluid specimen permits the accurate identification of the fetus at risk to develop antenatal anemia secondary to maternal red cell alloimmunization *(AmJObGyn, Oct 1991)*. Based on the recommended nomogram, 60% of affected fetuses require ≤2 cordocenteses and are permitted to deliver at term. Of the remaining group, 80% require transfusion therapy. We sought the ***risk of unexpected postnatal anemia and/or hyperbilirubinemia in those fetuses who prospectively were felt not to be at risk for antenatal anemia.*** Follow-up is presently available on 35/40 (88%) completed at risk pregnancies. 71% were delivered by their referring physician at 38 ± 2w (range 34-41 w) with a BW of 3140 ± 565 gm. 24/35 (69%) had been placed in low to moderate risk groups and 69% underwent ≤2 cordocenteses. No procedure was performed after 35 w. The HCT at delivery was 46 ± 9% (range 24-58%) in the 17 neonates tested. There was one anemic neonate at birth (2.8%). On review, it was discovered that the risk pattern assigned to this fetus was in error. A second cordocentesis 4 weeks after the first should have been performed at 34w when this fetus may have already been anemic. Five (14%) underwent 1 or more double volume exchange transfusions for hyperbilirubinemia, and 4 (11%) received a simple transfusion for anemia that developed ≥ 48hrs after birth. 23/35 (66%) required some phototherapy (23-240 h). **CONCLUSION:** ***1) The development of fetal anemia can be accurately predicted weeks prior to delivery. 2) Affected but nonanemic neonates remain at risk for hyperbilirubinemia and hemolytic anemia and should be delivered in at least a secondary level hospital.***

288 TWIN TO TWIN TRANSFUSION. J. Castaner,[X] C. Cetrulo, M. D'Alton; Dept. of MFM, St. Margaret's Hospital for Women/Tufts Univ. School of Medicine, Boston, MA



Eighteen cases of twin to twin transfusion sydrome (TTS) were revieved to elucidate if gestational age at presentation or obstetrical management affected perinatal outcome. All cases met 2 or more criteria: 1) like sex twins with monochorionic placentas (18 pts.), 2) weight differences >20% (13 of 18), 3) polyhydramnios/oligohydramnios (17 pts.), 4) "stuck twin" (7 pts.), 5) hydrops fetalis (3 pts.), or 6) difference in hemoglobin >5 gm. (6 pts.) Obstetrical management consisted of conservative observation in 12 cases, decompression amniocentesis in 4 cases and Indomethacin therapy in 2 others. Eight cases presented before 25 weeks and 10 cases after 26 weeks. The perinatal mortality (PNM) rate was 12.5% for those with conservative management, 25% for the amniocentesis group and 75% for those treated with Indomethacin. In the amniocentesis group reversal of hydrops was visualized in 1 case. All the perinatal deaths were confined to the group who presented before 25 weeks gestation. The PNM rate was 22.2% for the total group, 50% for those presenting <25 weeks and zero if presentation was after 26 weeks. Three patients with one IUFD continued their pregnancy for another 4, 10, and 14 weeks respectively. One case developed IUGR, microcephaly, multicystic encephalomalacia. The other 2 pregnancies proceeded to 34 and 35 weeks respectively with uneventful outcomes. In conclusion, we observed that TTS presenting before 25 weeks gestation demonstrates poor outcome irrespective of management while those presenting after 26 weeks has a zero PNM rate. Because of the high PNM associated with Indomethacin we discourage its use. Decompression amniocentesis needs further study to elucidate its role in management of TTS.

289 RENAL FUNCTION AFTER IN-UTERO INTERVENTION FOR FETAL OBSTRUCTIVE UROPATHY. Melissa Fries,[X] Mary Norton,[X] James Goldberg, Michael Harrison,[X] Roy Filly,[X] Peter Callen,[X] Ruth Goldstein,[X] Mitchell Golbus[X]. Univ. CA, San Francisco

In-utero vesicoamniotic shunting and vesicostomy by open fetal surgery have been used to relieve fetal urinary outflow obstruction, theoretically preventing pulmonary hypoplasia and preserving renal function. Past studies have suggested that hypotonic fetal urine (Na $\leq$100meq/dl; Cl $\leq$90meq/dl; osmolality $\leq$210mOsm/l) predicted fetal survival with normal renal function. Twenty-four cases of fetal intervention (16 shunts; 8 open surgeries) were performed from 1981-1991, with shunts producing 7 survivors, 4 neonatal demises (NND), and 5 TAB's; and surgery leading to 3 survivors, 4 NND, 1 TAB. Five of the 7 shunt survivors had hypotonic urine electrolytes and ultrasonically-normal kidneys; values were hypertonic on 1 survivor and not studied on the other. All 7 had variable renal dysfunction at birth, with Cr 1.1-9.0 mg/dl and BUN 18-56 mg/dl. Renal transplant is planned for 3 pts. Of shunt non-survivors (9 pts), only 2 had hypotonic urine. In the fetal surgery survivors, 1 had hypotonic urine and one had borderline hypertonic values (osm=221); both these pts. have normal renal function. The other survivor had hypertonic urine (osm=255) and has had renal transplant. Of the non-survivors, electrolytes were not studied in 2 pts. and were hypotonic or borderline hypertonic (osm=215) in the remaining 3. NND were from complications of prematurity. Hypotonic urine may predict survival but not good long term renal function for fetuses treated by intervention. A randomized trial of intervention vs non-intervention and early delivery appears indicated.

290 FETAL HEMOGLOBIN QUANTITATIONS USING THE HEMOCUE® SYSTEM ARE FAST AND ACCURATE. S.M. Berry, M. Dombrowski, W.B. Blessed,[X] J.A. Bichalski,[X] T.B. Jones, D.B. Cotton, Dept. of Ob/Gyn, Hutzel Hosp./WSU, Detroit, MI

Rapid and accurate quantitations of fetal hemoglobin (hgb) levels during cordocentesis (PUBS) are critical in making the decision to perform an intrauterine transfusion, and in deciding how much blood to transfuse. Hemocue (weight = 700g) provides Hgb levels in 45 seconds. Accuracy of the Hemocue system has not been adequately validated for prenatally obtained fetal blood. We compared fetal Hgb's from the Hemocue versus those from the Coulter S-Plus IV on 44 fetal specimens obtained via PUBS. Gestational age (GA) = 26.7 ± 5.7 wks (range = 18 to 37).

The Hemocue values ranged from 3.3 to 16.4 gm/dl. GA and extremes in Hgb levels were not significantly correlated to Hemocue values by stepwise regression. Conclusions: 1) The Hemocue system is fast and accurate for fetal Hgb quantitations throughout gestation, despite varying Hgb F/ Hgb A_1 ratios. 2) The accuracy of the Hemocue system is not significantly affected by extremes in fetal Hgb levels.

291 FETAL PLATELET COUNTS IN RED CELL ALLOIMMUNIZATION CORRELATE WITH THE SEVERITY OF THE DISEASE. George R. Saade, M.D.,[X] Kenneth J. Moise, Jr., M.D., Michael A. Belfort, M.D.,[X] Diane Hesketh, R.N.,[X] Robert J. Carpenter, Jr., M.D.; Dept. of Ob/Gyn; Baylor College of Medicine; Houston, Tx.

Thrombocytopenia has been noted in hydropic neonates with HDN and its presence could complicate intrauterine vascular transfusions (IVT). **Purpose:** To determine whether any subgroup of fetuses with red cell alloimmunization have lower platelet counts (Plt). **Material and Methods:** The records of 53 patients undergoing IVT for red cell alloimmunization were reviewed. The pre-transfusion fetal Plt was compared between hydropic and non-hydropic fetuses and with the fetal bilirubin, hct, and retic count at the initial IUT. In addition, the hct was adjusted for gestational age by calculating the number of standard deviations (#SD) below the mean for that age. The student t test and the Pearson R coefficent were used to analyze the data. **Results:** 29 fetuses were hydropic; 24 non-hydropic. Hydropic fetuses had a significantly lower Plt count than non-hydropic fetuses (195.8 ± 96.0 vs 250.0 ± 78.6 $10^3/mm^3$; p = .02), with 31% and 17% of hydropic fetuses having plt counts less than 150,000 and 100,000/mm^3 respectively. Plt counts correlated positively with the hct (r = .65; p <.01) and negatively with the retic count (r = .65; p <.01), and the hct #SD below the mean (r = .65; p <.01), but did not correlate with bilirubin (r = .07; p = NS). **Conclusions:** Hydropic and severely anemic fetuses are at risk for thrombocytopenia. We suggest that increased erythropoeisis drives the hematopoietic stem cell away from platelet production.

292 TRANSVAGINAL EMBRYONIC ASPIRATION (TEA) - A SAFER METHOD FOR SELECTIVE REDUCTION IN MULTIFETAL GESTATION

Itskovitz J[X], Drugan A[X], Levron J[X], Thaler I[X], Brandes JM[X]. Dept. Ob/Gyn, Rambam Medical Ctr. and Faculty of Medicine, Technion, Haifa, Israel

Selective reduction of fetal numbers in high multifetal gestation is usually performed transabdominally at 10-12 wks gestation with a pregnancy loss rate of 15-25%. We performed TEA in 18 multifetal pregnancies at 7-8 wks of gestation. In 17 cases, the initial fetal number of 3-7 was reduced to 2; in 1 case, the number of embryos was reduced from 4 to 3. None of the remaining fetuses vanished following the procedure. In 17 cases, the procedure was accomplished in 1 session, with 1 or 2 needle insertions. 1 patient required 2 sessions for reduction from quintuplets to twins. Mean procedure time was 10 minutes. 15 patients delivered successfully at/after 35 wks and 2 patients at 32 wks. The procedure-related loss rate was 5.6% - 1 premature delivery at 25 wks. We suggest that TEA is safer than the transabdominal route and simpler to perform; and the earlier procedure may be more acceptable to patients from moral and religious points of view.

293 **IN-UTERO FETAL ELECTROCARDIOGRAM: A METHOD FOR EVALUATING FETAL ARRYTHMIAS**

Mark T Cullen MD, Jacqueline J Green RDMS, Luis Sanchez-Ramos MD. University of Florida, Jacksonville, FL.

Fetal tachyarrhythmias can be associated with fetal decompensation, hydrops and death. While the in-utero medical treatment of fetal cardiac arrhytamias is promising, proper drug selection is dependent on an accurate diagnosis of the dysrhythmia. The incorrect choice of medication could lead to a worsening of the condition or fetal death. Diagnostic tests available include real time ultrasonography and M mode echocardiography. M mode echocardiography can be difficult to perform and interpret, requiring significant expertise and sophisticated equipment. The purpose of this study is to describe a new method and equipment for direct in-utero evaluation of the fetal heart rate. The technique utilizes a fetal electrode that is placed transabdominally through a 20g spinal needle performed similar to a transabdominal amniocentesis. Under ultrasound guidance, the thin wire electrode is threaded through the needle and comes in contact with the fetal skin. The electrode is grounded to the maternal abdomen and attached to a fetal monitor (Advanced Medical Systems, Inc. model IM76, Hamden, CT). A fetal electrocardiogram is printed to the monitor strip or transferred to an electrocardiograph. The technique has proven effective when tested on fetuses prior to termination of pregnancy.

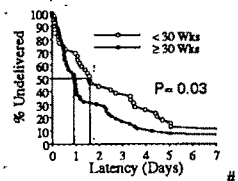
294 **OUTCOME IN REPEAT PREGNANCIES AMONG BLACK AND WHITE TEENAGERS.**

SP Cliver*, RL Goldenberg, CA Hickey,* J Jin,* ML Blankson.* University of Alabama Hospitals, Birmingham, Alabama.

Teenage women are at higher risk than adult women for delivering growth retarded or preterm infants. To assess these risks in repeat teen pregnancies, first and second pregnancies of 737 indigent teenagers who delivered singletons were compared. The population studied was 80% black, 20% white, and 30% had a first delivery before age 15. Fetal growth retardation (FGR) fell from 9.3% in the first pregnancy to 4.2% in the second ($p=.0001$), and the preterm delivery (PTD) rate (<37 weeks gestation) rose from 14.8% to 18.9% ($p=.04$). The PTD rate in white teenagers fell slightly while the rate in black teens rose from 15% to 21% ($p=.02$). Maternal height and self-reported use of cigarettes, alcohol, and street drugs did not change significantly from the first to the second pregnancy. Maternal body mass index (BMI), the proportion of married women, and gestational age at first prenatal visit all increased significantly from the first to the second pregnancy ($p<.05$). The mean number of prenatal visits decreased by 2 visits ($p=.0001$). In a multivariate analysis adjusting for race, gestational age, infant sex, age at first delivery, and interval between pregnancies, the increase in mean birthweight in the second pregnancy was partly explained by an increase in maternal BMI from the first to the second pregnancy. For teenagers whose first pregnancy resulted in PTD, the recurrence rate was 46%, compared to a PTD rate of 14% for teenagers whose first delivery was at term ($p<.001$). The recurrence rate was especially high for black teens (49%) compared to white teens (32%) despite a significantly greater weight gain between pregnancies in blacks ($p=.02$) as well as a longer interval between pregnancies ($p=.004$). Black teens, however, presented two weeks later for care in both pregnancies and had fewer prenatal visits. Previous PTD in teenagers appears to confer a greater risk for recurrence than in adults, particularly among black women.

295 **THE NATURAL INTERLEUKIN-1 RECEPTOR ANTAGONIST PREVENTS INTERLEUKIN-1-INDUCED PRETERM PARTURITION.**

R. Romero, M. Mazor, B. Tartakovsky[X], Depts. of Ob/Gyn, Yale Univ. School of Med., New Haven, CT; Wayne State Univ., Detroit, MI; Soroka Med. Center, Ben Gurion Univ., Israel; The Weizmann Institute, Rehovot, Israel



Interleukin-1 (IL-1) has been implicated in the mechanism responsible for preterm labor in the setting of infection. The participation of IL-1 in this process has important diagnostic, prognostic and therapeutic implications. Indeed, patients with IL-1α and IL-1β in the amniotic fluid have a high rate of intraamniotic infection and frequently fail to respond to tocolysis. Recently, a new member of the IL-1 gene family, the natural IL-1 receptor antagonist (IRAP), has been isolated, purified and cloned (Nature 1990;343:341 and 1990;344:633). This polypeptide blocks prostaglandin biosynthesis in several cell types and thus may have a role in the treatment of preterm labor. The purpose of this study was to determine if IRAP can prevent IL-1-induced parturition in mice (AJOG 1991;165 [in press]). Materials and Methods: A clinical trial was conducted in 17-day-pregnant mice (BALB/C) impregnated by B6D2 F-1 males. Mice were randomly allocated into four groups: group 1, placebo (saline); group 2, IL-1; group 3, IRAP (Upjohn, Kalamazoo, MI); group 4, IL-1 and IRAP. All compounds were administered in one subcutaneous injection. Results: 1) IRAP prevented IL-1-induced parturition and other behavioral IL-1-induced biological effects; 2) IL-1 induced preterm labor and delivery in all cases within 18 hours post-injection; 3) IRAP administration was not associated with any demonstrable side effects including vaginal bleeding. Conclusion: IRAP prevented IL-1-induced preterm labor and delivery. These data suggest that anti-cytokine agents may have value in the treatment of preterm labor associated with infection and open new therapeutic horizons for preterm parturition.

296 MAGNESIUM SULFATE IS A POOR INHIBITOR OF OXYTOCIN-INDUCED UTERINE CONTRACTILITY IN PREGNANT SHEEP. Margaret L. Watt-Morse, Steve N. Caritis, Jye Ping Chiao[X], University of Pittsburgh, Magee-Womens Hospital, Pittsburgh, PA

We have previously demonstrated that magnesium is a poor inhibitor of oxytocin-induced contractility in sheep. Steady state concentrations were maintained for only 2-3h in that study, but clinical studies suggest that magnesium sulfate requires more time to inhibit uterine contractility. In the present study, we evaluated inhibition of oxytocin-induced uterine contractility by magnesium sulfate after 24h of infusion. We inserted catheters in the femoral artery and vein and amniotic cavity of 6 pregnant sheep between 110 and 117 days gestation (term = 147). Two to four days after surgery, animals received a loading dose of magnesium sulfate followed by maintenance infusion to achieve magnesium concentrations of 6.1-7.8 mEq/L. Animals received 500 mU boluses of oxytocin prior to and after 4 and 24h of infusion. Uterine activity was quantified by integrating the area under the time uterine pressure curve. Mean inhibition of uterine contractility was 18% after 4h and 24h of magnesium infusion. Previous work from our laboratory shows that uterine contractility induced by the same oxytocin dose are inhibited 48-64% when ritodrine concentrations are 1-11 ng/ml. When compared with ritodrine, magnesium sulfate is a poor inhibitor of oxytocin-induced myometrial contractility in pregnant sheep.

297 OUTCOME OF MULTIPLE GESTATION COMPLICATED BY PRETERM PROM (pPROM). B Mercer[X], L Crocker[X], M Dahmus[X], F Pierce[X], B Sibai. University of Tennessee, Memphis.

Currently there is little information as to the latency period and perinatal outcomes after pPROM in multiple gestations. Specifically, the relative risks of morbidity and mortality between the presenting and non-presenting infants have not been addressed. The purpose of this clinical investigation is to report the natural history and clinical outcome in 101 pregnancies having this complication. **Method:** The study population included all such pregnancies managed at this institution over a 10 year period. Outcome variables studied included: latency from membrane rupture to delivery, maternal infectious morbidity including placental histology, and neonatal morbidity with special emphasis on differences between the presenting (A) and non-presenting (B) fetus. **Results:** The mean gestation at pPROM was 30.0±4.4 weeks (range 18-36). There were 2 triplet gestations. Eight were delivered on admission because of advanced gestation. The median latency of the 93 remaining pregnancies was only 1.08 days, with 91% delivering within 7 days. The latency to delivery, stratified by gestational age at rupture, is summarized in the Figure (analysis by Life-table methodology). Pathologic chorio-amnionitis was identified in 29% of placentas (22/75), and 29.7% developed clinical chorioamnionitis. Outcomes of the 204 infants are summarized in the Table. Three infants > 600 grams were stillborn. **Conclusions:** The multiple gestation complicated by pPROM is associated with a brief latency regardless of gestational age. Paired analysis reveals no difference in infant survival, but a significant increase in respiratory morbidity in the non-presenting infant.

	A	B
Birth weight (gr.)	1468	1463

298 SAFETY AND EFFICACY OF THE OXYTOCIN ANTAGONIST ATOSIBAN IN THREATENED PRETERM LABOR: INITIAL U.S. TRIAL. TM Goodwin, RH Paul (Univ. of So. California, Women's Hospital, Los Angeles, CA), H Silver (UC Davis), M Parsons, R Chez, W Spellacy (Univ. of So. Florida), R Hayashi (Univ. of Michigan), L North,[X] R Merriman[X] (RWJ Pharmaceutical Research Institute).

Atosiban (deTVT/DETO-OXY) is a potent antagonist of oxytocin which lacks significant cardiovascular, pulmonary, and central nervous system activities. A double blind, placebo controlled trial was conducted to test the hypothesis that intravenous Atosiban (300 µg/min) is more effective than bedrest in reducing the frequency of preterm contractions. 120 women between 20 and 36 weeks gestation with >4 uterine contractions/hour were randomized to receive placebo (N=60) or Atosiban (N=60) for 2 hours. Eight subjects (4 Atosiban and 4 placebo) were excluded after randomization. The two groups did not differ in demographic characteristics or cervical findings. Baseline contraction frequency, as determined by external tocodynamometry was similar in Atosiban and controls (15.1±4.8 vs. 16.8±6.7, mean±SD). The overall mean decrease in contraction frequency was 8.2±5.8 for Atosiban compared to 4.6±5.8 for controls (p=0.001) In patients receiving Atosiban, 27/56 (48%) had ≤4 contractions/hour during the second hour of infusion compared to 11/56 (20%) of controls (p=0.003). Five Atosiban patients had cervical change compared to 8 controls (NS). Mild gastrointestinal symptoms were noted in 2 Atosiban patients and in one control. **Atosiban is more effective than bedrest in reducing preterm uterine activity. No significant adverse effects were observed with a two hour infusion. We are currently studying the safety and efficacy of Atosiban in patients with preterm labor evidenced by cervical change.**

299 AMNIOTIC FLUID LAMELLAR BODY COUNT: A RAPID AND RELIABLE FETAL LUNG MATURITY TEST. C. Dalence,[X] L. Bowie,[X] J. Dohnal,[X] E. Farrell,[X] M. Vye,[X] Evanston Hospital and Northwestern University Medical School, Evanston, IL

The lamellar body count (LBC), a rapid and quantitative test for fetal lung maturity (FLM), has previously been shown to correlate with other tests for FLM. Lamellar bodies are structures secreted by fetal Type II pneumocytes and consist almost entirely of surfactant phospholipids. In this study, we compared the ability of the LBC vs a lung phospholipid profile to predict the respiratory outcome of 118 well documented cases. Fetal lung phospholipid profiles were performed by thin-layer chromatography. Maturity was indicated by a ratio of phospholipids (lecithin+PG+PE+PI)/sphingomyelin ≥3:1. LBC was determined for all amniotic fluid specimens using the platelet channel of a conventional Coulter counter. Calibrated spheres and commercial controls were used to verify the accuracy of the particle counts. Data and predictive values (PV) are summarized below:

Clinical	Lung Profile		LBC		LBC	
Outcome	<3:1	≥3:1	≤30K	>30K	≤10K	>10K
RDS	10	1	14	0	10	4
No RDS	9	92	44	60	9	95
Sens/Spec	0.91/0.91		1.00/0.58		0.72/0.91	
+PV/-PV	0.53/0.99		0.24/1.00		0.53/0.96	

Using a value greater than 30,000/uL to predict FLM, the LBC showed no false negative results while the phospholipid profile had one false negative. Therefore, the LBC demonstrated 100% sensitivity in the critical function of predicting the absence of RDS. Furthermore, we found the number of false positives indicated by the LBC could be minimized by using a second cutoff of 10,000/uL to indicate a high-risk for RDS. LBC values between 10,000/uL and 30,000/uL appear to be of intermediate risk for developing RDS (4 of 39 cases). Conclusion: The LBC appears equivalent to traditional phospholipid determination in predicting fetal lung maturity. However, the LBC offers considerable advantage over traditional phospholipid determination based upon its simple technique and rapid availability.

300 NEONATAL MORBIDITY BETWEEN 34-37 WEEKS' GESTATION. M.D. Fox,[X] J.F. McCaul, R.W. Martin, W.E. Roberts, B. McLaughlin,[X] J.C. Morrison, Dept. Ob/Gyn, Univ. Mississippi Med. Ctr., Jackson, MS

Objective: To determine the risk of significant neonatal morbidity between 34-37 weeks in women with preterm labor (PTL) who are not given tocolytic therapy. Study Design: Women between 34 and 37 weeks' gestation with documented PTL and intact membranes were given informed consent and offered entry into this prospective trial. Population: One hundred and one women met inclusion/exclusion criteria; 90 gave informed consent and were randomized. Intervention: Women were randomized by a disinterested third party (pharmacy) from a random number table to receive either intravenous magnesium sulfate tocolysis followed by oral therapy using magnesium gluconate tocolysis (treatment group - T) or conservative management with hydration, sedation and observation (control group - C). Main Outcome Measured: The incidence of maternal side effects from tocolysis, interval from diagnosis of PTL to delivery, birth weight, and neonatal outcome were noted. Results: Of the 90 women entering the study, 45 in T and 45 in C, two discontinued tocolytic therapy because of gastrointestinal side effects. There were no serious neonatal complications. In both T and C there were 3 who had TNN and 1 RDS in each group.

	N	GA at diagnosis (weeks)	Interval to delivery (days)	Birth weight (grams)	GA at delivery
T	45	34.9 ± .7	15.7 ± 12.0	2741 ± 496	36.5 ± 1.7
C	45	35.1 ± .7	15.4 ± 13.6	2762 ± 585	37.7 ± 1.9

The gestational age on admission, cervical dilatation at PTL diagnosis, interval to delivery, and birth weight were not significantly different between T and C. Conclusion: Neonatal morbidity following delivery between 34 and 37 weeks' gestation is unchanged whether or not attempts to arrest labor are successful. The extra expense and maternal risk of tocolysis is not justified by beneficial results in the infant.

301 **PRETERM PREMATURE RUPTURED MEMBRANES IN THE TWIN GESTATION: A CASE CONTROL STUDY**

Montgomery DM[X], Perlow JH[X], Asrat T, Morgan MA, Bahado-Singh RO, Garite TJ Long Beach Memorial Womens Hospital, Long Beach, CA. University of California Irvine Med Center, Orange, California

The natural history of premature preterm ruptured membranes (PPROM) in the twin gestation has not previously been described. Therefore, we sought to describe the clinical course of PPROM in the twin gestation, and to determine if perinatal outcomes are similar in twin and singleton pregnancies complicated by PPROM. Over the previous decade, 80 sets of twins between 25-36 weeks estimated gestational age (EGA) presented with PPROM (TProm) to our institution. A control group (n=80) consisting of singletons matched for EGA at time of PPROM (SProm) was selected and perinatal outcome between groups was analyzed. Maternal demographic characteristics were not significantly different between groups. During the study period, our general management protocol for PPROM was expectant and did not include use of tocolysis, antibiotics, or steroids.

Outcome	Tprom(%)	Sprom(%)	P value
EGA at PPROM(Wk)	30.5 ± 4.5	30.3 ± 4.7	NS
Latency period			
<48 hr	70.0	65.0	NS
49hr-7da.	16.3	21.3	NS
>7da.	13.8	13.8	NS
Chorioamnionitis	18.8	23.6	NS
Fetal distress	0.05	0.14	NS
RDS	35.0	35.0	NS
Neonatal infection	18.8	21.3	NS
Neonatal death	11.3	13.8	NS

The natural history of PPROM in the twin gestation parallels that in the singleton pregnancy and suggests that similar antepartum management strategies are appropriate for both groups.

302 **A COMPARISON OF FIVE METHODS OF AMNIOTIC FLUID FETAL LUNG MATURITY TESTS: SENSITIVITY, SPECIFICITY, AND COST EFFECTIVENESS OF INDIVIDUAL VS. COMBINED TESTS.** **Chris T. Sloan, M.D.; Robert P. Lorenz, M.D.; Claire Michael, M.D.[X]; Division of Maternal Fetal Medicine and Department of Clinical Pathology, William Beaumont Hospital, Royal Oak MI and, Wayne State University**

OBJECTIVES: 1) To compare the sensitivity and specificity of commercially available rapid tests and chromatographic tests of fetal maturity and 2) propose an algorithm for cost effective utilization of tests. METHODS: A retrospective study of lecithin/sphingomyelin(L/S), phosphotidylglycerol(% PG)(Gluck method), FLM[R](Abbott TDx), Lumedex FSI[R](Beckman), and Amniostat[R](Hana), and newborn outcome was performed. Direct costs were estimated for materials and labor. RESULTS: 153 pregnancies (35.7 +/- 2.6 weeks gestation) were analyzed, respiratory distress syndrome occurred in 13 (8.5%). Diabetic pregnancies were analyzed separately. For nondiabetics (n=102), the number of studies, definition of maturity, sensitivity (for the outcome of RDS), and specificity for each test was: L/S n=80, 2.0, 92%, 88%; PG n=80, trace,75%, 79%; FLM n=91, >=60,100%, 85%; FSI n=67, >47, 80%, 66%; Amniostat n=39, ≥ 0.5, 67%, 55%. For diabetics (n=51): L/S n=48, 2.0, 100%, 94%; PG n=48, trace, 100%, 92%; FLM n=46, >=60, 100%, 87%; FSI n=41, >47, 100%, 68%; Amniostat n=23, ≥ 0.5,(sens=??(no RDS), 61%. Testing sequences were compared for sensitivity, specificity, and direct costs. CONCLUSIONS: This retrospective study suggests the least costly method is a first step using the FLM[R] (Abbott TDx), then an L/S and %PG only for the 26% that are immature by FLM. This method has a sensitivity of 90% , a specificity of 92%, and an average direct cost of $27.40 in our nondiabetics and should be prospectively studied.

303 THE EFFECT OF PHYSICIAN OFFICE VISITS ON UTERINE ACTIVITY AS DETERMINED BY HOME UTERINE MONITORING. T.L. Bennett, M.D. , P Winchester, M.D.[X] , B.E. Finley, M.D. , Humana Hospital of Overland Park, KS and University of Kansas Medical Center, Kansas City, KS

Life-style modifications, with limitation of both physical activity and mental-stress, are quite often an integral part of the management of the pregnant woman at risk for preterm delivery. In-office clinical evaluations necessitate that women at risk for preterm labor leave the home environment with a curtailment of prescribed rest. To determine the effect of physician office visits on uterine activity, home uterine monitoring records of 24 women at risk for preterm labor were retrospectively reviewed. The average activity was determined for the morning (AM) and the late afternoon (PM) for days with and without physician visits. No statistical difference was found between the AM uterine activity for days with and without physician visits. A statistically significant rise in uterine activity the PM after a physician office visit was seen when compared to the average PM activity for those days without such visits (paired t-test $p<0.02$). This increased activity tended to subside over the next 24 hours. In conclusion, uterine activity as recorded by home uterine monitoring, is increased subsequent to a prenatal office visit in those woman previously determined to be at risk for preterm delivery. The implications of this "white-coat labor" should be considered in protocols to evaluate and manage woman at risk for preterm events.

AVERAGE UTERINE ACTIVITY (Contractions in One Hour)

	No Physician Visit		Physician Visit	
	AM (n=24)	PM(n=24)	AM (n=24)	PM(n=21)
Mean	3.19	3.06	3.84	5.75
S D	1.53	1.96	2.54	3.74

304 **A RANDOMIZED COMPARATIVE TRIAL OF INDOMETHACIN AND SULINDAC FOR THE TREATMENT OF REFRACTORY PRETERM LABOR.** S.J. Carlan, W.F. O'Brien, T.D. O'Leary[X], D.S. Mastrogiannis[X]. Dept. Ob/Gyn, Univ. of South Florida College of Med. Tampa, FL

This study was designed to investigate the efficacy and safety of sulindac (clinoril) in the treatment of preterm labor. Thirty-six women in preterm labor who had failed initial attempts at tocolysis with magnesium sulfate were randomized to receive either oral indomethacin or oral sulindac for 48 hours. Mean gestational age at admission was 29 weeks and 30 weeks for the sulindac and indomethacin groups respectively. There was a significantly greater hourly fetal urine output, depth of deepest amniotic fluid pocket, and amniotic fluid index in the sulindac group. Fetal ductus arteriosus flow velocities were elevated in the indomethacin but not the sulindac group. The drugs had similar rates of success in delaying delivery for both 48 hours and 7 days. Mean birth weight was 2000 grams and 2323 grams for the sulindac and indomethacin group respectively. Sulindac appears to be as effective as indomethacin when used to treat refractory preterm labor, but with fewer fetal side effects.

(Mean ± SD)	Sulindac	Indomethacin	P
EFW at admission	1492 ± 384	1608 ± 453	NS
Cervical dilatation at admission	2.8 ± 1.7	2.8 ± 1.0	NS
Cervical dilatation after $MgSO_4$ failure	3.5 ± 1.5	3.6 ± 1.4	NS
Serum magnesium at randomization	5.9 ± .9	5.6 ± .9	NS
L/S	1.4 ± .5	1.4 ± .5	NS
Fetal urine production at 24 hrs. (cc)	15 ± 2	9 ± 2	<.001
Interval delivery 2 days	19 ± 24	24 ± 23	NS
Delivery delayed >48 hrs.(%)	88	83	NS
Delivery delayed >7 days (%)	55	61	NS
Umbilical artery pH	7.3 ± .07	7.3 ± .1	NS
Number of NICU days	25 ± 30	16 ± 26	NS

305 **A COMPARISON OF PREDISCHARGE SURVIVAL AND MORBIDITY IN SINGLETON AND TWIN VERY LOW BIRTHWEIGHT INFANTS.** E.J. Wolf, A. M. Vintzileos, T. Rosenkrantz[X], J.F. Rodis, L. Lettieri, A. Mallozzi[X], Univ. of Connecticut Health Center, Farmington, CT

The perinatal mortality rate of twins is 4 - 11 times higher than that of singletons and they are widely reported to have more morbidity than singletons, mainly due to higher preterm birth and anomaly rates. However it is not clear that liveborn preterm twins suffer greater morbidity than comparable singletons. In fact, twins have been reported to develop pulmonary maturity earlier than singletons and this might result in decreased morbidity relative to comparable preterm singletons. This retrospective review of 496 consecutive singleton and 104 twin infants weighing 500-1499 grams and born alive at 24 through 31 weeks gestational age was conducted to determine if predischarge survival and morbidity in VLBW twin infants were greater than that of comparable singletons. The mean (± SD) gestational age of the singletons was 27.5 (±2.0) weeks and for the twins was 27.6 (±2.0) weeks. There were no statistically significant differences in mean gestational age, gestational age distribution, mean birthweight, birthweight distribution, gender or race between the two groups. The predischarge survival rate for twins (77%) was not significantly less than that of singletons (82%). There were no statistically significant differences between twins and singletons in the incidence of neonatal respiratory distress syndrome (63 vs 71% respectively), pulmonary interstitial emphysema (14 vs 16%), patent ductus arteriosus (28 vs 29%), necrotizing enterocolitis (3 vs 5%), intraventricular hemorrhage (11 vs 16%), retinopathy of prematurity (11 vs 18%) or survival to discharge (23 vs 18%). The incidence of bronchopulmonary dysplasia was significantly less in twins (28%) vs. singletons (46%) (p=.001). These results suggest that very low birthweight twins do not necessarily suffer greater morbidity or mortality than singletons of comparable birthweight and gestational age and actually develop less bronchopulmonary dysplasia.

306 **DOES THE PREGNANCY COMPLICATION RESULTING IN PRETERM DELIVERY INFLUENCE PREDISCHARGE SURVIVAL AND MORBIDITY?** E. Wolf, A. Vintzileos, T. Rosenkrantz[X], J. Rodis, J. Mead, S. Gray[X], Univ. of CT Health Center, Farmington, CT.

This retrospective study was conducted to determine how the principal pregnancy complication leading to preterm delivery influences predischarge survival and morbidity of VLBW infants. The hospital records of 535 consecutive liveborn singleton infants weighing 500-1499 grams were reviewed and five primary complications resulting in preterm delivery were identified: 1) PROM (n=244 or 46%); 2) idiopathic preterm labor or PTL(n=97 or 18%); 3) Antepartum hemorrhage (n=58 or 11%); 4) PIH (n=98 or 18%); and 5) "other" indications (n=38 or 7%). Neonatal records were studied to determine the presence of RDS, bronchopulmonary dysplasia (BPD), pulmonary interstitial emphysema (PIE), PDA, NEC, IVH, retinopathy of prematurity (ROP) and infant death prior to hospital discharge. The mean (± SD) gestational age and birthweight were 27.9 (± 2.4) weeks and 1032 (± 263) grams, respectively. The EGA of infants delivered due to PIH (29.3 ± 2.0) and "other" indications (30.0 ± 3.1) was slightly greater than that of PROM (27.6 ± 2.2), PTL (26.8 ± 1.0) and hemorrhage (27.1 ± 1.9) infants ($p < .05$). There were no statistically significant differences in mean birthweight, race, and discharge survival rates (range 71-83%) between the 5 groups. Those delivered due to PROM developed significantly less RDS (63%), BPD (40%), and PDA (19%) than the PTL (77%, 57%, and 38%, respectively) or hemorrhage (81%, 59%, and 41%, respectively) groups ($p<.05$). The PTL group developed more PIE (26%) and IVH (31%) than the PROM (11% and 11%) or hemorrhage (9% and 13%, respectively) groups ($p<.05$). The PIH group developed more RDS (74%), PIE (20%) and PDA (35%) than the PROM group (62%, 11% and 19%, respectively) and developed less BPD (33%) and IVH (11%) than the PTL group (57% and 31%, respectively). In summary, the principal pregnancy complication resulting in preterm delivery significantly influenced predischarge morbidity but not predischarge survival of liveborns.

307 **TACHYPHYLAXIS TO RITODRINE IS DEPENDENT ON RITODRINE CONCENTRATION AND NOT ON MAGNITUDE OF BETA-ADRENERGIC RECEPTOR LOSS.** Ashi Daftary, M.D., Steve Caritis M.D., Jye Ping Chiao, M.S. University of Pittsburgh School of Medicine, Pittsburgh, PA

Infusion of ritodrine, for 24 hours, leads to a decrease in myometrial beta-adrenergic receptor (BAR) density. This is associated with a decrease in ritodrine's ability to maintain inhibition of oxytocin-induced myometrial contractions, i.e., tachyphylaxis. In order to determine if the magnitude of the receptor change is dose-dependent, we utilized an *in vivo* model to define the relationship between ritodrine concentration, myometrial BAR density, and loss of contraction inhibition. Ritodrine was infused continuously for 24 hrs in 27 chronically-catheterized sheep (GA 110-120 d; term=147d). Myometrial biopsies were obtained before and after the infusions and receptor density was quantified using standard techniques with tritiated dehydroalprenolol. Intermittent oxytocin boluses of 500 mu were given into the aorta and uterine response was measured. Infusion rates between 0.12 and 4.0 μg/kg/min yielded ritodrine concentrations from 3 to 156 ng/ml. No significant correlation was found between ritodrine concentration and the magnitude of decrease in BAR density ($R^2=0.137$, $p>0.05$); the average decrease in BAR density was 34%. Loss of BAR did not reduce ritodrine's ability to inhibit oxytocin-induced uterine contractions. Ritodrine did, however, lose it's effectiveness when plasma concentrations exceeded 40 ng/ml. Thus, tachyphylaxis to ritodrine is dependent on the ritodrine concentration and not the magnitude of BAR loss.

308 IMPROVING LONG TERM MENTAL AND NEUROLOGIC OUTCOMES IN INFANTS < 1500 G OVER PAST 5 YEARS. W.J. Morales, D. Hurford, S. Schorr, Orlando Regional Medical Center, Orlando, FL

Over 10 year period, 1981-1991, 1,605 infants < 1500 g were admitted to NICU and of these 809 were born in the second half of the decade. Mental and neurologic examinations were performed on 603 infants at corrected one year of life, 300 born from 1986-1990. The mean birth weight was 796 gm for the first 5 years as compared to 809. While no significant improvement was achieved in the last 5 years in neonatal survivor (88 vs 85%), RDS (59 vs 59%), ROP (27 vs 22%) and NEC (2 vs 2%), there has been a significant decrease in the incidence of BPD (23 vs 16%), IVH - total (43 vs 30%), IVH - grade 3, 4 (21 vs 12%) and more importantly, in the proportion considered to have NORMAL development - (MDI and PDI>80, no blindness or chronic lung disease or cerebral palsy) - 66% vs 79%. These encouraging findings remain valid when groups were compared at different birth weight groups < 750 g, 750-999 g, 1000-1249 g, 1250-1500 g. Improved long term neonatal outcomes were related to antenatal combined with neonatal pharmacology therapy in the form of combined steroids and TRH along with artificial surfactant in addition to advances in perinatal and neonatal outcome.

309 CLINICAL DECISION ANALYSIS IN PRETERM PREMATURE RUPTURE OF THE MEMBRANES. Bebbington, Michael W. Grace Hospital, Vancouver B.C. Canada.

Preterm premature rupture of the membranes (PPROM) is responsible for a significant amount of perinatal morbidity and mortality. There are no consistent guidelines that help to answer the question; At what gestational age should delivery take place when presented with PPROM? A non-recursive decision analysis model was developed to answer this question. Analysis was carried out for three separate gestational ages; 26, 30 and 34 weeks. Utility values were determined for each of the outcomes using a standard gamble technique. Probability values for each branch of the model were determined using values from data at our institution. As expected, at 26 weeks the model preferred the conservative therapy option, while at 34 weeks, the immediate delivery option was preferred. At 30 weeks, the preferred treatment option varied with how the patient ranked the outcomes of pregnancy prolongation and intact survival of the newborn. If preference was given to prolonging the pregnancy the model preferred conservative therapy whereas if intact survival was given priority then the immediate delivery option was preferred. This study shows the value of clinical decision analysis in perinatal medicine and the importance of patient input into management decisions.

310 THE EFFECT OF SUBCUTANEOUS TERBUTALINE INFUSION ON UTERINE ACTIVITY IN PATIENTS AT RISK FOR PRETERM DELIVERY. P.J. Weinbaum AND M. Olson, Dept. OB/GYN, Albany Medical College, Albany, N.Y. AND Healthdyne, Inc., Marietta, GA.

Continuous subcutaneous infusion of Terbutaline via pump (T-pump) has recently been utilized as tocolytic therapy for ambulatory management of preterm labor. The concomitant use of home uterine activity monitoring allowed us to examine the effect of T-pump therapy on the pattern of uterine activity. A group of 202 patients at risk for preterm delivery were monitored for a minimum of 10 days prior to the onset of preterm labor and tocolytic therapy. The mean gestational age (GA) at the initiation of monitoring was 28.5 wks. and 30.1 wks. at start of T-pump. Mean frequency of uterine contractions over that 10 day period was 3.3/hr., with an increase to 6.6/hr., over the final 72 hrs. This increase in uterine activity was associated with an increase in subjective symptoms and/or cervical change in the majority of patients. T-pump was initiated and over the first 24 hrs. mean uterine activity was significantly decreased to 3.3/hr. With appropriate alterations in either bolus or basal infusion dosage, contractions were maintained at a mean of 3.9/hr. over the duration of T-pump therapy lasting an average of 4.9 wks. Repeat hospitalization for excessive uterine activity unresponsive to home manipulation of T-pump occurred in only 9.6%. Mean GA at delivery was 36.2 wks. and 70% of patients completed 35 wks. This study confirms the observation of a significant increase in monitored uterine activity shortly before the onset of preterm labor. It also suggests that T-pump rapidly and effectively decreases mean uterine activity and sustains this effect delaying delivery for a clinically significant period.

311 EXPANDED PUBLIC FINANCING OF PRENATAL CARE: IMPACT ON BRONX PRETERM BIRTHS 1985- 1989. JE Deaver, Albert Einstein College of Medicine (AECOM), Dept Ob/Gyn, Bronx, New York.

There have been few rigorous birth outcomes evaluations of policies designed to reduce financial barriers to utilization of prenatal care. The New York State Prenatal Care Assistance Program (PCAP), from 1985-1989, provided prenatal care to women lacking health insurance with incomes between 100% (the Medicaid limit) and 185% of the poverty level. The present study hypothesizes that PCAP-eligible patients who were not enrolled in the program (i.e. self-pay) had increased rates of preterm birth compared to PCAP enrollees. Prenatal, birth outcome, and PCAP enrollment data in the POPRAS database of the AECOM were linked using Oracle and Structured Query Language (SQL) to produce 11,013 complete records. Logistic regression analysis with SPSS determined that self-pay status was a significant predictor of preterm birth (p=0.0354, odds 1.38) along with previous preterm birth (p=0.00005, odds 1.95) and delivery in the impoverished South Bronx (p=0.00005, odds 2.14) while age, race, ethnicity, gestational age at onset of care, location of prenatal care, and program year were not predictive. Selection bias is an important consideration with respect to interpretation of these data since the assignment to PCAP versus self-pay was not random. However, it appears that eligible patients who did not participate in a public prenatal care financing program experienced increased rates of preterm birth compared to participants even while all other factors were controlled.

312 **AMNIONIC FLUID INDEX AND PREGNANCY OUTCOME IN PATIENTS WITH PREMATURE RUPTURE OF THE MEMBRANES.** M.Hussey*, N.Carlson, R. Besinger, J.Gianopoulos, Loyola Univ. Med. Ctr., Maywood, IL.

Retrospective analysis of 127 singleton pregnancies with premature rupture of membranes (PROM) between 25 and 35 weeks gestation was performed. Patients included presented within 72 hours of rupture and had no evidence of labor, infection, bleeding or fetal distress. Patients who received tocolysis or corticosteroids were excluded. Patients were divided into three groups based on their four quadrant amniotic fluid index (AFI) at admisssion. Complications and outcome (severe variable decelerations (SVAR), amnionitis, latency period, 1 and 5 minute Apgar scorus less than 7) were compared. There was no difference in incidence of cesarean section (C/S), birth weight or perinatal mortality.

	GROUP 1	p (1,2)	GROUP 2	p (2,3)	GROUP 3	p (1,3)
AFI (CM)	< 4		≥4,<8		≥8	
N	59		52		16	
(%)	(46.5)		(40.9)		(12.6)	
LATENCY (DAYS)	1.6±.16	≤.01	3.0±.58	≤.01	14.6± 1.6	≤.01
SVAR	23.7%	≤.005	7.7%	≤.005	0	≤.005
C/S	49.2%	NS	32.7%	NS	37.5%	NS
AMNION-ITIS	18.6%	NS	11.5%	<.01	0	<.01
1 MIN APGAR<7	52.5%	≤.005	9.6%	≤.005	0	≤.005
5 MIN APGAR<7	8.5%	≤.005	0	≤.05	0	≤.005

Conclusion: Initial AFI in patients with preterm PROM is predictive of unfavorable pregnancy outcome as defined by shortened latency period, severe variable decelerations during labor, amnionitis, and low 1 and 5 minute Apgar scores. C/S rates were increased in all groups.

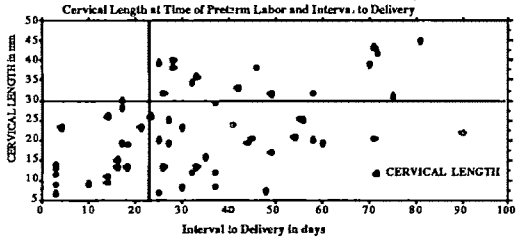
313 **DOES "IDIOPATHIC PRETERM LABOR EXIST?"** L. Lettieri, A. Vintzileos, M. Albini[X], M. Martins[X], C. Salafia[X], J. Mead, Univ. of CT Health Center, Farmington, CT.

Williams Obstetrics (18th Edition) states: "In the majority of instances, the precise cause or causes of labor before term are not known." In an effort to elucidate possible causes of preterm labor, we undertook a prospective study of all patients with a singleton pregnancy (23-36 weeks) admitted with preterm labor and intact membranes requiring tocolysis. A comprehensive evaluation plan was instituted including a detailed history and physical examination, targeted ultrasound, amniocentesis for gram stain, culture and glucose, laboratory analysis for infection (CBC, C-reactive protein, urinalysis, cervical, urine cultures) and for antiphospholipid antibody syndrome (ANA, LA, ACA), pathological examination of the placenta, urine toxicology screen and a 12 week postpartum hysterosalpingogram. Thirty consecutive patients who eventually had a preterm birth constitute the focus of this report. The mean gestational age at admission was 29.3 weeks and the mean cervical dilatation was 2.8 cms. The following possible causes of preterm labor were identified: intrauterine infection 14/30 (47%), faulty placentation (abruptio/previa) 12/30 (40%), immunological 10/30 (33%), uterine (uterine anomalies, hydramnios) 6/30 (20%), cervical incompetence 5/30 (17%), maternal (systemic infection, preeclampsia, drug intoxication, etc.) 3/30 (10%), fetal anomalies 2/30 (7%), trauma/surgery 1/30 (3%) and idiopathic 1/30 (3%). Of the 30 patients, 17 (57%) had 2 or more possible causes, 12 (40%) had one cause and only 1 (3%) had no cause identified. As compared to other causes, cervical incompetence and intrauterine infection were associated with a lower mean gestational age at admission and delivery (ANOVA, p<.05). Pregnancy prolongation, gestational age at admission and delivery, birthweight and Apgar scores were not different between patients having one vs. two or more possible causes. We suggest that an exhaustive evaluation can identify possible causes in the overwhelming majority of "idiopathic" preterm labor.

314 **WEST LOS ANGELES PRETERM BIRTH PREVENTION PROJECT (LAPPP): PROGRAM IMPACT.** C.J. Hobel, M.G. Ross, R.L. Bemis[X], J.R. Bragonier[X], M. Bear[X], B. Mori[X], Dept. Ob/Gyn, Cedars-Sinai Med. Ctr. and Harbor-UCLA Med. Ctr., Los Angeles, CA.

The LAPPP is the first prospective randomized controlled trial using a risk scoring system derived from the same population to test education (ED) plus selected interventions. Eight West LA clinics were randomized to form 5 experimental (EXP) and 3 control (CTL) clinics. From Sept. 1983 to Dec. 1988 2084 high-risk patients in the EXP clinics received a program of special ED and frequent visits and each were randomized to a selected intervention (bed rest, psychosocial counseling, oral Provera, a matched placebo and an internal control/special ED alone). There was an 18.8% reduction in preterm births (<37 wks) in the EXP clinics vs. CTL clinics [7.38% vs. 9.09% (p=0.063)]. None of the selected interventions had an effect greater than the internal control/special education alone. However, high-risk patients receiving bed rest had the lowest rates for very low preterm births [<31 wks (p=0.074)]. We believe that the 18.8% reduction in preterm births is due to the overall program effect of special education, frequent visits and the greater attention given patients while applying the selected interventions. Even though the statistical evidence is borderline, the interpretation of these findings should be judged on clinical and biological plausibility and cost effectiveness (see Abstract: Ross, et. al.). Supported by State of California Dept. Health Services, Maternal Child Health Branch.

315 EFFICACY AND SAFETY OF RITODRINE WITH INTRAVENOUS OR INTRAMUSCULAR ADMINISTRATION. Steve N. Caritis, M.D., Karen Leonhard, R.N.[X], Peggy Cotroneo, R.N.[X], Jye Ping Chiao, M.S.[X], University of Pittsburgh, Magee-Womens Hospital, Pittsburgh PA



Ritodrine is equally effective in treating preterm labor whether administered intravenously or intramuscularly (Gonik, et al AJOG 159:323, 1988). The two regimens, however, have not been specifically compared in regards to side effects particularly when the dosing regimens are kinetically optimized. We compared these two regimens in 83 pregnant women in preterm labor. The dosing regimens were based on kinetic data in pregnant women. (AJOG 162, p. 429 and 1215, 1990) Significantly, fewer women experienced one or more side effect (SE) with the intramuscular regimen than with the intravenous regimen (p<0.004). Efficacy was comparable in the two groups.

	I.M.	I.V.
SUBJECTS	44	39
With chest pain	2	7
With shortness of breath	5	2
With vomiting	3	6
With heart rate >130 bpm	6	18
With diastolic BP <40mmHg	12	18
With 1 or > of above SEs	18 (41%)	29 (74%)*
With failed therapy	16 (36%)	16 (41%)

I.M. administration of ritodrine offers advantages over I.V.

316 ULTRASOUND ASSESSMENT OF CERVICAL LENGTH (CL) IN PRETERM LABOR (PTL). J Paraskos*, M Waxman*, F Johnson*, J Teteris*, J Iams. The Ohio State University Department of Obstetrics & Gynecology, Columbus, OH

Studies of PTL therapy are complicated by imprecision in diagnosis. We performed transvaginal ultrasonic measurement of CL in 60 women with PTL treated with parenteral tocolysis between 24 - 34 weeks. Measurements were obtained as soon as possible after completion of parenteral medication. Each patient was examined once. Findings were not available for clinical care. Mean gestational age at examination was 31.0 ± 2.6 weeks. Mean CL was 2.2 ± 1.37 mm, range 6.6 - 45.0 mm. CL correlated with interval from admission to delivery(r= 0.48 , p=0.0001,by logistic regression analysis). No patient whose CL was ≥ 3.0 cm had an admission to delivery interval of <21 days. Digital assessment of CL also correlated with interval to delivery (r=0.43, p=0.0006), but was less clinically useful because there was no clinical cutoff to predict low risk of preterm delivery. Ultrasound assessment of CL is useful in PTL to select a group at low risk of preterm birth. Transvaginal scanning may improve the accuracy of diagnosis of PTL.

317 AGGRESSIVE PERINATAL INTERVENTION BASED ON GESTATIONAL AGE DERIVED MORTALITY RATES. L.M.Lopez ,[X] S.B. Effer, M. Whitfield, [X] Division Maternal Fetal Medicine, University of British Columbia, Grace and BCCH Hospitals, Vancouver, Canada.

The aim of the study is to present outcome data, specific to each week of gestation, focusing on weeks 23 to 28, adjusting for potential confounders and with enough power and precision to use in both clinical management, decision making, and counselling patients, appropriately informed. All births between 23 and 28 completed weeks gestation, born in Grace Hospital, Vancouver, during 7-year period from January 1983 to December 1989, were included for analysis. Gestational age errors present in 34.3 % of the patients were corrected by early ultrasound reports available in 88.3% of patients. Neonatal mortality was calculated for each week of gestation (Table I).The effects on neonatal mortality of : fetal sex, use of steroids, premature rupture of membranes (PROM) , and delivery mode in breech presentation were statistically analyzed for each week of gestation. Significant difference was found in : fetal sex at 27 and 28 weeks; PROM at 27 weeks; delivery mode in breech at 25 weeks ; and steroids at 28 weeks. Long term follow up in this population was limited to survivors with birthweight under 800 grams. Major disability decreased in frequency in each week from 23 to 26 weeks ((71.4% to 10.0%) with a dramatic increase at 27 weeks (50%). This , we postulate is due to the fact that 27 weeks survivors who weighted less than 800 grams , have a major degree of IUGR. We conclude that these mortality rates, coupled with known severe degree of disability should deter us from recommending aggressive measures with major risks to mother, with no significant fetal benefit, at gestational ages less than 25 weeks.

Table I - Neonatal Mortality - 1983-1989 Grace Hospital -Vancouver, B.C.

Weeks	total	LVB		SB		NN. SURV.		NN. MORT. RATE
	N	N	%	N	%	N	%	%

318 **CERVICAL DILATION IS THE BEST PREDICTOR OF RISK FOR PRETERM BIRTH** J. Smeltzer, J. Lewis,[X] P. VanDorsten, D. Cruikshank, Depts. OB/GYN, Medical College of Virginia, Richmond, VA, Washington University, St. Louis MO

Preterm birth is the most important cause of death and disability of the normally-formed infant. Interventions to prevent preterm birth must be able to identify those at highest risk. To evaluate the importance of the factors which can lead to preterm birth, data on social, historical and current pregnancy risk factors were collected from 971 patients with 1067 consecutive pregnancies referred to a special treatment clinic by city public clinics for fixed criteria. Of these, 981 participated at or after 25 weeks, with 63786 days of observation from 25 to 37 weeks. Complete data were available on 973 (99.2%). Cervix exam data were prospectively collected semi-weekly to 34 weeks on outpatients. Intensive treatment was used to 34 weeks. There were preterm labor or ROM in 40.8%, and birth in 30.1%, perinatal death in 10.4 per 1000. The effects of the factors were estimated in a stepwise fashion by a censored regression iterative least squares (ILS) model on cohorts by weeks at exam. Of social, historical and pregnancy scores, only twins had a consistent effect. Cervix dilation at the internal os was a consistent predictor of a shortened pregnancy across gestational ages. Other parts of the exam were much less important, but of expected direction.

Effect of factor on mean interval to delivery

Week, (n)		Dilation	Length	Station[1]	Twins
		days/cm	*days/cm*	*days/score*	*days*
27	(202)	-10.148[c]	5.094[b]	-8.027[b]	-18.218[a]
28	(336)	-5.087[c]	2.283	-0.524	-4.088
29	(313)	-9.164[c]	2.535	-3.570	-20.535[a]

319 **EARLY CERVIX DILATION WARNS OF PRETERM LABOR** J. Smeltzer, J. Lewis[x], D. Cruikshank, P. VanDorsten
Depts. OB/GYN, Medical College of Virginia, Richmond, VA, Washington University, St. Louis MO

Effective treatment of preterm labor requires its early recognition. Only when the condition is recognized prior to advanced cervical dilation or rupture of membranes can the labor be effectively arrested. Home uterine monitoring and periodic clinic monitoring are available for this purpose. Their high cost and low specificity make them useful only for high-risk groups. Most preterm births occur in women without prior risk factors. An ideal system would be low cost and identify most of those with truly high risk. Hendricks described an exponential increase in cervix dilation in the weeks prior to labor in term patients. This study addresses the ability of cervix exam to predict new onset preterm labor from 26 to 36 weeks gestation. Cervical exams were recorded semi-weekly in this period from 2070 exams of 842 pregnancies at risk for preterm birth but with no preterm labor in the index pregnancy. Data were analyzed using a regression model for censored data by weekly cohort. Independent variables were social risk score, obstetric history, twins, cervix consistency, station, length, and dilation. Other variables' coefficient estimates were weaker and inconsistent, but cervix dilation had a strong, consistent effect on time to spontaneous labor. Controlled for all other variables, the estimated change in mean time to labor ranged from -5.09 days/cm dilation at 32 weeks gestation to -13.39 days/cm at 27 weeks, with high estimates at early ages (p <.0001). The power of cervix dilation alone to predict preterm labor in this sample was computed by week from exam for exams <31 weeks.

Labor before end of week=>	1	2	3	4
Sensitivity	.603	.524	.457	.419
Specificity	.771	.778	.781	.783
Positive predictive value	.157	.217	.263	.308
Negative predictive value	.965	.933	.893	.858

Cervix dilation predicts most labors within two weeks of exam.

320 **A NEW MODEL FOR PRETERM BIRTH RISK ESTIMATION.**
J. Smeltzer, Dept. OB/GYN, Washington Univ., St. Louis, MO

Clinical studies of preterm birth risk suffer from two problems:

1. Censored observations: patients who withdraw by induction of labor for unrelated reasons or leave the study, because exclusion and inclusion both bias the study results.
2. No statistical model of delivery time to permit both control for the effects of multiple factors and estimation of risk.

The proportional hazards model of Cox (PH) meets the first problem, but can not be used for risk projection. The iterative least squares regression model with censoring (ILS) of Schmee and Hahn estimates risk directly and shows factor effects in days. ILS was tested versus PH in a simulation with three independent factors of prevalences of 50%, 30%, and 10% and effects of -2, -10, and -5 days on a normal random variable with mean = 25 days, S.D. = 7 days, n = 200, over 50 trials. This was repeated with a random censoring of 1% per day. Power of ILS was compared with PH at alpha=.05. Results for percent power and censored mean estimation are:

Effect, prevalence=>		-2 days, 50%	-10 days, 30%	-5 days, 10%
Power	ILS	56%[!]	100%	98%[*]
(No censor)	PH	44%	100%	92%
Power (censored	ILS	60%[!]	100%	98%[!]
1% per day)	PH	36%	100%	86%
ILS Mean ± S.E. d.		-2.132±.153	-10.111±.180	-5.194±.223

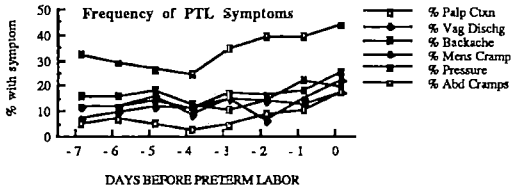
[*]p<.05 [!]p<.01, better than PH by exact test

The ILS model is more powerful than PH and not biased under these conditions. ILS assumes a normal survival distribution, and linear effect of the factor. A study population of 1067 pregnancies with risk for preterm birth was tested for these assumptions using interval to delivery by cervical exam of cohorts by weeks gestation at exam. The normal survival model fit the data best of the six tested. Estimates and residuals were normally distributed, homogeneous, and met model assumptions. ILS is ideal for estimating birth risk with censoring during the third trimester, simultaneously controls for multiple risk factors, and yields understandable results.

321 EFFECT OF TIME AND TEMPERATURE ON AMNIOTIC FLUID GLUCOSE CONCENTRATION. W. Meyer[X], D. Gauthier[X], A. Bieniarz, University of Illinois, Chicago, IL.

Amniotic fluid glucose concentration (AFGC) has been used to detect intraamniotic infection. However, immediate analysis of AFGC may not always be practical. The purpose of this study was to determine the effect of time and temperature on AFGC. METHODS. Amniotic fluid was obtained from patients with preterm labor or preterm rupture of membranes who underwent amniocentesis to assess for infection. Twenty samples were kept at 37°C, 13 samples were frozen (-20°C). Baseline and 12 hour AFGC was determined on all samples. AFGC was assessed at 2,4, and 6 hour intervals on unfrozen samples. Aerobic, anaerobic, and mycoplasma cultures were performed on all samples. Paired T-test was used for analysis. RESULTS. In noninfected samples, a decrease of ~7% (1-3 mg/dl) in AFGC was noted over 12 hours at 22°C and 37°C (p=NS). In samples with positive cultures, AFGC decreased ~54% over 2 hours (p=0.016) but then remained stable. AFGC was unchanged from baseline levels in frozen samples regardless of culture results. CONCLUSION. AFGC IN NONINFECTED SAMPLES DID NOT CHANGE OVER 12 HOURS AT ANY OF THE 3 TEMPERATURES TESTED. THIS QUALITY OF AFGC MAY BE HELPFUL IN DIFFERENTIATING NONINFECTED FROM INFECTED SAMPLES.

322 **PREDICTING PRETERM LABOR AND BIRTH**
G. Ashmead. M. Krew[X], J. Ashmead[X], L. Mann, S. Amini[X], C. Sulzman[X], L. Fradley[X], E. McKelvey[X]. MetroHealth Medical Center, Cleveland, Ohio.



An ongoing prospective study of pregnant women with past preterm deliveries without uterine anomalies or medical problems was initiated in order to develop a possible predictive model for preterm delivery. Creasy scores, cervical cultures, vaginal ultrasounds, weekly uterine activity monitoring, vaginal pH, and cervical Bishop were obtained (20-37 weeks) from 314 weekly observations on 20 patients (8 preterm, 12 term). Preterm patients had 1 ± 1.5 contractions (mean ± standard deviation) initially and 3.3 ± 3.2 prior to delivery (within one week). The initial Bishop score was 2.4 ± 1.8 and 6 ± 3.3 prior to delivery. Full term patients had no contractions initially and 4.5 ± 5.7 prior to delivery. The initial Bishop score was 1 ± .75 and 5.4 ± 2.6 prior to delivery. Differences between cumulative Bishop scores and cumulative contractions in preterm and term groups were statistically significant after 32 weeks gestation. These initial results encourage continuation of the study. Supported by NIH #RR00210-26.

323 PLACENTA PREVIA: DOES PRETERM LABOR CAUSE BLEEDING?
E.F. Magann,[X] C.A. Johnson,[X] K.S. Gookin,[X] W.E. Roberts, R.W. Martin, J.C. Morrison, Dept. Ob/Gyn, Univ. Mississippi Med. Ctr., Jackson, MS

Objective: Determine if an increase in uterine activity (UA) precedes bleeding in patients with placenta previa (PP). Patient Population: This descriptive study involves 22 women > 24 weeks with total PP. Because of other risk factors for preterm birth (PTB) (multifetal gestation, prior PTB due to PTL, etc.), they monitored UA for 2 hours per day and received daily phone contact by perinatal nurses (Tokos Medical Corp., Santa Ana, CA) in addition to regular high-risk care. Monitoring began at 26.3 ± 4.4 weeks' gestation and continued until 37 weeks (or delivery if preterm). Compliance with monitoring requirements, confirmation of PP, and a documented bleeding episode after monitoring began (and before PTL) were inclusion criteria. Main Outcomes Measured: Number of patients with PTL, number of bleeds, early delivery due to bleeding, gestational age at delivery, and UA for the week prior to bleeding. Results: Of the 22 patients, two had documented PTL. All subjects had at least one bleed, 7 women had two bleeds, and 4 subjects had three episodes of bleeding. Only three patients delivered at term while the remainder (86%) delivered preterm. The gestational age at first episode of bleeding was 29.1 ± 3.6 weeks and at delivery was 34.3 ± 3.3 weeks. Nine women (41%) had an increase in UA above baseline the day of or the day preceding the first bleed. The increase in UA was not statistically significant when compared to the 6 days prior to bleeding when all 22 patients were considered. Eleven patients were prescribed prophylactic tocolytic drugs during pregnancy but there was no alteration of UA or in the relationship to bleeding in these subjects. Conclusion: This data suggests that bleeding from PP in some cases may be due to increased UA but may also be associated with thinning of the lower uterine segment and detachment of the anchoring villi without UA.

324 PROSPECTIVE EVALUATION OF SYMPTOMS (Sx) PRECEDING PRETERM LABOR (PTL): J D Iams, M Parker*, FF Johnson*, The Ohio State University Department of Obstetrics & Gynecology, Columbus, OH.

The clinical utility of reported Sx in diagnosing PTL is controversial, based on studies of patient recall. No prospectively collected data about PTL symptomatology has been published. During a trial of an ambulatory contraction monitor, we collected information prospectively about several common Sx of PTL. Data were obtained by daily telephone contact with subjects at risk of preterm birth who had not had PTL in the current pregnancy. Fifty seven women developed PTL. Their answers to a standard battery of yes/no questions for the 7 days preceding their admission for parenteral tocolysis form the basis of this descriptive report. There is a 2 to 3 day period prior to PTL in which several common Sx, (self-detected contractions, vaginal discharge, menstrual cramps and backache), are seen to occur with increased frequency. These Sx are common in normal pregnancy, and are unlikely to be individually predictive of PTL. However, the persistence of these Sx, especially in combination, should prompt an office visit for cervical examination and uterine activity monitoring.

326 **A PROSPECTIVE RANDOMIZED CLINICAL TRIAL COMPARING A NEW ORAL SUSTAINED RELEASE RITODRINE VERSUS CONVENTIONAL RITODRINE TABLETS** Zion Hagay[X], M. Epstein[X], Z. Gotlib[X], C. Goldchmit[X], I. Blickstein[X], A. Mazkel[X], V. Insler[X] and E.A. Reece*, Kaplan Hospital, Rehovet, Israel and *Temple University School of Medicine, Philadelphia, PA

Oral conventional ritodrine (OCR) therapy requires multiple daily doses. A new sustained-release (SR) form of ritodrine was introduced which allows a reduction in the frequency of drug intake. Although, such may improve compliance and efficacy it remains unknown whether this presumed benefit is at the expense of increase cardiovascular side effects. **MATERIALS AND METHODS:** All patients (mean GA: 30.7±3 weeks) admitted to the study had successful IV tocolysis. Patients were randomly assigned to treatment that consisted of either 10 mg of OCR administered every 8 hours (80 mg/day) or one 40 mg SR capsule administered every eight hours (120 mg/day). The first oral treatment course lasted 5 days in each patient and then was switched to a second oral treatment course of the other drug for another 5 days. Every patient underwent non-invasive hemodynamic evaluation on days 4 and 9 of therapy. **RESULTS:** In this ongoing clinical trial, 18 patients were studied. Hemodynamic parameters assessed included: shortening fraction (SF), left ventricle ejection fraction (LV-EF), left atrial diameter (LAD), heart rate (HR) and changes in cardiac axis. Results are presented in Table 1.

Hemodynamic Parameter	During OCR Therapy	During SR Therapy
SF (mm)	0.60 (±0.123)	0.55 (±0.125)
LV-EF (%)	67 (±9.08)	69 (± 5/47)
LAD (mm)	34.4 (±2.5)	31.8 (±2.1)
HR (beats/mm)	108 (±19.2)	104 (±10.2)
Cardiac Axis (degree)	44.0 (±20.7)	46 (±26.0)

* Statistical analysis, t-test for paired samples. **CONCLUSION:** This preliminary results show no significant differences in maternal hemodynamic responses during treatment with the new S.R. form (120 mg/day) as compared to conventional ritodrine therapy.

325 PROLONGATION OF TWIN PREGNANCY WITH MAGNESIUM SULPHATE/SUBCUTANEOUS TERBUTALINE PUMP THERAPY IN THE FACE OF ADVANCED CERVICAL DILATATION AND EFFACEMENT, Robert N. Wolfson, M.D./Ph.D, Sandra K. Winn[X], B.S.N., R.N. Memorial Hospital, Colorado Springs, CO

The literature suggests that tocolytic efficacy is lost when there is advanced cervical dilatation and effacement. Since January, 1989 nine sets of twins have been treated in advanced preterm labor (cervical dilatation ≥ 3 cm. and cervical effacement ≥ 80%) with aggressive acute magnesium sulphate tocolysis followed by subcutaneous terbutaline pump therapy. On admission median cervical dilatation was 3.7 cm. (range 3-5 cm.) Median cervical effacement was 90% (range 80-100%) and median gestational age was 31 weeks (range 27-34 weeks). All patients received 72 hours of magnesium sulphate tocolysis, median maximum magnesium maternal serum level 6.4 mg/dl (range 4.2-9.5 mg/dl) and were transitioned to subcutaneous terbutaline pump therapy, median basal infusion rate 0.106 mg/hr, (range 0.088-0.15 mg/hr). Median duration of pump therapy was 14 days, (range 12-29 days). All patients received betamethasone therapy for enhancement of fetal lung maturity and antibiotic prophylaxis for beta-hemolytic Strep. One patient delivered preterm after discontinuing therapy against medical advice. Of the remaining eight, six (75%) achieved either 37 weeks or mature lung indices on amniocentesis. The two preterm births occurred at 29 and 32 weeks gestation after 12 and 14 days of pump therapy respectively. We conclude from this preliminary experience that twin pregnancies complicated by advanced preterm labor can often be prolonged to fetal lung maturity through the use of subcutaneous terbutaline pump therapy.

327 NIFEDIPINE VS. RITODRINE AS TOCOLYTIC AGENTS. Gustaaf A. Dekker MD PhD*, Karin van Dijk*, and Herman P. van Geijn MD PhD* Dept. of Obstetrics, Free University Hospital, Amsterdam, The Netherlands

The effectiveness of ritodrine in the treatment of premature labour remains controversial. In most patients treated with ritodrine tachyphylaxis develops in 2-4 days probably because of homologous receptor regulation and/or induction of cyclic nucleotide phosphodiesterase activity. Nifedipine is effective as smooth muscle relaxant and at the same time has low toxicity and teratogenicity. In the current retrospective study the results of nifedipine (N = 33) in the treatment of premature labour were compared with a control group treated with ritodrine (N = 36). The 2 groups were comparable with regard to parity, age, and gestational age at initiation of therapy. Nifedipine was found to be considerably more succesful in halting labour than ritodrine. The average (± SD) prolongation of pregnancy was in the nifedipine treated women 36,3 days (SD 42,1) vs. 8.9 days (SD 15,2) in the women treated with ritodrin. In the ritodrine group all patients delivered before 34 weeks' gestation. In contrast in the nifedipine group delivery could be postponed till > 34 weeks' gestational age in 8 patients. Side effects with nifedipine were minimal, patients treated with ritodrine demonstrated well known side effects such as nausea, vomiting, palpitations and malaise. Treatment for a patent ductus arteriosus was needed in 18 neonates in the ritodrine group and in only 6 neonates in the nifedipine group. A prospective study has been initiated to assess the definite clinical value of nifedipine as tocolytic agent.

328 **COMPARING THE EFFICACY OF AGGRESSIVE PRETERM LABOR PREVENTION PROGRAM USE BEFORE AND AFTER THE ONSET OF PRETERM LABOR AMONG HIGH AND LOW-RISK PATIENTS.** A.W. Cohen, I. Forouzan, C. Lindenbaum[X], W. Mulla[X], Dept. Ob/Gyn, University of Pennsylvania Medical Center, Phila., PA

The role of home uterine activity monitoring (HUAM) in the prevention of preterm labor and delivery remains a controversial issue. A retrospective review of 245 patients (divided in 3 groups) was conducted. Initially 156 patients were identified at high-risk for preterm labor (PTL), and were started on a preterm labor prevention program including HUAM. Group A consisted of 46 (29.5%) patients from this high-risk population who developed PTL during the index pregnancy. The remaining 110 (70.5%) patients who did not develop PTL were designated as Group B. Group C consisted of 89 patients who initially were classified as low-risk, but developed PTL, and were enrolled in the "program". The proportion of patients who successfully delivered at >37 weeks of gestation was significantly lower in Group A than Groups B and C (41.3% vs. 70% and 66.3% respectively) (P<0.05). The proportion of patients who delivered at gestational ages ranging 29-34 weeks was significantly higher in Group A than Group B (23.9% vs. 7.3%) (P<0.05). We conclude that despite the application of the "program" including HUAM, a significant proportion of high-risk patients will ultimately develop PTL and eventually deliver at <37 weeks and especially at 29-34 weeks gestation.

329 WEST LOS ANGELES PRETERM BIRTH PREVENTION PROJECT (LAPPP): COST BENEFIT OF HIGH RISK PREGNANCY INTERVENTIONS. M.G. Ross, M. Sandhu[X], R. Bemis[X], S. Nessim[X], J.R. Bragonier[X], B. Mori[X], C.J. Hobel. Dept. of Ob/Gyn, Harbor-UCLA and Cedars Sinai, Los Angeles, CA.

Despite intensive investigation, preterm delivery remains the major cause of neonatal morbidity and mortality. The LAPPP, a randomized, controlled study of preterm birth prevention, achieved an 18.8% reduction in the incidence (9.1%) of preterm, singleton births among high risk patients (31% of patients). To evaluate the cost-benefit of the high risk interventions, maternal and neonatal care data were collected on all preterm deliveries (159) and a random sample of term deliveries (140) from high risk patients in control and experimental clinic sites. Costs were determined for prenatal care, inpatient preterm labor, delivery and postpartum care, and newborn inpatient care. The LAPPP experimental clinics resulted in additional maternal prenatal care ($261) and preterm labor inpatient ($127) costs per high risk patient than the control clinics, although delivery and postpartum costs were similar. Experimental clinic high risk patients had an average cost savings of $1,708 for newborn care (p=0.02) resulting in a net savings of $1,320 per maternal/infant pair. Programs of comprehensive prenatal care and patient education may be highly cost-effective in the prevention of prematurity.

330 PLACENTAL PATHOLOGY AND MATERNAL HEMODYNAMICS IN HYPERTENSIVE PREGNANCIES C Salafia[X], TR Easterling, CA Vogel[X], KC Carlson, DA Brateng. Department Laboratory Medicine, Danbury Hospital, CT, University of Washington, Seattle, WA

Women with high resistance hypertension deliver infants who are significantly more growth retarded than women with high output hypertension. The goal of the present study is to examine the relationship between maternal hemodynamics and placental pathology in hypertensive pregnancies.

Material and Methods: 22 hypertensive and 9 normotensive pregnancies were studied. Hypertension was defined by a sustained dBP >90 mmHg. Hypertension was characterized as high resistance if the total peripheral resistance was ≥ 1150. Cardiac output was measured by Doppler technique. Gross and microscopic villous lesions were determined by blinded observer. The data were analyzed by Fischers exact.

Results:

	Normal	High TPR Htn	Low TPR Htn
Degenerative Knots	1/9 (.001)	11/11	1/11 (.001)
Fibrosis	0/9 (.01)	8/11	3/11 (.01)
Accelerated maturity	0/9 (.05)	4/11	0/11 (.05)

P values represents comparisons with the high resistance group. Placentas from high resistance pregnancies exhibited increased perivillous fibrin, fibrinoid necrosis, X-cell proliferation, and decidua atherosis which did not reach significance with this sample size.

Conclusions: We observed a parallel between placental histopathology and maternal hemodynamics which may provide an anatomical basis for previously observed differences in fetal growth and pregnancy outcome.

331 **INTERLEUKIN 6 LEVELS IN AMNIOTIC FLUID.** **R. Silver,* B. Schwinzer,* J. McGregor, Univ. Colorado Sch. Med, Denver, CO**

Interleukin 6 (IL6) has multifaceted activity in inflammatory and immunological processes. Elevated AF IL6 levels were found in patients with intraamniotic infection (IAI) and preterm labor (PTL) refractory to tocolysis. Because of a possible immune basis for both preeclampsia and intrauterine growth impairment, we measured AF IL6 levels in women with small-for-gestation (SGA) fetuses and preeclampsia, as well as in PTL. Third-trimester AF samples were obtained by amniocentesis, and IL6 levels were determined by an ELISA (AMGEN). Controls were obtained from uncomplicated pregnancies at term. Results:

	N	IL6 Level (pg/ml) mean	Range - pg/ml Standard Error		T-test vs Controls
Controls	**25**	**430**	**160-1352**	**57.2**	**–**
SGA	**8**	**144**	**38-353**	**44.0**	**p = 0.01**
Preeclampsia	**15**	**234**	**73-543**	**38.2**	**p = 0.019**
PTL' < 37	**13**	**625**	**215-1609**	**103**	**p = 0.811**
PTL' > 37	**16**	**299**	**130-515**	**34.5**	**p = 0.098**

'Eventual delivery < or > 37 weeks' gestation. Data were normally distributed. Cases of culture + IAI were excluded. IL6 levels were significantly decreased in patients who delivered SGA fetuses and in those with preeclampsia. Results were not significantly different in patients with PTL. Values in patients with PTL delivering prior to 37 weeks were significantly elevated when compared to patients with PTL responsive to tocolysis (p = 0.0032). Of 11 placentas examined in patients with refractory PTL, 7 (64%) showed histological evidence of IAI. Findings of low levels of AF IL6 in preeclampsia and SGA fetuses may signify an immune alteration which merits further study. We confirm that elevated AF IL6 correlates with PTL and delivery. ELISA determination of AF IL6 may become a clinically useful measurement which should be assessed in future trials.

332 **PREGNANCY-SPECIFIC B1 GLYCOPROTEIN LEVELS IN MATERNAL SERUM AND AMNIOTIC FLUID: PREECLAMPSIA, SMALL-FOR-GESTATION FETUS, AND FETAL DISTRESS.** Silver RM,* Heyborne K, Leslie K, Univ. Colorado Sch. Med., Denver, CO

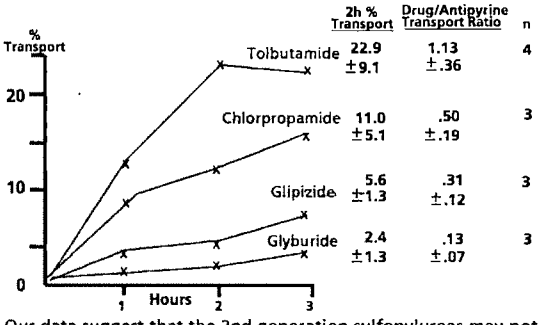
Pregnancy-specific B1 glycoprotein (SP1), produced by syncitiotrophoblast cells, can be measured in maternal serum (MS) and amniotic fluid (AF). MS SP1 levels have been used clinically to predict spontaneous abortion and small-for-gestational age fetuses (SGA). We assessed MS SP1 levels in 135 patients in the third trimester; 79 had uncomplicated pregnancies and 56 were complicated by preeclampsia, SGA, or fetal distress (FD) in labor. SP1 was also tested in AF samples obtained by genetic amniocentesis from 47 uncomplicated pregnancies and 25 complicated by SGA. SP1 levels were determined by radioimmunoassay (Behringwerke). MS SP1 values for complicated pregnancies were compared with those for normal patients matched for gestational age. Despite trends toward low values in the groups with complications, no statistically significant differences were found. MS SP1 levels less than 80 ug/ml (1 to 1.2 standard deviations below the mean for nl controls) have been used to predict SGA in gestations > 30 weeks. This value ascertained 31% (11/35) of women with preeclampsia, 54% (7/13) with FD, and 37% (3/8) delivering SGA fetuses. AF SP1 levels for SGA perinates were also not significantly different than age-matched normal controls, despite a trend towards low values in the SGA group. An AF SP1 value < 260 ng/ml yielded a sensitivity of 40% (10/25) and a specificity of 89% (42/47) in discriminating SGA fetuses. A discriminatory value < 1000 ng/ml increased sensitivity to 80% (20/25) but decreased specificity to 17% (8/47). These data do not support the use of SP1 values in clinical practice. Conversely, trends toward low values in women with preeclampsia, SGA fetuses, and FD merit further research to elucidate the biological function of this protein.

333 PROSTACYCLIN (PGI2) AND THROMBOXANE (TxA2) PRODUCTION IN FIRST TRIMESTER TROPHOBLASTS: EFFECTS OF ARACHIDONIC ACID (AA) AND ASPIRIN (ASA). E Diss*, A Robinson*, S Gabbe, R O'Shaughnessy, R Reiss, J Moore*, R Fertel*, and D Kniss*, The Ohio State University Hospitals Depts. of OB/GYN and Pharmacology, and Cytogenetics, Children's Hospital, Columbus, OH.

Placental levels of PGI2, a potent vasodilator, and TxA2, a potent vasoconstrictor, are reportedly altered in preeclamptic patients. We developed a model to study PGI2 and TxA2 in first trimester trophoblastic cells. Trophoblastic tissue was obtained via transabdominal CVS from 32 pregnancies at 9-11 weeks gestation. Tissue was first grown in culture for cytogenetic studies for 2-3 weeks. Initially, all cell lines were morphologically consistent with villus core cells. Through altering cell density and passage, the cells became morphologically consistent with cytotrophoblasts. Both cell lines were then exposed to AA and varying concentrations of ASA for 24 hours. RIAs were performed to measure the stable metabolites of PGI2 (6-ketoPGF1a) and TxA2 (thromboxane B2). Core cells and cytotrophoblasts demonstrated statistically significant increases in production of both PGI2 and TxA2 in the presence of AA. The villus core cells produced significantly greater amounts of both PGI2 and TxA2 than the cytotrophoblasts. However, the percent inhibition of prostaglandin production by ASA, was greater in the cytotrophoblasts than the core cells (see table). This model may be a useful tool to study the role of the placenta in preeclampsia.

% REDUCTION IN PROSTAGLANDIN SYNTHESIS

	ASA 1μM	ASA10 μM	ASA 100 μM
CORE 6-KETO	8	17	30*
CORE TxB2	3	7	37
CYTO 6-KETO	37*	47*	74*
CYTO TxB2	18*	45*	64*



CORE =VILLUS CORE CELL CYTO=CYTOTROPHOBLASTS, *=P<.03

334 **INCREASES IN O_2 TENSION APPEAR TO CAUSE PROSTAGLANDIN-MEDIATED CONTRACTION OF HUMAN PLACENTAL VEINS VIA H_2O_2 GENERATION.** H.A. Omar[X], R. Figueroa, N. Tejani and M.S. Wolin[X], Depts. Physiol. & Ob/Gyn, New York Medical College, Valhalla, NY

Isolated 1-2 mm diameter placental arteries (PA) and veins (PV), obtained from normal-term deliveries, in the presence or absence of endothelium, precontracted with 1-10 nM U46619 to ~2 g of tone, were found to undergo a relaxation of ~250 mg (PA, n=6) and ~400 mg (PV, n=7) when exposed to a Po_2 of 8-10 torr from a Po_2 of 35-40 torr. Reexposure to a Po_2 of 35-40 torr produced a contraction of 466±95 mg in the PV, but not in the PA ($p<0.05$). When exposed to 1-100 μM H_2O_2, the PV produced a contraction of up to 700±190 mg, which was markedly greater ($p<0.05$) than the contraction of 185±59 mg in the PA. Removal of the endothelium did not alter any responses to H_2O_2 or reoxygenation. The contractions to reoxygenation or H_2O_2, but not the relaxation to hypoxia, was eliminated or reversed to a modest relaxation by pretreatment with 10 μM indomethacin, consistent with mediation via the formation of contractile prostaglandins (PG). We hypothesize that reoxygenation may cause a PG-mediated contraction of PV via the generation of H_2O_2 and this mechanism could contribute to vasospasm of the PV.

335 **ORAL HYPOGLYCEMIC AGENTS: PROFOUND VARIATION EXISTS IN THEIR RATE OF HUMAN PLACENTAL TRANSFER.** B. Elliott,[X] S. Schenker,[X] O. Langer, R. Johnson,[X] T. Prihoda,[X] Depts. OB/GYN, Medicine & Pathology. Univ. Texas HSC at San Antonio, Texas.

Our recent finding that the oral hypoglycemic agent glyburide does not significantly cross the human placenta has renewed interest in its use in gestational diabetes. The purpose of this study was to determine whether this unique characteristic is shared by other members of this drug category. The single-cotyledon human placental model was used to compare the maternal to fetal transport of the sulfonylureas. C14-antipyrine was added to these perfusions as a standard reference for simple diffusion. Liquid scintillation spectrometry and high performance liquid chromatography were used to calculate transport from the serial samples obtained during each 3-hour perfusion. The transfer rates below are significantly different (ANOVA, $F<.0003$):

Our data suggest that the 2nd generation sulfonylureas may not reach the fetus in significant levels, and therefore, may be better suited for use in pregnancy than their older counterparts. Further studies to ascertain their clinical utility are required, however.

336 **MATERNAL FLOOR INFARCTION: RELATIONSHIP OF X-CELLS, MAJOR BASIC PROTEIN AND ADVERSE PERINATAL OUTCOME.** **K.K. Vernof,[x] K. Benirschke, G.M. Kephart,[x] T.L. Wasmoen,[x] J.A. Ney and G.J. Gleich,[x] Dept. Ob/Gyn and Immunology, Mayo Clinic, Rochester, MN and Dept. Pathology, UCSD, San Diego, CA.**

To expand our knowledge of pregnancy-associated major basic protein (pMBP) and the X-cell in reproductive physiology, we analyzed pregnancies complicated by maternal floor infarction (MFI). MFI placentas are grossly abnormal showing a striking increase in the number and size of subchorionic cysts and histologically show increased proliferation of X-cells. The pregnancies have poor outcomes with either intrauterine growth retardation or fetal death. Previously, pMBP has been localized to the placental X-cell and identified at elevated levels in serum and amniotic fluid in all normal pregnancies. Here, we present a classic example of MFI along with seven other cases. We analyzed placental tissue, serum, amniotic fluid, and placental cyst fluid. Serum pMBP levels were variably elevated both in normal and MFI pregnancies. Placental tissue from MFI pregnancies had increased numbers of X-cells and fibrinoid material that occupied or surrounded degenerating villi and which stained intensely for pMBP. These results indicate that pMBP, a potent cytotoxin and platelet agonist, is deposited in close proximity to chorionic villi in MFI, and may contribute to the pathophysiology of this disorder.

337 VOLUME REGULATION IN SECOND TRIMESTER CYTOTROPHOBLAST CELLS. Robert S. Egerman,[x] Joan M. Bissonnette,[x] Gail B. Willeke,[x] Dept. Ob/Gyn, Oregon Health Sciences Univ., Portland, OR.

Although ion transport systems have been described in syncytiotrophoblast brush border vesicles, no study as yet addresses cell volume regulation in placental cells. These mechanisms are important in understanding fetal H_2O acquisition in physiologic and in pathologic states (e.g. hyperosmolar ketosis). Cytotrophoblast cells were isolated from 17-19 week human placentas by enzyme digestion and density gradient centrifugation. Video-microscopy captured interval cell images as cells were exposed to various solutions. These recorded images were stored in a MacIntosh computer and later recalled for area measurements using Image 1.22 software. In the continued presence of mannitol (400mM) shrunken cytotrophoblasts increased their area 1.8 to 3.2 fold after an 8-12 minute latency period. When extracellular NaCl was replaced with N-methyl glucamine, the latency period was extended and final volume was depressed. In the presence of the Na^+-H^+ exchanger antagonist, ameloride (100μM), no increase in cell area occurred. Conclusion: 1) Cytotrophoblasts are osmotically active. 2) Na^+ is necessary for regulatory cell volume increase. 3) Na^+-H^+ exchanger is an important system for Na^+ (H_2O) entry into the cell. 4) The latency period suggests that the Na^+-H^+ exchanger must be activated before these cells can regain their volume.

338 **THE EFFECT OF DIFFERENT EXTRACELLULAR MATRIX PROTEINS AND DIFFERENT SERUM-FREE MEDIA ON THE OUTGROWTH OF TROPHOBLAST CELLS ISOLATED FROM HUMAN TERM PLACENTAE**

J. Leyten,* C. Luyten,* R. Pijnenborg* & A. Van Assche

Department of Obstetrics & Gynecology, University of Leuven, Belgium

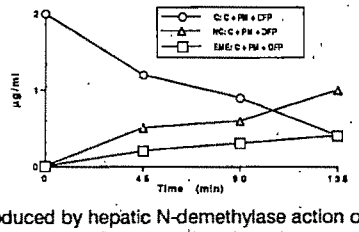
In order to study the interaction of trophoblast cells with maternal tissue, a monolayer culture system was established. We modified the methods described by Kliman et al (Endocrinology 118,1567,1986) and Loke & Burland (Placenta 9,173,1988). The isolated cells were grown on substrates coated with the following extracellular matrix proteins (ECM-proteins) : Matrigel (Mg.), Collageen IV (Col.), Laminin (Lam.), Fibronectin (Fib.). Serum-free media used : RPMI1640, MEM-D-VAL, Ham's F12, DMEM, K-SFM (GIBCO). Unwanted fibroblast proliferation was evaluated for the different ECM-proteins and media. Immunocytochemical staining of cytokeratin and vimentin was used to differentiate the different cell types in culture. The results are summarized in the table.

Trophoblast outgrowth : + (very low) → ++++ (strong).
Fibroblast proliferation : * (low) → *** (strong).

		ECM - PROTEINS				
		Without	Col.	Mg.	Lam.	Fib.
MEDIA	RPMI1640	+ **	+ *	+ **	+ *	+ *
	MEM-D-VAL	+ *	+ *	+ **	+ *	+ *
	Ham's F12	+ **	+ *	++ ***	++ **	+++ **
	DMEM	++ *	+ *	++ **	++ *	+++ *
	K-SFM	++ *	+ *	+++ *	+++ *	++++ *

Concerning the ECM-proteins, fibronectin, followed by laminin, gives the best result. Matrigel seems to stimulate fibroblast proliferation more than the other media do. For the serum-free media, K-SFM followed by DMEM is more favourable than Ham's F12, MEM-D-VAL and RPMI1640. Ham's F12 seems to stimulate fibroblast proliferation more than the other media do.

339 **SINGLE INTRAUTERINE DEMISE IN TWIN PREGNANCY.** M. Eglowstein and M. D'Alton, Department of OB/GYN, Tufts University School of Medicine, Boston, MA



Eighteen twin pregnancies with one intrauterine fetal demise (IUFD) noted after the first trimester were managed using a standard protocol between January 1, 1987 and July 1, 1991, during which time 367 twin deliveries occurred. Of the 17 delivered pregnancies, placentation was determined in 16; 9 were diamniotic/dichorionic (DC) and 7 were diamniotic/monochorionic (MC). Of the DC placentations, 5 cases of IUFD were unexplained, 2 were associated with major fetal anomalies, 1 with nonimmune hydrops and 1 with placental infarct. Of the MC placentations, IUFD in 6 cases was associated with twin-twin transfusion (TTTS); the seventh was associated with preterm rupture of membranes and chorioamnionitis. The interval from diagnosis of IUFD to delivery ranged from 2 days to 11 weeks in DC placentation, and 1 day to 14 weeks in MC placentation. The management protocol consisted of frequent ultrasound for fetal growth, weekly norstress test and biophysical profile after 28 weeks, and weekly coagulation profile. There were no elective preterm deliveries. Incidence of preterm delivery was 82.3% overall (14/17); 7 of 9 DC and all MC gestations delivered preterm. Estimated gestational age at delivery ranged from 28 to 38 weeks in DC gestations and 20 to 36 weeks in MC gestations. No patient required treatment for coagulopathy. 1 case of periventricular encephalomalacia was diagnosed prenatally by ultrasound 24 hours after the death of the co-twin. This seems to indicate that the timing of this neurological insult happened before the death of the co-twin. This report confirms our previous findings of a low risk of clinically significant maternal coagulopathy and a low incidence of periventricular encephalomalacia in co-twins of single IUFD. This series demonstrates a higher incidence of spontaneous preterm delivery in both types of placentation than has been previously reported.

340 **THE DEPENDENCE OF THE PLACENTAL/FETAL RATIO ON FETAL WEIGHT.** R.E. Kurzel, M.D., U.C.L.A./L.A.C. - Olive View Medical Center, Sylmar, CA

Because of the enormous range in placental weights (P-Wt) vs gestation, studies of the placental/fetal weight ratio (P/F) are felt to be more meaningful than P-Wts in predicting the physiologic adequacy of the placenta. Fetal (F-Wt) and P-Wts were obtained from 1633 singleton liveborn pregnancies prepared according to Thomson et al. Mean P-Wt and P/F were determined for 500 gm F-Wt intervals, from 500-6,000 gms, using a fixed F-Wt as the criteria to study the variation in these parameters. P/F's were obtained from the mean F-Wt and P-Wt for each weight interval. RESULTS & CONCLUSIONS: (1) For the entire population, mean F-Wt = 3394 gm, mean P-Wt = 640 gm, and P/F = 0.189 = 1/5.3 (2) Mean P-Wts increase with increasing F-Wts. (3) For a given F-Wt group, the P-Wt follows a Gaussian distribution, with a wide range, ≈ 900 gms. (4) At a given F-Wt, fetal sex does not influence P-Wt. (5) The P/F ratio vs F-Wt shows a decreasing hyperbolic trend, achieving the assymptote (P/F = 0.190) for F-Wts ≥ 2500 gms (term). The leveling off of P/F with F-Wt indicates efficiency achieved at term (minimum in P/F), and supports the concept of Placental reserve.

341 **Metabolism of Cocaine by N-demethylase in Rat Placentae: An Induced Placental Enzyme System.** Bertis B. Little, Ph.D.,+ Daniel A. Roe, B.S.,+ R. William Stettler, M.D.+, Van R. Bohman, M.D.+ Dept. of Ob/Gyn, The Univ. of Texas Southwestern Medical Center, Dallas, Texas.

Previous investigators reported cholinesterase activity (CA) of placenta *in vitro*. Four treatment groups were incubated with cocaine (C) over 4 time periods: placental microsomes (PM) + C, PM + DFP (anticholinesterase) + C, PM + C + butyryl-cholinesterase (BC), and a blank (C only). Gas chromatography was used to quantify C (limit of quantitation-LOQ = 19 ng/ml) and metabolites. BC enhanced C metabolism to ecgonine methyl ester (EME). More than 40% of C was metabolized to NC by rat placenta when DFP suppressed CA (FIG.).

NC is produced by hepatic N-demethylase action on methyl-bearing nitrogen in C, suggesting that placenta as well as liver has this capacity. Hence, this biotransformation of C may be a primary metabolic pathway induced in the cholinesterase deficient placenta. This has clinical implications because NC is 9-fold more active physiologically than C or EME.

342 IS PLACENTAL GROWTH OPTIMAL? LJ Groome, JM Benanti. University of Arkansas for Medical Sciences, Little Rock, Arkansas.

At the present time the relationship between fetal well-being and placental growth is largely unknown, although abnormally small or large placentas are thought to be a marker of fetal compromise. Oxygen (O_2) delivery to the fetus is reduced, because of a reduction in transport area, if the placenta is too small; in addition, the high rate of O_2 consumption by a large placenta can similarly limit fetal O_2 delivery. This relationship between placental size and O_2 exchange raises the question "Is there an optimal placental growth pattern which maximizes fetal oxygenation?" Ordinary non-linear differential equations were derived to describe the axial PO_2 profiles in the maternal (M) and fetal (F) streams for concurrent flow. A Fibonacci search routine was used to assure consistency between umbilical artery and venous PO_2 profiles and fetal O_2 consumption (V_f). Model parameters were well within the range cited for a 3 kg sheep fetus: 1000 ml/min (M) and 500 ml/min (F) blood flow; 18% (M) and 8% (F) flow shunts; 2 ml O_2/min-mmHg placental O_2 diffusivity; data of Edelstone (AJOG, 1985) for V_f; and Hill equations (AJP, 1972) for the oxyhemoglobin binding curves. Based on this mathematical model, we found that O_2 delivery to the sheep fetus is maximized at a placental mass (m_p) of 800 gms. Furthermore, $(\Delta PO_2)UmV/\Delta m_p$ is an order of magnitude greater for placentas weighing <800 mg than for placentas weighing >800 mg (0.04 vs 0.003 mmHg/gm), suggesting that a smaller placenta limits fetal oxygenation to a greater extent. Conclusion: Fetal oxygenation may be an important factor regulating placental growth.

343 THE POST-TERM PLACENTA: SMALL OR NOT? MP Dombrowski, HM Wolfe, AA Saleh, RJ Sokol, Depts of Ob/Gyn and Pediatrics, Wayne State Univ./Hutzel Hosp., Detroit, MI

Placental weight has been directly related to total placentofetal metabolism. Placental growth has been reported to plateau beyond 40 menstrual weeks, with the small, post-term placenta associated with "placental insufficiency". The purpose of this study was to examine placental growth beyond 40 weeks using obstetric estimates of gestational age (GA-OB) based on LMPs, but corrected by fetal ultrasounds and confirmed by Ballard exam, and then compare data based solely on LMP (GA-LMP). Placental weights were obtained from a perinatal database of 33,135 viable, singleton, structurally normal neonates.

	GA-OB		GA-LMP	
weeks	n	weight ± S.D.	n	weight ± S.D.
40	9,648	678 ± 144	4,689	671 ± 146
41	3,538	700 ± 146	3,782	686 ± 153
42	1,353	715 ± 152	2,442	687 ± 154
43	130	781 ± 198	1,287	680 ± 155
44	3	853 ± 103	815	684 ± 150
45	0		578	690 ± 142
46	0		306	691 ± 157
>46	0		356	679 ± 155

Consistent with previous reports based on GA-LMP, there was a plateau beyond 40 weeks; weights at 43 weeks were similar to 40 weeks ($p > .08$). However, when dated by GA-OB, placental weights increased from 40 to 44 weeks ($p < .0001$). The incidence of pregnancies ≥ 42 weeks was significantly less ($p < .0001$) when gestational age was corrected by ultrasound. We conclude 1) typical placental growth continues beyond 40 weeks 2) gestational dating solely by LMP markedly overestimates the true incidence of post-datism and distorts apparent placental growth pattern 3) the concept of placental insufficiency requires re-examination.

344 THE EFFECT OF HYPOXIC ACIDEMIA INDUCED BY PLACENTAL EMBOLIZATION OF MYOCARDIAL CONTRACTILITY AND SYSTOLIC TIME INTERVALS IN FETAL SHEEP. R.M. Lewinsky*, R.J. Morrow*, J.W.K. Ritchie. University of Toronto, Toronto, Ontario, Canada.

A study was designed to examine the hypothesis that hypoxic acidemia adversely affects fetal myocardial contractility, thereby causing a prolongation of cardiac systolic time intervals (STI). Fetal sheep (n=7) at 133 days gestation, were studied *in utero* under isoflurane anaesthesia. ECG electrodes were applied to the fetal chest and a 2F catheter-tip pressure transducer (Millar) was introduced through a carotid artery into the left ventricle (LV). Hypoxic acidemia was induced by placental embolization with repeated injections of $5{\cdot}10^5$ 50μM microspheres every 15 minutes via a catheter placed in the fetal abdominal aorta. The LV pre-ejection period (PEP), isovolumetric contraction time (ICT) and ventricular ejection time were continuously measured from the processed ECG and Dopplercardiogram (DCG) obtained with an HP 8040A monitor. Myocardial contractility was assessed by the maximal value of the first time derivative of the ventricular pressure waveform (dP/dt_{max}) corrected for heart rate and preload. A decrease in fetal arterial pH from 7.3 to pH 7.0 was associated with a significant decrease in dP/dt_{max} ($p=0.003$), a prolongation of PEP ($p=0.004$) and ICT ($p=0.002$) as well as with a significant increase in the PEP/VET ratio ($p=0.0002$). We conclude that hypoxic acidemia decreases fetal myocardial contractility, thereby causing a prolongation of the pre-ejection period and the isovolumetric contraction time.

345 THE EFFECT OF CHANGES IN PRELOAD AND AFTERLOAD ON THE CARDIAC SYSTOLIC TIME INTERVALS IN FETAL SHEEP. R.M. Lewinsky*, R.J. Morrow, J.W.K. Ritchie. University of Toronto, Toronto, Ontario, Canada.

Systolic time intervals (STI) are potentially useful for the noninvasive assessment of fetal wellbeing. The effect of changes in cardiac loading on these intervals has not been directly examined in an experimental model. Fetal sheep (n=7) at 133 days gestation, were studied *in utero* under isoflurane anesthesia. ECG electrodes were applied to the fetal chest and a 2F catheter-tip pressure transducer (Millar) was introduced through a carotid artery into the left ventricle (LV). The LV pre-ejection period (PEP), isovulumetric contraction time (ICT) and ventricular ejection time (VET) were continuously measured from the processed ECG and Dopplercardiogram (DCG) obtained with a HP 8040A monitor. Myocardial contractility was assessed by the maximal value of the first time derivative of the ventricular pressure waveform(dP/dt_{max}) corrected for heart rate and preload. Preload was decreased and afterload was increased by brief partial occlusions of the inferior vena cava and the descending aorta respectively, with inflatable balloon catheters in these vessels. Both a decrease in preload and an increase in afterload, caused a significant prolongation of PEP and ICT. ICT is contained within PEP and is the major contributor to its prolongation. VET shortened with both interventions, mostly due to the effect of an increase in heart rate. Myocardial contractility as assessed by dP/dt_{max} did not change during these interventions. This study shows that fetal cardiac STIs are directly affected by changes in preload and afterload, changes which are associated with compression of the umbilical cord.

346 FETAL URINE PRODUCTION IN PREMATURE RUPTURE OF THE MEMBRANES. W. L. Donald, University of Illinois at Chicago, Chicago, IL.

The purpose of this study was to determine if fetal urine production is decreased in premature rupture of membranes (PROM). A 3.5 MHz linear transducer was used to perform serial measures every 5 mins. of the longitudinal (A), transverse (B), and antero posterior (C) diameters of the fetal bladder in 51 patients with PROM between 30 and 34 weeks, 79 patients with intact membranes between 30 and 34 weeks served as controls. Fetal bladder volume was calculated from the formula for an ovoid sphere: $4/3(pi) \cdot [(A/2)\cdot(B/2)\cdot(C/2)]$. Volumes(ml) were plotted against time (mins) and linear regression was used to determine the fetal urinary output (FUO) as m/hr.

RESULTS

	PROM			CONTROLS			P
Gestation	30	32	34	30	32	32	
Mean FUO	10	12	19	16	19	26	0.05
(SD)	(3)	(3)	(6)	(5)	(3)	(6)	
Fill Time	29	34	29	23	27	20	0.05
(SD)	(7)	(6)	(9)	(8)	(7)	(5)	

There was no difference in the maximal bladder volume. CONCLUSION: THERE IS A REDUCTION IN THE FETAL URINARY OUTPUT IN PROM. THE ETIOLOGY REMAINS UNCLEAR.

347 LONGITUDINAL STUDY OF THE AMNIOTIC FLUID INDEX IN POSTDATES PREGNANCY. Ariel D. Marks*, M.S., Michael Y. Divon, M.D. Dept. Ob/Gyn, Albert Einstein College of Medicine, Bronx, New York.

Previous invasive studies of the physiology of amniotic fluid levels in postdates pregnancies used dye dilution techniques and documented a weekly decrease of 28% to 51%. Oligohydramnios was a common finding. Recent sonographic studies of the amniotic fluid index (AFI) in postdates patients indicate a mean weekly decrease of 3% - 12%. The incidence of oligohydramnios in recent studies is unclear. These studies were cross-sectional in design and lacked reliable methods to establish gestational age. Purpose: To prospectively and longitudinally evaluate the change in AFI in postdates. Materials and Methods: Serial AFIs were obtained semi-weekly in 121 well dated (by certain LMP consistent with early sonographic exam) pregnancies > 41 weeks' gestation. Poor fetal testing, oligohydramnios (i.e. AFI≤5.0cm) or a favorable cervix were used as indications for delivery. Results: The AFI increased in 42 patients (35%), did not change in 3 patients (2%) and decreased in 76 patients (63%). The mean AFI at 41 weeks of gestation was 12.4 ± 4.2 cm (±SD). Overall, there was a significant mean weekly decrease in AFI of 25.2% ($p<0.0005$). Oligohydramnios was diagnosed in 13% of these patients. The results of this longitudinal study indicate that in postdates patients:

1. There is a 25.2% weekly decrease in AFI.
2. There is a considerable patient variation in AFI as a function of gestational age.
3. Oligohydramnios is absent in most of these patients with accurate dating.

348 **BETA$_2$-MIMETICS INHIBIT EGF-INDUCED PGE$_2$ SYNTHESIS IN AMNION-DERIVED (WISH) CELLS** *Su, H.-C.[x], *Fertel, RH.[x], *Gabbe, SG., and *Kniss, DA.[x] Departments of *Pharmacology, and *Obstetrics and Gynecology (Division of Maternal-Fetal Medicine), The Ohio State University College of Medicine, Columbus, OH

Studies have shown that prostaglandins (PGs) produced in amnion, especially PGE_2, increase with gestation and with the progress of labor. The processes which regulate the production of these important mediators of labor are not fully understood; however, there is increasing evidence to support the concept that the labor-initiating signals emanate from the fetus. One such signal is epidermal growth factor (EGF), which is derived from the fetal kidney. Therefore, we have investigated the effects of EGF on the regulation of PG production in human amnion-derived WISH cells. Our previous studies have shown that EGF causes a time- and dose-dependent increase in PGE_2 production in human amnion-derived WISH cells. In addition, preexposure of WISH cells to epinephrine inhibits EGF-induced PGE_2 production. Since the β-adrenergic tocolytics used clinically are derivatives of epinephrine, we determined whether terbutaline and ritodrine are also able to inhibit the EGF response. Our results indicate that terbutaline at 10^{-7}, 10^{-6}, 10^{-5}, and 10^{-4} M causes a 16.2%, 27.1%, 31.6%, and 31.4% decrease in EGF-induced PGE_2 production, respectively. Similarly, ritodrine reduced PGE_2 production in response to EGF. The inhibition could be eliminated by a selective β_2-adrenergic receptor antagonist, butoxamine. Since both terbutaline and ritodrine stimulated cAMP accumulation in WISH cells, we conclude that the inhibitory effect of terbutaline and ritodrine on EGF-induced PGE_2 production is mediated via a β_2-adrenoceptor-coupled adenylate cyclase. Our results suggest an alternative mechanism for the tocolytic effects of β_2-mimetic drugs.

349 ENDOTHELIUM-DERIVED NITRIC OXIDE INHIBITION AUGMENTS ANGIOTENSIN II RESPONSIVENESS IN THE PREGNANT RAT HINDLIMB VASCULATURE. R.A. Ahokas,[x] B.M. Sibai, Dept. Ob/Gyn, Univ. Tenn., Memphis, TN

The vascular endothelium modulates constrictor responsiveness by producing locally active vasodilators; e.g., prostacyclin (PGI_2) and endothelium-derived nitric oxide (EDNO). PGI_2 may be responsible for blunting vascular responsiveness to angiotensin II (AII) and norepinephrine (NE) during pregnancy, but the mechanism is unclear. To determine if EDNO plays a role, we measured the concentration-pressor responses to NE (10^{-8} to 10^{-4}M) and AII (10^{-10} to 10^{-6}M) in the hindlimb vasculature of nonpregnant (NP) and term-pregnant (PG) normotensive Wistar-Kyoto (WKY) and spontaneously hypertensive (SHR) rats, untreated or infused with N^G-monomethyl-L-arginine (L-NMA, 10^{-4}M) to inhibit EDNO production. Hindlimbs were perfused with Krebs-Ringer (4 ml/min) containing indomethacin (10^{-5}M) to inhibit PGI_2 production. There were no significant differences in baseline perfusion pressure between NP and PG hindlimbs of either strain, and L-NMA had no effect on perfusion pressure. NE induced similar pressor responses in NP and PG hindlimbs of both strains, and L-NMA increased these responses moderately. Pregnancy attenuated vascular AII responses in both WKY and SHR (Table). L-NMA enhanced vascular AII responses of PG, but not NP, hindlimbs of both strains. These results suggest that pregnancy is not associated with generalized vascular refractoriness to all vasoconstrictors and that increased EDNO, not PGI_2, activity is responsible for blunting vascular responsiveness to AII during pregnancy.

350 **EFFECT OF LOW DOSE ASPIRIN (ASA) DURING PREGNANCY ON DOPPLER WAVEFORM ACROSS THE MATERNAL LEFT VENTRICULAR OUTFLOW TRACT (LVOT) AND AORTA (Ao).** J.C. Veille, R. Hanson, L. Henderson, B. Veille, M. Sivakoff*, Dept. of Ob/Gyn, Bowman Gray School of Medicine, Winston-Salem, NC and Case Western Reserve University, Cleveland, OH*.

Maternal ingestion of low dose ASA (40-80 mg/day) may lead to changes in blood flow across the LVOT and Ao. To test this, 126 pulsed Doppler were done in left lateral decubitus in patients on ASA and in controls. Studies were done at three different gestational groups (GRP): I = 10-20 weeks, II = 21-30 weeks, III = 31-40 weeks. Six cardiac cycles were analyzed and averaged. Results are expressed as X ± SD. ANOVA was done to assess differences.

GRP	$LVOTPFV_N$	$LVOTPFV_{ASA}$	$LVOTCo_N$	$LVOTCo_{ASA}$
I	105.8 ± 22.6*	119.6 ± 24.0*	5.12 ± 1.3	4.89 ± 1.5
II	111.7 ± 18.7	119.1 ± 17.7	5.39 ± 1.2	5.00 ± 2.2
III	112.3 ± 24.1	113.6 ± 20.3	5.44 ± 1.7	5.43 ± 1.7
	*p < 0.05			

GRP	$AoPFV_N$	$AoPFV_{ASA}$	$AoCo_N$	$AoCo_{ASA}$
I	123.4 ± 23	111.9 ± 21	5.53 ± 1.7*	4.37 ± 1.5*
II	129.3 ± 26	130.9 ± 15	5.87 ± 1.8	5.39 ± 2.1
III	129.6 ± 25	123.8 ± 17	5.98 ± 1.9	5.04 ± 1.4
			*p < 0.03	

(Legends: $AoPFV_{N,ASA}$ = Aortic peak flow velocity in normal and ASA GRP [cm/sec]; AoCo = Aortic cardiac output [l/min]; LVOTPV = Left ventricular outflow tract peak flow velocity [cm/sec]). Results: No major differences were observed among the parameters studied in the three GA studied EXCEPT in early. $AoCo_N$ vs. $AoCo_{ASA}$ and $LVOTPFV_N$ vs. $LVOTPFV_{ASA}$ were significantly different. Conclusions: The significant ↑ in LVOTPFV < 20th week in the ASA may reflect an early effect of low dose ASA which is not present as pregnancy advances. The association of ↑ PFV in the LVOT with ↓ AoCo in the ASA group (GRP I) may reflect a smaller LV outflow tract initially in these patients which then normalizes as pregnancy advances. (Supported by NIH Grant HL38296).

351 **EFFECT OF LOW DOSE ASPIRIN (ASA) ON MATERNAL HYPOGASTRIC BLOOD FLOW.** J.C. Veille, R. Hanson, S. Humphrey, M. Sivakoff*, Dept. of Ob/Gyn, Bowman Gray School of Medicine, Winston-Salem, NC and Pediatrics, Rainbow Children's Hosp, Cleveland, OH*.

Maternal systemic effects of low dose oral ASA have not been studied. Patient Population: Twenty six control (normal) patients and seventeen patients taking 80 mg ASA daily from the 12th week on had blood flow of the right hypogastric artery assessed repeatedly during their pregnancy. Patients were on ASA because of previous history of PIH, IUGR, IUFD or positive ANA or anticardiolipins or lupus anticoagulants. Method: The right hypogastric artery was located using a 3 or 5 MZ transducer (UM9 ATL). Pulsed Doppler was placed in the lumen of the artery. Six cycles were analyzed and averaged using a light pen tablet to trace the outer part of the waveform (Digisonics). Analysis was done at four different gestational age Groups (Grp): I-12-18 wks; II-19-26 wks; III-27-34 wks; IV-35-42 wks. Results expressed as X±SEM. An ANOVA with repeated measurements was done to detect significance.

Grp	HRn	HRASA	PFVn	PFVASA	VIn	VIa
I	79±3	77±3	66±3	64±4	142±14	167±22
II	84±2	85±3	61±4	61±5	143±15	194±3
III	88±2	92±4	65±3	68±4	215±22	199±32
IV	78±3	89±3	71±3	67±7	168±26	129±24

(Legends: HRn=heart rates normal (beats per minute); ASA=aspirin; PFVn=peak flow velocity normal (cm/sec); VIn=volume index normal, i.e., volume of blood through the vessel cross-sectional area/min adjusted for body size (ml/min/kg/m^2); VIa=Volume index in ASA group) Results: 1) HRn and HRASA ↑ until the 35th wk; 2) HRn ↓ afterwards. However, in patients taking ASA, HR did not show this ↓; 3) No * in PFVn vs. PFVASA; and 4) No * in vol/unit area was found between the two groups. Conclusions: Low dose ASA has no significant effects on the right hypogastric artery blood flow. (Supported by NIH Grant HL38296).

352 THE PRODUCTION OF INSULIN-LIKE GROWTH FACTORS (IGF) I AND II IN HUMAN PREGNANCY. H. N. Winn, M.D., W.H. Daughaday, M.D.[x](*), B. Travedi, M.S.[x](*). Div. of Maternal-Fetal Medicine, St. Louis U. and Div. of Metabolism (*), Washington U., St. Louis, MO.

While it well-established that the insulin-like growth factors play an important role in postnatal growth, the impact of these substances on fetal growth remains to be determined. In this study, we measured the concentrations of the Pro-IGF-II E 1-21, IGF-II, and IGF-I in the maternal serum (MS), the umbilical cord serum (CS) and the amniotic fluid (AF) during the third trimester of pregnancy. The IGFs and Pro-IGF-II E 1-21 were measured using the radioimmunoassay (RIA) after acid-acetone extraction.

	PRO-IGF-II (Mean ± SD)	IGF-II (Mean ± SD)	IGF-I (Mean ± SD)
MS	120 ± 38	824 ± 550	560 ± 171
CS	232 ± 48	292 ± 46	126 ± 31
AF	933 ± 67	1280 ± 290	78 ± 16

Conclusions: 1) The **AF** concentrations of both **Pro-IGF-II** and **IGF-II** are significantly higher than the paired **CS** concentrations; 2) The concentrations of both **Pro-IGF-II** and **IGF-II** are significantly higher than those of **IGF-I** in both **CS** and **AF**; 3) There is no correlation between maternal levels of **IGFs** and those in the **AF** or **CS**. Speculations: 1) The production of IGFs in the fetal compartments does not appear to depend on maternal IGFs; 2) IGF-II may play a more important role than IGF-I in modulating fetal growth.

353 **ELEVATED LEVELS OF MSAFP & cICAM-1 IN AMNIOTIC FLUID AT 16 WEEKS MAY MARK EARLY INTRAUTERINE INFLAMMATION.** CM Salafia[x], CAVogel[x], JP ezzullo[x], M Lentner[x] E Mainolfi[x], JPBurns[x], EPhillipson[x], RRothlein[x] G Foye, L Silberman[x] DeptLab Med+ Ob/Gyn Danbury Hospital CT, Boehringer-Ingleheim Corp CT, Dept Ob/Gyr Hartford Hospital CT, TRC, Rhode Island Hospital, RI.

Elevated MSAFP concentrations ([eMSAFP]) in mid trimester are associated with increased risk of poor outcome for the structurally normal fetus. We previously dentified an increased incidence of chronic placental inflammation (villitis) in cases of growth retardation associated with midtrimester [eMSAFP]. The hypothesis that chronic intrauterine inflammation is also present in the midtrimester was tested by assaying amniotic fluid (AF) for the circulating form of intercellular adhesion molecule-1 (cICAM-1), a marker of inflammatory responses demonstrated in increased serum levels in the presence of hepatic and cardiac allograft rejection. 40 patients had amniocentes s at 16-17 weeks for maternal age/anxiety with normal [MSAFP]. 20 patients had amniocentesis at 16-17 weeks for evaluation of [eMSAFP] (>2.0 corrected MOM). cICAM-1 assays were performed by ELISA. Non-parametric testing of data gave the following results (mean +/- SE).

AF-[cICAM-1], normal [MSAFP] = 36.8 pg/ml +/-8.0. AF-cICAM-1],[eMSAFP] =132.6 pg/ml +/- 33 ($p<0.001$).

In cases of both normal [MSAFP] and [eMSAFP], [AF-AFP] was not elevated. These data suggest that in cases of midtrimester [eMSAFP] chronic intrauterine inflammation may be present. This could directly cause [eMSAFP] by changing membrane permeability, either in the extraplacental membranes or in villi and would produce [eMSAFP] when [AF-AFP] was normal. Further studies may confirm the utility of AF-[cICAM-1] in the detection of early intrauterine inflammation and potentially for maternal fetal immunopathology.

354 **RELATIONSHIP OF AMNIOTIC FLUID C-PEPTIDE LEVELS TO NEONATAL BODY COMPOSITION**

M.A. Krew, P.M. Catalano, R.J. Kehl, A.Thomas[x], MetroHealth Medical Center, Case Western Reserve University, Cleveland, Ohio.

Amniotic fluid C-peptide levels have been previously shown to correlate with birth weight in diabetic pregnancies. It has been suggested that insulin acts as a fetal growth hormone and that amniotic fluid C-peptide levels correlate with fetal insulin production. The purpose of this study was to examine whether amniotic fluid C-peptide levels have a stronger correlation with neonatal body composition as compared with total birthweight. We hypothesized that fetal insulin production as reflected by amniotic fluid C-peptide would more closely correlate with fetal fat deposition. In order to obtain a sample with a wide range of fetal fat mass 13 women with singleton pregnancies consisting of 9 diabetics (Class A1-2, A2-5, B-1, D-1) and 4 women with normal glucose screening underwent amniocentesis after an overnight fast within one week of delivery. Gestational age range was 37-40 weeks. 3 infants were LGA, 10 AGA, and 1 SGA by normative birthweight data for our institution. C-peptide was measured by RIA. Neonatal body composition was analyzed within 24 hours of delivery with anthropometric measurements. For the total group there was a significant correlation between C-peptide and fat mass (r=.58, p=.038) and % fat mass (r= .59, p=.035) but not with total weight (r=.30) or lean mass (r= .11). The SGA infant (from an A1) had the lowest % fat mass and was clinically growth retarded. Removing it from the analysis strengthened the correlation of C-peptide with fat mass (r= .68, p=.014) and % fat mass (r=.69, p=.014) but not with total weight or lean mass. These data suggest that the level of fetal insulin production affects fetal growth primarily through body fat when adequate substrate is available and that continuation of this study is warranted to determine if this relationship holds for subgroups based on diabetic status and weight for gestational age. Supported by NIH RR-00210 and 22965

355 **CALCIUM METABOLISM IN PREGNANT WOMEN RECEIVING CHRONIC MAGNESIUM THERAPY FOR PRETERM LABOR.**

L. G. Smith, Jr., R. J. Schanler[x], P. Burns[x], USDA/ARS Children's Nutr. Res. Ctr. and Dept. Ob/Gyn, Baylor Coll. Med., Houston, TX.

Because short-term MgS04 affects calcium metabolism in pregnant women , we hypothesized that long-term use of MgS04 would affect mineral homeostasis and bone mineralization adversely. We studied 22 women receiving long-term MgS04 (duration 8 to 66 d, average daily dose 52 ± 10 g/d, mean ± SD) as therapy for preterm labor. A control population (n=31) also requiring a similar degree and duration of strict bedrest for obstetrical indications were enrolled and matched for age (30 ± 3 wk) and delivery (33 ± 4 wk). Weekly serum and urine measurements were obtained for 4 wk. The groups had similar serum concentrations of albumin, osteocalcin, and vitamin D metabolites and urinary excretion of creatinine, phosphorus, and zinc. The following indices differed from the baseline (in the MgS04 group), did not fluctuate during the study interval, and remained significantly different between the two groups:

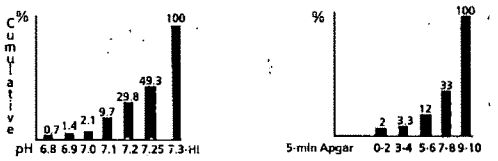
Average values	MgSO4	Control	p
Serum Mg(mg/dl)	5.2 ± 1.1	1.8 ± 0.2	<0.001
Serum Ca (mg/dl)	7.0 ± 0.5	8.3 ± 0.4	<0.001
Serum PTH (pmol/l)	60 ± 16	48 ± 8	=0.001
Urine Mg (mg/24-h)	245 ± 96	94 ± 67	<0.001
Urine Ca (mg/24-h)	844 ± 313	342 ± 145	<0.001

There were no differences in bone mineral content at delivery. Our data suggest that perturbations in calcium metabolism do not adapt to long-term MgS04 therapy and that large urinary losses of Ca are a concern.

356 **THE EFFECT OF TOCOLYTIC AGENTS (INDOMETHACIN AND TERBUTALINE) ON FETAL BREATHING (FBM) AND BODY MOVEMENTS (FM): A PROSPECTIVE, RANDOMIZED, DOUBLE BLIND, PLACEBO-CONTROLLED CLINICAL TRIAL.** Mordechai Hallak, Kenneth J. Moise, Jr., Noe Lira,[x] Karen Dorman,[x] E. O'Brian Smith,[x] David B. Cotton; Dept. Ob/Gyn; Baylor College of Medicine; Houston, Texas

Since two of the important parameters to evaluate fetal well-being are FBM and FM, an increase in these will influence the assessment of the fetal status and subsequent patient management. **Material and Methods:** Inclusion criteria: Normal, low risk pregnancy, normal level II ultrasound, gestational age 26-32 weeks, and no signs of preterm labor. At the same time of the day, a baseline evaluation of FBM and FM was performed over a period of one hour with continuous videotape recording, using an Aloka 680 (Corometrics, Inc). The patients were then randomized to one of three groups and received a capsule which was previously prepared and coded that contained either terbutaline (5mg), Indomethacin (50mg), or placebo. Three hours later, repeat evaluation of the fetus was performed for another one hour period. Maternal venous blood for glucose level and gases was drawn at the start, middle, and end of each of the evaluation periods. Statistical analysis included ANOVA, ANCOVA, and a multiple comparison procedure (Fisher's LSD). **Results:** Ten patients were enrolled in each group. Baseline demographic data were not statistically different. Pre- and post-treatment glucose, pH, pO_2, pCO_2 were the same. Comparison of the groups with respect to FM showed no statistically significant treatment effect. Indomethacin significantly increased FBM from 20.8 ± 13.1 minutes pre-treatment to 42.2 ± 14.8 minutes post-treatment, while terbutaline significantly increased FBM from 19.8 ± 9.0 minutes to 35.2 ± 12.4 minutes. There was no statistically significant change in the placebo group. **Conclusions:** 1. Indomethacin increases FBM by 103% ($p = 0.003$) and terbutaline increases FBM by 78% ($p = 0.008$) when compared to the pre-treatment value, 2. no significant treatment effect was detected on FM, 3. these findings can affect the way FBM is being used to interpret the fetal status in a patient treated with Indomethacin or terbutaline.

357 **IS FETAL HEART RATE VARIABILITY A PREDICTOR FOR FETAL OUTCOME?** A. Samueloff,[x] M. Berkus, N. Field,[x] L. Ridgway, E. Xenakis,[x] O. Langer. Dept. OB/GYN, Univ TX HSC San Antonio, Texas.



It has become axiomatic that normal variability is an excellent predictor for normal pH and good fetal outcome (FOC). However, paucity of studies evaluated the role of variability as a single predictor for FOC. We, therefore, investigated the hypothesis that normal fetal heart rate (FHR) variability is a single predictor of good FOC. In over 1700 consecutive deliveries, FHR tracings were analyzed. For purpose of analysis, 3 windows of FHR tracings were evaluated: 1) early in labor (30 min); 2) in active phase, 1h prior to complete dilatation (30 min); 3) throughout the entire 2nd stage in segments of 30 min. Variability was calculated by the amplitude from baseline and the number of oscillations in the best 1-min of each 30-min segment. Excluded were twins, fatal malformations and stillbirths. We used variability as the screening criteria (last tracing prior to delivery: normal ≥3) to predict different outcome parameters (with threshold for normality: pH >7.2, Apgar 5 min >7, good outcome - fetus going home after 3-5 days with no NICU admission).

	Sensitivity	Specificity	Positive Pred. Value	Negative Pred. Value
Outcome	9.6%	91.5%	16.5%	91.5%
pH	8.2%	95.4%	25.0%	84.7%
Apgar 5 min	27.3%	95.1%	7.6%	98.9%

Furthermore: 1) infants with low variability had RR of 7.25 for low 5 min Apgar score and 1.85 for pH <7.2; 2) low variability was associated with a 2.1-fold increase for adverse outcome. In contrast, 90% of the adverse outcome was associated with good variability; additionally, 15.2% of the good variability group had a pH <7.2. In conclusion, variability in labor, by itself, cannot serve as a single predictor for fetal outcome.

358 **CAN PH AND APGAR SCORE PREDICT NEONATAL OUTCOME?** A. Samueloff,[x] M. Berkus, N. Field,[x] L. Ridgway, E. Xenakis,[x] O. Langer. Univ. TX HSC at San Antonio, San Antonio, TX.

Although most studies use cord blood gases (CBG) and Apgar score as grouping criteria to evaluate fetal outcome, controversy exists regarding the "cut-off point" for bad outcome. Utilizing immediate neonatal outcome to determine the predictability of Apgars and CBG, values should help resolve the controversy. Therefore, we chose to use a study design that a priori defined 2 immediate outcome groups (good and adverse) and then assessed the characteristics of the corresponding Apgars and CBG. In an on-going study, over 1670 consecutive deliveries were analyzed. Good outcome was defined as newborns going home 2-5 days after delivery with no NICU admission (n=1454). Adverse outcome was defined as newborns admitted to level III NICU with respiratory support or complications (i.e. hypotonia, IVH, neonatal death, sepsis or convulsions [n=144]). Twins, fatal malformations and stillbirths (n=72) were excluded from the study. The cumulative incidence of immediate adverse outcome in relation to 5 min Apgars and arterial cord pH is listed:

In addition: 1) the positive predictive value and sensitivity of pH and 5 min Apgar categories ranged from 0.9%-50% and 11-50%, respectively; 2) in preterm newborns, pH and 5 min Apgars were even less predictive of adverse outcome. Our data show that neither pH nor Apgars can be used as predictors for immediate adverse fetal outcome. In contrast, Apgar score of ≥7 and cord arterial blood pH >7.1 were associated with good outcome in 99.4% and 97.7% of cases, respectively. We conclude that although a good outcome can be characterized by traditional 5-min Apgars and pH "cut-offs," neither Apgars nor pH can be used as predictors for immediate adverse neonatal outcome.

359 SOUND LEVELS IN THE HUMAN UTERUS DS Richards, BS Frentzen,[x] KJ Gerhardt,[x] RM Abrams,[x] ME McCann.[x] University of Florida, Gainesville.

A intrauterine hydrophone was placed transcervically in five laboring women. Sound pressure levels (SPL) were measured in air anterior to the abdomen and compared with intrauterine hydrophone measurements for the following parameters: The pregnant woman speaking, a tape recording of a male voice, and recordings of pure tones ranging from 125 to 10,000 Hz played through loudspeakers. There was a very strong effect of frequency on SPL ($p=0.002$), with enhancement at low frequencies, and attenuation at high frequencies. Intrauterine SPL was very similar to air SPL for the male voice; there was substantial attenuation of the pregnant woman's voice. This study confirms our prior finding in sheep that low frequency sounds readily penetrate into the pregnant uterus.

360 **ARACHIDONIC ACID APPEARS TO CAUSE RELAXATION OF PLACENTAL ARTERIES AND VEINS VIA A CYTOCHROME P-450 METABOLITE.** R. Figueroa, H.A. Omar[X], N. Tejani and M.S. Wolin[X], Depts. Physiol. & Ob/Gyn, New York Medical College, Valhalla, NY

Isolated endothelium-intact (+E) and endothelium-denuded (-E) human placental arteries (PA) and veins (PV) of 1-2 mm diameter obtained from normal term deliveries and precontracted with $PGF_{2\alpha}$ were found to undergo an endothelium-independent relaxation of 40-50% and 60-70%, respectively, when exposed to micromolar concentrations of arachidonic acid (AA). This relaxation (e.g. @ 10 μM AA PA+E = 37±8% (n=7) & PV+E = 61±6% (n=6)), was not altered by pretreatment with the inhibitor of prostaglandin production, 10μM indomethacin (PA+E = 46±9%, PV+E = 59±15%), but was significantly ($p<0.05$) reduced (from PA+E = 49±11% (n=7), PV+E = 65±8% (n=8) @ 10 μM AA) by pretreatment with an inhibitor of cytochrome P450, 30μM SKF525A (PA+E = 26±4% & PV+E = 27±4%), suggestive of AA metabolism via the epoxygenase/monooxygenase pathway. Thus, in HPA and HPV the relaxation to exogenous AA seems to be mediated by metabolites formed via cytochrome P450-linked enzymes. This mechanism could help prevent vasospasm in the placental circulation.

361 **COCAINE METABOLISM DURING PREGNANCY IN MATERNAL, PLACENTAL, AND FETAL COMPARTMENTS: AN *IN VIVO* ANIMAL MODEL.** R. William Stettler, M.D.,[+], Van R. Bohman, M.D.,[+] Donna I. Standard B.S.,[+] K.L. Westfall, M.S.,[+] Bertis B. Little, Ph.D.[+] Dept. of Ob/Gyn, The University of Texas Southwestern Medical Center, Dallas, Texas.

Others have shown rodent fetuses can metabolize cocaine (C) to norcocaine (NC), and human placentae transform C to ecgonine methyl ester (EME). This implies that placentae possess cholinesterase activity (CA), and term rodent (parallel to human second trimester) fetal livers have N-demthylase. EME and NC were not previously quantitated in a single study. It is unknown whether: (1) EME crosses to the fetus, or if (2) the fetus possesses CA. We studied this in rats given C (25 mg/kg) on day 18 of gestation. Four animals were sacrificed at each time period (0, 25, 45, 90, and 135 min. post-IV injection). Maternal and fetal tissues (liver, kidney, brain, heart), placentae, and maternal blood were collected at sacrifice. C, EME and NC levels were analyzed by gas chromatography. C metabolized to NC and EME in the mother, and both were found in placentae. Fetal tissues contained NC and C, but only trace amounts of EME. Fetal liver NC levels increased over time. This implies: (1) fetal liver produces NC and (2) EME and NC only minimally transfer across placenta, perhaps due to high polarity. Thus, C metabolism is different in mother and fetus, likely due to immature fetal enzyme complement. NC in fetus has clinical implications: (1) NC was higher in fetal brain over time, (2) NC is 9-fold more active than C, and (3) fetal brain growth retardation is associated with cocaine abuse.

362 **T CELL DEVELOPMENT IN THE HUMAN FETAL THYMUS: AN IN VITRO MODEL**

JP Smith[X], CK Walker[X], WC Hyun[X], DV Landers,
Dept. Ob/Gyn and Reprod. Sci., University of California at San Francisco General Hospital, San Francisco, California

Objective: Current knowledge of T cell development in the fetal thymus has been largely derived from murine studies. Studies of the human fetal thymus has been limited by the difficulty in obtaining specimens. This system was developed to study human fetal thymocyte maturation in vitro. **Methods:** We studied six human fetal thymuses, 18 to 22 weeks gestation. Single cell suspensions were co-cultured with an EBV transformed B cell line as an allogeneic stimulus. Cell surface antigens, CD3 (pan T cell marker), CD4 (helper/inducer), CD8 (supressor/cytotoxic), IL-2R (activation) and T cell receptor (TCR), were analyzed by flow cytometric analysis at days 0, 2, 5, and 7. **Results:** The majority of thymocytes expressed the characteristic double positive (CD4/CD8) precursor T cell form. At this point in development 2.5% of the cells expressed IL-2R and 35% expressed the TCR. After 7 days in vitro the thymocytes lost the immature double positive expression and developed into either CD4+/CD8- or CD4-/CD8+ phenotypically mature T cells. By day 7 expression of IL-2R and TCR was 79% and 90%, respectively. **Conclusion:** Although the cells were not subjected to positive and negative selection which occurs in the thymus before release into the periphery, this in vitro system parallels the in vivo phenotypic maturation processes. This system may prove useful in studying the effects of infectious agents (i.e., HIV) on fetal T cell development.

363 DO PATIENTS WITH A HISTORY OF RECURRENT ABORTION (RA) HAVE SOME UNDERLYING IMMUNOLOGICAL ABNORMALITY? M MacLean[+], R Wilson[+], C Jenkins[+], S H Miller[+], JA Thomson[+], JJ Walker. Departments of Obstetrics and Medicine, Glasgow Royal Infirmary, Scotland, UK.

We have shown that compared to healthy pregnant women, patients with a history of RA have a number of immunological abnormalities. As it is not known whether these changes are triggered by the pregnancy we have investigated 5 patients with a history of RA prior to and following confirmation of their pregnancy. The results show that while there was no significant difference pre and post pregnancy all parameters differed significantly from a group of healthy controls ($n = 25$).

	^{3}H THYMIDINE X 10^3CPM			B CELLS	CYTOTOXICITY
	C	PWM	PHA	CON A	Ig	% 51Cr
PRE PREG	0.3	15.4	27.3	23.2	1373	35.0
POST PREG	0.5	17.0	31.1	24.7	1407	36.8
CONTROL	2.1**	34.5**	52.0**	46.9*	844**	23.2**

** $P < 0.002$ * $P < 0.02$

Mixed lymphocyte reactions carried out between the 5 women and their partners showed activity to be significantly reduced compared to controls (76 + 28 vs 118 + 25% $p<0.03$)), suggesting there are a number of common antigens between the partners. **Conclusions.** These results would suggest that in women with RA there is some underlying immunological abnormality which is present prior to the pregnancy.

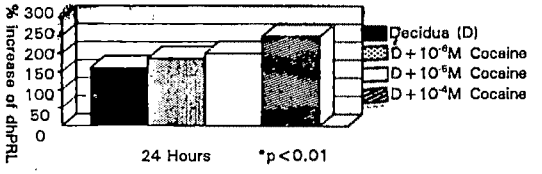
364 VENTILATION-PERFUSION MATCHING AND RESPIRATORY ECONOMY DURING MATERNAL EXERCISE. J.M. Pivarnik[X], N.A. Ayres[X], M.B. Mauer[X], B. Kirshon, G.A. Dildy, T. Spillman[X], and D.B. Cotton. Baylor College of Medicine, Houston, TX.

We examined the effects of pregnancy and maternal aerobic fitness on ventilation-perfusion (VA/Q) and physiological dead space-tidal volume (VD/VT) ratios during an acute bout of submaximal exercise. It is possible that these parameters are affected by chronic physical activity if it is continued throughout gestation. Method Seven physically active (PA) and 4 sedentary (SED) women who were tested twice during pregnancy (25 wks, 36 wks) and 12 wks postpartum. Each woman performed cycle exercise for 15 min at a HR of 140 b·min^{-1} (range = 137-142 b·min^{-1}). This insured that relative exercise intensity did not differ between subject groups. Indirect calorimetry was used to measure volumes and fractional concentrations of respiratory gases. End-tidal CO2 (PETCO2) was used as an estimate of alveolar CO2 (PACO2). Cardiac output (Q) was estimated via the indirect Fick method (CO2 rebreathing). Results Exercise metabolic rate was significantly ($P<.001$) greater in the PA (7.2 kcal·min^{-1}) vs SED (4.7 kcal·min^{-1}) subjects, but was not affected by pregnancy status. Alveolar ventilation (VA) and Q responses to exercise were proportionally greater ($P<.001$) in the active subjects which resulted in similar VA/Q in both PA (2.71) and SED (2.63) women. PA subjects had significantly lower minute ventilations per unit of O2 consumed (VE/VO2) compared to SED controls (33.3 vs 39.5). However, VD/VT was less ($P<.01$) in the PA (0.19) than SED (0.24) subjects. Conclusions Pregnancy status did not affect cardiorespiratory parameters as each individual's responses to exercise were similar at both gestational ages and postpartum. These preliminary data indicate that ventilation-perfusion matching during aerobic exercise is not affected by pregnancy status or fitness level. However, physically active gravidas demonstrate more economical ventilation than their sedentary counterparts during cycling performed at similar relative intensities.

365 CAN CIRCULATING CELLULAR FIBRONECTIN PREDICT LABOR ? O. Irion[x], M. Müller Sapin[x], P. Bischof[x], Ph. Extermann[x], F. Béguin. Dept Ob/Gyn, University Hospital, GENEVA, Switzerland

Fibronectin has been isolated from amniotic fluid and placental tissue extracts. Immunohistochemical studies showed its localization to the extracellular matrix of the decidua basalis. Its role as a marker for labor or ruptured membranes has been advocated. Such a marker would be very useful in many clinical situations, especially preterm, and could modify the therapeutic approach. The aim of this study was to evaluate the correlation between cellular fibronectin release into the maternal circulation and imminence of delivery. Methods: 152 patients due to deliver were included in the study from april 19th to may 15th 91. A protocol was completed and 5 ml of native maternal blood was taken. Serum cellular fibronectin was blindly measured (enzyme immunoassay by Adeza Biomedical). Results: Fibronectin was found ≥ 0.1 ug/ml in 32 women (21%), and was absent in the remaining 120. The two groups did not differ with respect to maternal age (29.4 vs 28.5), gravidity (1.7 vs 2.0), parity (0.8 vs 1.0) or gestational age at time of blood sampling (39.7 vs 39.7) or delivery (39.7 vs 39.8). No correlation was found between presence or absence of fibronectin and ruptured membranes (31.3% vs 38.3%), mean temperature (36.5 vs 36.7°C), leucocyte counts (9900 vs 10826/mm3), or presence of uterine contractions (70.4% vs 73.8%). Time measured in hours between blood sampling and rupture of membranes (6.5 vs 2.9), between blood sampling and delivery (10.8 vs 8.2) or between rupture of membranes and delivery (4.4 vs 5.3) was not statistically different for the two groups. Only one patient had preeclampsia (fibronectin < 0.1 ug/ml). Conclusion: we observed serum fibronectin ≥0.1 ug/ml in 21% of our patients. However, this group did not show any difference compared with the other patients. Presence or absence of cellular fibronectin was not correlated with ruptured membranes, uterine contractions, or imminence of delivery. In our hands, this test cannot predict labor and delivery. Further studies may help us to understand the significance of a positive measurement of fibronectin in maternal serum.

366 **MATERNAL SERUM CAFFEINE AND PARAXANTHINE LEVELS AND THIRD TRIMESTER FETAL BIOPHYSICAL ACTIVITY.** **L.Devoe,MD C.Murray RN[x], A.Yossef,MD[x],M.Arnaud,PhD[x], Dept. OBGYN, Med. Coll. Georgia, Augusta, GA; Nestle Research Center, Lausanne, SZ**



Caffeine and paraxanthine (PX) are found in the blood of most pregnant women and achieve higher concentrations in fetal blood. Their effects on fetal biophysical activity are not well known. We performed 120 2-hour continuous ultrasound observations of fetal heart rate (FHR) and fetal breathing and body movements (FBMs and FMs) in normal 32 - 40 week gestations, standardized for time of day and overnight fasting state. These data were correlated with maternal serum levels of caffeine and PX obtained before and after each study and measured by HPLC.

	Caffeine		PX	
	r	p	r	p
FHR Baseline	-.30	.03	.13	.37
FHR Variation	.12	.38	.002	.99
FBM Incidence	.24	.08	.08	.58
FBM Rate	.47	.004	.25	.07
FM Incidence	.15	.29	.16	.27

Most biophysical variables had weak or insignificant correlations with maternal caffeine or PX levels. The positive correlation of caffeine levels and breath rate agrees with previous neonatal observations. Fetal biophysical testing should not be affected by typical maternal caffeine consumption in normal third trimester pregnancy.

367 THE EFFECT OF COCAINE ON DECIDUAL PROLACTIN SECRETION *IN VITRO*. C.D. Hsu,* H.A. Zacur,* T.R.B. Johnson, Dept. Gyn/Ob, The Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Cocaine use in pregnancy has been implicated in increasing the risk of premature labor and in decreasing the volume of amniotic fluid. Mechanisms for these activities remain unknown. Prolactin secretion from human decidual tissue has been documented and increased decidual prolactin (dhPRL) secretion associated with lowered amniotic fluid volume and advancement in fetal lung maturation. We have previously reported that the separation of fetal membranes from the decidual exerts a progressive inhibiting influence on prolactin secretion (AFS Abstract P-175, 1991). Consequently, we sought to determine whether cocaine could affect *in vitro* prolactin secretion from decidua. Fresh decidual tissue was obtained at term during elective cesarean section (n=4) and placed in Gey's buffer with varying concentrations (0,10^{-4},10^{-5},10^{-6} M) of cocaine in a 5% CO_2, 95% air incubator at 37°C for 24 hours. At intervals (0,4,24 hrs), a 0.8 ml buffer aliquot was taken and the prolactin concentration determined by enzyme immunoassay. Prolactin concentrations rose after exposure to cocaine at all concentrations. However, only cocaine at the highest concentration (10^{-4} M) after 24 hours produced a prolactin concentration significantly different from the control group ($p<0.01$). This response of decidual prolactin secretion to cocaine may serve as one possible explanation for the diminished amniotic fluid volume and advancement in fetal lung maturation observed in chronic cocaine users.

368 **HYPOTHALAMIC-PITUITARY-ADRENAL AXIS FUNCTION IN THE HUMAN FETUS:** CJ Lockwood, M Alvarez, N Radunovic[x] Mt Sinai School of Med., New York, NY.

In human pregnancy the relationship between the fetal and maternal hypothalamic-pituitary-adrenal (HPA) axes has yet to be established. Therefore, we measured corticotropin-releasing factor (CRF), corticotropin (ACTH) and cortisol (Cs) levels in 104 paired fetal and maternal serum samples obtained at the time of cordocentesis between 18 and 39 weeks gestation. **RESULTS** CRF: Maternal CRF levels [1.54 ng/ml (±1.5)] were significantly higher than levels in either 26 nonpregnant controls [0.17 ng/ml (±0.07); p=0.001] or fetuses [0.34 ng/ml (±0.16) p=0.001]. Maternal but not fetal CRF levels correlated strongly with gestational age (GA) (r=0.73; p=0.001 vs. r=0.304; p=0.9). ACTH: Fetal ACTH increased (r=0.355; p=0.001) while maternal ACTH decreased with GA (r=-0.21; p=0.037). Cs: Both fetal and maternal Cs correlated with GA (r=0.569; p=0.001 and r=0.39; p=0.001). Significant Spearman Rank Correlations between HPA axes hormones in both fetal (F) and maternal (M) serum are presented below (p<0.05):

	CRF-M	ACTH-M	Cs-M	CRF-F	ACTH-F	Cs-F
ACTH-M	NS	--	-0.27	0.3	0.26	-0.24
Cs-M	0.26	-0.27	--	-0.28	NS	0.53
CRF-F	NS	0.30	-0.28	--	NS	NS
ACTH-F	NS	0.26	NS	NS	--	-0.44
Cs-F	0.37	-0.24	0.53	NS	-0.44	--

CONCLUSION: Maternal CRF increased dramatically across gestation, only weakly correlated with maternal and fetal CS and did not correlate with maternal ACTH. Although hormone bioactivity was not measured, these findings are consistent with a placental-derived CRF secretion, independent of feedback inhibition, which "inappropriately" drives maternal ACTH and Cs synthesis. Furthermore a substantial contribution by CRF-stimulated maternal Cs to the circulating fetal Cs pool may be responsible for the strong correlation between fetal and maternal Cs, their correlation with GA and their inverse correlation with declining maternal ACTH levels.

369 **ß-ENDORPHIN CONCENTRATIONS IN FETAL BLOOD DURING THE SECOND HALF OF PREGNANCY.** CJ Lockwood, N Radunovic[x], M Alvarez, RL Berkowitz. Mt. Sinai School of Medicine, New York, NY.

To evaluate changes in circulating ß-endorphin (BEP) concentrations during fetal adaptation to possible intrauterine stress we measured BEP values in paired fetal and maternal blood samples obtained during 81 "uncomplicated" and 18 "complicated" (multiple cord punctures) cordocentesis between 18 and 39 weeks of gestation as well as in 24 term neonatal samples. **RESULTS:** The mean fetal BEP value from the uncomplicated procedure group [90.5 pg/ml (±59.4)] was significantly lower than BEP levels from neonates [228.4 pg/ml (±166.2); p <0.001], and from the complicated procedure group [771.2 pg/ml (±335.9); p< 0.001] but significantly higher than mean maternal values [70.5 pg/ml (±48.8); p< 0.02]. Fetal BEP levels from the uncomplicated but not from the complicated group significantly correlated with maternal values (Spearman rank r=0.47; p< 0.001 vs. r= -0.08; p> 0.5). Fetal BEP levels did not correlate with gestational age. **SUMMARY:** These findings suggest that delivery and fetal adaptation to possible intrauterine stress are associated with significant increases in BEP levels. While a maternal and/or placental contribution to steady state circulating fetal BEP levels can not be excluded, it appears that the fetal pituitary is the primary source of circulating fetal BEP during possible intrauterine stress.

370 **MATERNAL AND FETAL RESPONSES TO ACUTE HEMATOCRIT REDUCTION.** D. Mostello, C. Chalk[x], C. Mack[x], B. Fisher[x], K. Clark[x], Perinatal Research Institute, University of Cincinnati, Cincinnati, Ohio 45267

Anemia was produced by a 2000ml exchange transfusion with plasma/crystalloid in 11 pregnant ewes; 4 underwent exchange transfusion with whole blood. Hematocrit reduction (from 28±2.9 to 17±3.4%) resulted in decreases in arterial O_2 content (O_2C_a)(6.4±0.6 vs 9.8±2.1 ml/dl, anemic vs control mean ± S.D.), uterine O_2 delivery(DO_{2ut})(by -34.8±5.2 vs -17.2±13.5%), mean arterial pressure (MAP)(by -11.3±5.2 vs -2.0±4.7mmHg), uterine vascular resistance (UVR)(by -27.1±7.2 vs -10.1±18.2%), uterine venous O_2C (3.6±0.7 vs 7.0±2.3 ml/dl), fetal p_aO_2(by -11.5±14.5 vs 6.1±10.6%) and fetal O_2C_a (by -23.0±14.6 vs 1.9±21.2%). Maternal heart rate (MHR)(by 15.6±18.8 vs -7.5±12.3bpm), fetal HR (by 12.4±14.6 vs -10.5±14.7bpm) and uterine O_2 extraction (43.1±7.5 vs 29.1±9.2%)increased. By the following day, MAP, UVR and FHR returned to control levels and cardiac output (C O) had increased (by 15.3±15.7 vs -8.8±8.1%). DO_{2ut} remained decreased (by -33.7±11.1 vs -8.4±10.1%). Fetal pH, pCO_2, lactate and hematocrit, maternal pH, pCO_2, pO_2, lactate, and uterine blood flow (UBF) were unchanged. Acute anemia probably results in uterine vasoconstriction as UBF did not increase despite increased C O and decreased viscosity of anemic blood. DO_{2ut} is limited by decreased O_2C and lack of increase in UBF. Despite increased uterine O_2 extraction, the fetus becomes mildly hypoxemic.

371 **EFFECT OF SOUND STIMULATION ON FETAL CEREBRAL METABOLISM AND FETAL OXYGENATION.** C. R. Chao[x], G P. Guy[x], K. E. Jack[x], S. S. Daniel[x], R. I. Stark[x], Dept. of Ob/Gyn, Columbia University, New York, NY

Previous studies have demonstrated that sound stimulation increases glucose metabolism in many regions of the fetal brain. However, the metabolic fate of that glucose has not previously been determined. **Methods:** Near-term fetal sheep were chronically catheterized in brachial arteries and the superior sagittal sinus. Sound stimulation was provided by 1) miniature waterproofed earphones attached to the fetus and 2) an electrolarynx applied to the maternal abdomen. Arterial and venous (sagittal sinus) samples were taken for glucose, oxygen, and lactate concentrations and blood gases prior to and during sound stimulation. All studies took place in the high voltage state. **Results:** Arterial and venous oxygen content and pO_2 were significantly decreased by 6-7% during sound stimulation. The arteriovenous difference for oxygen was unaffected by sound stimulation, whereas that for glucose increased significantly. The glucose:oxygen quotient, an index of the adequacy of oxygen uptake for glucose uptake, increased from 0.88 ± 0.08 to 1.13 ± 0.12 (p<0.01). These findings are consistent with *stimulated* or *aerobic* glycolysis which has been shown to increase brain lactate concentration in other models. No change in lactate arteriovenous difference could be detected, but this may be due to the relative impermeability of the ovine fetal blood-brain barrier to lactate. The metabolic changes were similar during both types of stimuli, but the electrolarynx group alone exhibited a transient increase in arterial blood pressure. Because sound stimulation may adversely affect fetal oxygenation and cerebral metabolism, caution should be exercised in the fetal diagnostic use of sound stimuli. (HD 26600)

372 **PLASMA ATRIAL NATRIURETIC FACTOR AND ARGININE VASOPRESSIN RESPONSES TO INDOMETHACIN IN THE OVINE FETUS.** Martin P.R. Walker MD, Cecilia Y. Cheung PhD[X], Robert A. Brace PhD[X]. Division of Perinatal Medicine, Dept of Reproductive Med., Univ. of California, San Diego, CA.

Prostaglandins have been implicated in the release of atrial natriuretic factor (ANF) and arginine vasopressin (AVP). We hypothesized that indomethacin (ID) would cause a fall in plasma ANF and AVP in the fetus. After a 1 hr control, we gave 0.31 mg/kg of ID i.v. followed by a 0.015 mg/kg/min infusion to 9 near term chronically catheterized ovine fetuses. Hemodynamic data were continuously monitored for 5 hours and plasma ANF and AVP levels determined hourly. During ID infusion, plasma ANF increased from control of 214 ± 58 pg/ml to 701 ± 193 pg/ml at 1 hr then remained at 427 ± 89 pg/ml (ANOVA, $P<0.00001$ after log transformation). Plasma AVP levels rose from 3.1 ± 0.8 pg/ml to 7.4 ± 2.5 pg/ml by 3 hr, to 20.5 ± 11.5 pg/ml at 4 hr, returning to 7.4 ± 2.5 pg/ml at 5 hr (ANOVA, $P=0.0005$). Multivariate analyses revealed that the increases in plasma ANF ($R=0.56$, $P=0.017$) and AVP ($R=0.76$, $P=0.0004$) were associated with changes in fetal arterial pressure but not in blood volume or venous pressure. In summary, our data do not support the hypotheses that ID, at these doses, causes a reduction in plasma ANF or AVP in the ovine fetus. We speculate that 1) The elevation in arterial pressure in response to ID leads to an increase in ANF and 2) The rise in AVP may mediate the increase in arterial pressure. In addition, the observed rise in AVP may explain the clinical observation that indomethacin use in the human fetus leads to oliguria and oligohydramnios.

373 **PREVALENCE OF COCAINE ABUSE IN A TERTIARY CARE CENTER:** M.J. Paidas[X+], M.G. Neerhof, M. Husson[X], R.J. Librizzi. Mount Sinai Medical Center, New York, NY and Pennsylvania Hospital, Philadelphia, PA.

To address the need for routine screening in a urban hospital with 4600 deliveries per year (65% private, 35% service), a cocaine prevalence study was undertaken at Pennsylvania Hospital. The screening was anonymous, and accomplished over 2 months. 441 urine specimens were obtained from pregnant women presenting or being admitted to Labor and Delivery. The urine was tested for benzoylecgonine, a cocaine metabolite, using the enzyme immunoassay, EMIT[R] d.a.u.[TM] Cocaine Metabolite Assay (SYVA Co, Palo Alto, CA)

RESULTS

Population	# patients	(+) Screen	Percentage %
Private	295	2	0.68
Service	132	4	3.03
Unregistered	14	3	21.43
Total	441	9	2.04

Service refers to patients followed in the prenatal clinic at our institution. This group (132) was divided into high risk (23), low risk (103), and teen (6). The number of positive screens were 0,4,0 respectively. Private (295) refers to patients followed by private practitioners (248) and those followed by a maternal fetal medicine practice (47). The number of positive screens in these latter two categories were 2 and 0 respectively.

CONCLUSION The overall prevalence of positive cocaine screening is low at our institution. Routine screening may be beneficial in selected populations including unregistered patients.

374 **THE RELATIONSHIP BETWEEN FETAL PLATELET FUNCTION IN THE THIRD TRIMESTER AND UMBILICAL DOPPLER VELOCIMETRY.** MJ Paidas[X+], MJ Haut[X], A Ludomirsky and RJ Bolognese. Mount Sinai School of Medicine, New York, NY and Pennsylvania Hospital, Philadelphia, PA.

Reduced fetal platelet counts have been associated with abnormal umbilical doppler waveforms. To investigate the relationship between fetal platelet function and umbilical artery doppler velocimetry, we retrospectively compared the results of platelet aggregation, a measurement of platelet function, with the systolic/diastolic (s/d) ratio of the umbilical artery flow velocity waveform. Our previous research in platelet function in the developing fetus suggests that 'normal' responses in platelet aggregation appear in the third trimester. The study population consisted of 10 pregnant women ranging from 28-36 weeks gestational age. Umbilical s/d ratios were obtained in all patients prior to cordocentesis. Platelet aggregation studies using ADP 2×10^{-4}M, were performed turbidometrically using a Sienco Dual Sample Platelet Aggregation Meter (Sienco, Inc., Morrison CO.). 200 microliters of platelet rich plasma were obtained from each fetal blood specimen after centrifugation.

RESULTS:

Gestational age (wk)	S/D	% Aggregation to ADP	Gestational age (wk)	S/D	% Aggregation to ADP
28	2.6	30.5	33	2.9	29.0
29	2.6	5.0	34	1.8	65.0
30	2.7	7.5	34	3.6	42.0
31	3.7	1.5	34	3.2	100
33	2.4	34.5	36	2.3	18

Doppler derived s/d ratio did not correlate with the platelet response to the aggregation agonist ADP 2×10^{-4}M. ($p > 0.05$, $r=0.07$).

CONCLUSION: In this small series, there is an apparent lack of correlation between a measurement of platelet function, namely aggregation response, and umbilical doppler velocimetry. Further studies in platelet activation and methodology are now in progress to verify our initial results of fetal platelet function.

375 SERUM CYTOTOXICITY LEVELS IN PATIENTS WITH SPONTANEOUS AND RECURRENT ABORTION. JJ Walker, M MacLean[+], R Wilson[+], JA Thomson[+], University Departments of Obstetrics and Medicine, Glasgow Royal Infirmary, Scotland, UK.

We have previously shown that there are immunological abnormalities in patients with spontaneous (SA) and recurrent abortion (RA). As the results suggested that these may be triggered by some serum factor we have studied serum cytotoxicity levels in 20 healthy pregnant women, 9 with SA and 20 with RA, by measuring the release of ^{51}Cr from K 562 cells. Serum cytotoxicity levels did not differ significantly between healthy pregnant women and those with SA (25.7± 7.7% VS 23.7±2.9%). Levels were significantly higher in women with RA (33.4±3.2% $P<0.001$) compared to controls and SA. Elevated serum cytotoxicity was also seen in 5 RA prior to and following confirmation of their pregnancy (35±1.9% vs 33.9±3.2%). **Conclusions.** These findings would suggest that the increased cytotoxicity seen in RA is not triggered by the pregnancy. Also it would appear that the mechanism responsible for triggering the immunological changes seen in SA and RA differ.

376 **OBSTETRICAL OUTCOME IN AEROBICALLY TRAINED WOMEN** Stephen R. Carr[1], Marshall W. Carpenter[1], Richard Terry[2X], Ann Lengle[2X], Barbara Haydon[1x]; Brown University/Women and Infants Hospital[1] and Human Performance Laboratory, Miriam Hospital[2]; Providence, RI

Previous studies examining the effect of physical exercise on pregnancy did not randomize or quantitate exertional duration or intensity. The effect of a 6 or 10 week training period during pregnancy on the incidence of PPROM, delivery EGA, bleeding, birthweight, labor length and Apgar scores at 1 and 5 minutes was examined. 38 women were randomized to either a sedentary pregnancy (S) or to either 6 or 10 weeks of training (T)which required 4 weekly sessions of 30 minutes cycle ergometer exercises at 60-70% VO_{2max} beginning at 20-28 weeks gestation. VO_{2max} was determined by an initial incremental exercise test employing a pregnancy-specific formula extrapolating from individual HR/VO_2 data. During exercise training the cycle resistance was increased to maintain exercise heart rate at the initially targeted rate. **RESULTS:**

	C/S	PPROM	Del EGA	Bldng	BW	LoL	A^1	A^5
T	3/16	3/16	39.7±9	0	3458 ±361	12.2 ±11.8	8.1 ±.6	8.9 ±.2
S	2/20	1/20	39.8±7	0	3435 ±427	12.6 ±12.0	7.1 ±1.2	8.5 ±.5
p	.37	.19	.73	-	.86	.93	.07	.40

CONCLUSIONS: Pregnant women participating in a training protocol experienced no difference in obstetrical outcome when compared to a sedentary cohort. Our results confirm the safety of our exercise protocol in evaluating cardiovascular response during pregnancy.

377 **ACTIVITY RESTRICTION TO TREAT HIGH RISK PREGNANCY: A PHYSICIAN SURVEY.** J. A. Maloni[X], A.W. Cohen, I. Forouzan, E. M. Graham[X], Dept. Ob/Gyn, University of Pennsylvania Medical Center, Phila., PA

There are no standard obstetrical protocols for inpatient or outpatient bedrest and reduced physical activity in patients with preterm labor, incompetent cervix, preeclampsia, placenta previa, or preterm rupture of membranes. A survey was conducted to determine patterns of activity restriction/bedrest therapy for these complications of pregnancy at given gestational ages. Questionnaires were sent to 70 Maternal-Fetal Medicine specialists and 200 General Ob/Gyns. They were asked tc select from varying levels of activity restriction treatment that they would prescribe at 20, 24, 28, 32, and 36 weeks gestation. There was no consensus within the obstetrical and Maternal Fetal Medicine community as to when patients should be hospitalized. There was strongest disagreement about the level of activity restriction required for patients with preeclampsia and placenta previa. Maternal-Fetal Medicine specialists tend to hospitalize these patients at an earlier gestational age and are less likely to deliver patients electively at 36 weeks gestation. Only 32% of physicians noted side effects from bedrest and the duration of the side effects ranged from a few days to several weeks. This study concludes that there is no "Standard of Care" across the nation for Maternal-Fetal Medicine specialists or general obstetricians in the treatment of many high-risk pregnancy complications that may require activity restriction.

378 **IN UTERO ETHANOL EXPOSURE INDUCES NURSING DEFICIENCY IN RAT PUPS.** M. Subramanian[x], X. Chen[x], B. Bergeski[x]. Dept. of Ob/Gyn, Wayne State Univ., Detroit, MI.

Prenatal ethanol exposure induces behavioral abnormalities in rats. In the present study, we examined suckling latencies and milk consumption during early (day 6) and mid- (day 10) lactation in prenatally ethanol exposed pups. On day eight of pregnancy, rats were assigned to control (rat chow) or liquid diet groups containing 0%, 17.5% and 35% ethanol-derived calories (EDC). The 0% and 17.5% EDC diets were similar to 35% EDC diet except that maltose-dextrin was substituted isocalorically for ethanol and both groups were pair-fed to the 35% groups. Following delivery, litters were adjusted to eight and transferred to untreated foster dams. On days six and 10 of lactation, pups were removed at 0800h and returned to dams at 1400h. The time taken for the majority of pups to attach to the nipple and start nursing vigorously (suckling latency) and milk consumption were determined. On day six, suckling latency for the 35% group (10.69 ± 1.43 min) was greater ($p < .05$) than control (7.4 ± 0.63) or 17.5% (6.0 ± 0.79) groups. However, on day 10, the suckling latencies among groups were comparable. Milk consumption was lower ($p < .05$) for the 35% group on day six (4.66 ± 0.29, 5.02 ± 0.52 and 3.46 ± 0.40 gm) and on day 10 (7.97 ± .42, 7.17 ± 0.77 and 5.14 ± 0.63 g for control, 17.5% and 35% respectively). Pups exposed to 35% EDC weighed less up to weaning. These results illustrate the continued nursing difficulties offspring experience following prenatal alcohol exposure. (Supported by NIAAA AA07670).

379 THE MITOGENIC ACTIVITY OF SERUM AND LYMPHOCYTES FROM PATIENTS WITH RECURRENT ABORTION (RA). R Wilson±, M MacLean+, JA Thomson+, JJ Walker University Departments of Medicine and Obstetrics, Glasgow Royal Infirmary, Scotland, UK

We have shown that peripheral blood lymphocytes (PBL) from women with a history of RA have an impaired response to mitogenic stimulation. The aim of this study was to determine the mechanism responsible. Serum and PBL were obtained from healthy pregnant women and from RA. The PBL were made to a standard concentration in RPMI + serum from both patient groups. The PBL were then incubated + mitogens. The activity was determined by ^3H thymidine incorporation. The results (Table) showed significantly greater incorporation when PBL from healthy pregnant women were incubated with their own serum. The response was significantly reduced when PBL from RA were mixed with RA serum.While PBL from the control mixed with RA serum or vice versa gave a reduced response this was not always significant.These results would suggest that PBL from RA are unable to respond maximally to mitogenic stimulation and that this is due, at least in part, to some serum factor.

380 FETAL HEMOLYTIC ANEMIA AND FETAL GROWTH.
AR Gregg+ and CP Weiner. Dept OB/GYN, U. of IA, Iowa City, IA.

Products of hemolyzed blood inhibit the action of insulin in vitro (Steinke *Blood 30:359-63; 1967*) and hyperinsulinemia has been observed in fetuses with hemolytic anemia (Brown *Am J Obstet Gynecol 131:682-86; 1978*). It was recently reported without explanation in a small number of alloimmunized pregnancies that the normal maternal-fetal glucose gradient was absent (Nicolini *Am J Obstet Gynecol 161:924-27; 1989*). We hypothesized that hemolytic fetal anemia as defined by gestational age dependent norms (Weiner *Am J Obstet Gynecol 165:546-53; 1991*) would be associated with intrauterine growth retardation (IUGR). 22 fetuses with hemolytic anemia who received 0 (15/22) or 1 (7/22) transfusion after 33 wks gestation were identified from our database. Fetal intravascular transfusion was performed when the hematocrit fell below 30%. Serial sonographic measurements were available for 15 pregnancies. Scattergrams of the data points for estimated fetal weight percentile (EFW), fetal abdominal circumference percentile (AC), and birthweight percentile (BW) were constructed. In all cases, the initial AC was < the 50th percentile ($p<0.001$ from expected distribution) at the time of the first sonogram and diagnostic cordocentesis (26.9wks±5wks). In 12/15 (80%), the AC was ≤ 50th percentile ($p=0.05$ from expected) at the last scan. EFW was evenly distributed at both the initial scan and the last scan. BWs were available from 11 neonates; they were evenly distributed. The fetal AC strongly reflects fetal liver size. The low ACs are consistent with inactivation of insulin by products of hemolysis and the reported absent maternal-fetal glucose gradient. Rather than a loss of glycogen from the liver, these findings more likely represent failure of the fetal liver to perform glycogenesis normally in the presence of hemolysis. CONCLUSIONS: ***The growth limiting effects of fetal hemolytic anemia appear confined to the liver, a reticuloendothelial organ of the fetus. Hemolytic fetal anemia is not a risk factor for IUGR when defined by BW.***

381 THE NONVERTEX SECOND BORN TWIN: INFLUENCE OF PRESENTATION AND MODE OF DELIVERY ON APGAR SCORES AND UMBILICAL BLOOD GAS DATA. SA Ordorica*, IA Hoskins, J Blackstone*, F Inamoratti*, BK Young. NYU School of Medicine, Division of Maternal-Fetal Medicine. New York, NY 10016.

The optimal mode of delivery for the nonvertex second born twin remains controversial. Several studies have demonstrated increased perinatal compromise for the vaginally delivered nonvertex second twin, while other investigators have not shown such an association. A prospective study was therefore undertaken which examined 166 sets of twins, 69 of which included a nonvertex second born. Using umbilical blood gas data and Apgar scores as indices of neonatal condition, oxygenation and acid-base status, vaginal and cesarean delivered nonvertex second born twins were compared by means of the student t-test. No significant differences in either Apgar scores or in umbilical blood gas parameters related to the mode of delivery were noted. A similar analysis of nonvertex and vertex second born twins delivered vaginally also showed no significant differences in these parameters due to the type of presentation. In conclusion, increased perinatal compromise for the vaginally delivered nonvertex second born twin due to mode of delivery is not reflected in either Apgar scores or in umbilical blood gas parameters. Also, there is no significant difference in these parameters related to presentation in vaginally delivered second born twins.

382 AMNIOTIC FLUID ERYTHROPOIETIN IN THE SMALL FOR GESTATIONAL AGE FETUS. T.C.C. Peng, S.McCoy[X] DEPT OB/GYN MEDICAL COLLEGE VIRGINIA/VCU, RICHMOND, VA.

Differentiating the growth retarded fetus (IUGR), at increased risk of adverse perinatal events, from one that is constitutional small for gestational age (SGA) is difficult by ultrasound but a common problem when a SGA fetus is detected by ultrasound biometry. Percutaneous umbilical cord blood studies demonstrate a reduction of pO2 in SGA vs appropriate weight for gestational age (AGA) fetuses. Reduction in pO2 has been shown to elicit fetal specific increased erythropoietin (EPO) production measureable in fetal blood and amniotic fluid (AF). Therefore EPO may be useful in discriminating the SGA fetus that is hypoxic and probably IUGR. This preliminary study investigated the efficiency of AF EPO in discriminating AGA from SGA fetuses, using a commercial RIA kit (EPO-TRAK by Incstar). This kit has a sensitivity of 4.4 mu/ml. AF was obtained in 20 pregnancies prior to labor as labor can increase EPO levels. AF EPO was measured in 4 discrete groups, term AGA and SGA and preterm AGA and SGA. In term AGA (5) fetuses the AF EPO was 4.26±4.4 mu/ml vs 40.5±72.6 mu/ml in term SGA (4); and 8.5±4.3 mu/ml in preterm AGA (4) vs 62.3±123 mu/ml in preterm SGA (7) fetuses. The mean AF EPO level was 8-10 fold higher in SGA then AGA fetuses. However, the sample sizes were small and differences between the groups were not statistically significant. In summary, EPO may be useful as a prenatal test to discriminate AGA vs SGA and IUGR vs SGA but larger sample sizes are needed.

383 **AMNIOTIC FLUID PLATELET FACTOR 4 AND BETA-THROMBOGLOBULIN DO NOT PREDICT LUNG MATURITY.**
AA Saleh, T Ozawa, MP Dombrowski, NB Isada, MP Johnson[X], MI Evans, W Blessed[X], SF Bottoms, EF Mammen[X], Dept Ob/Gyn, and Center for Fetal Diagnosis and Therapy, Hutzel HospitalWayne State University, Detroit, MI.

Platelet activating factor (PAF) has been identified in human embryos and fetuses. Possible sources are fetal lungs, kidneys and amniotic membranes. Cultured human fetal lung tissue showed time-dependent increase in PAF associated with accelerated glycogenolysis which may supply energy, glycerol and acetyl Co-A needed for surfactant synthesis (Hoffman et al, 1986). Platelet factor 4 (PF4) and beta-thromboglobulin (BTG) are unique markers of irreversible platelet activation and cleared by endothelium and kidneys respectively. If *in vivo* fetal PAF production increases with gestational age, fetal platelets will become more activated as term approaches and levels of fetal platelet activation products should also increase and correlate with surfactant production. To study this potential relationship, we measured PF4 and BTG by ELISA in 78 genetic amnios and 35 pulmonary maturity amnios. Results were analyzed by Mann-Whitney U test.

	Genetic Amnio	Maturity Amnio	p
PF4 (IU/ml)	1.30±2.34	0.24±0.36	<0.001
BTG (IU/ml)	18.2±13.8	8.55±14.12	<0.001

Using multiple regression PF4 and BTG did not predict PG%. We conclude: 1) the 3rd trimester drop in PF4 and BTG may be due to increased fetal endothelial and kidney maturity, diminished fetal platelet responsiveness to PAF, decreased transudation in fetal skin or other factors regulating platelet function. 2) This pattern, opposite to maternal increase PF4 and BTG with gestational age, support fetal origin, and 3) amniotic fluid PF4 and BTG do not predict lung maturity.

384 NORMALISATION OF GLUCOSE TOLERANCE IN ADULT OFFSPRING OF DIABETIC PREGNANT RATS BY ISLET TRANSPLANTATION IN THE MOTHER.

L. Aerts*, F.A. Van Assche, Department of Obstetrics and Gynecology, University of Leuven, Belgium.

Our previous work clearly shows that streptozotocin-induced diabetes in the pregnant rat has long-term consequences for the offspring. This effect is not of genetic origin, but is due to metabolic adaptations induced in the fetus by the diabetic intra-uterine milieu.

In the adult offspring of mildly diabetic mothers the insulin-secreting B-cells are affected ; in the adult offspring of severely diabetic mothers both insulin secretion and peripheral insulin-resistance are involved.

A definite conclusion can be made by normalizing the diabetic state during pregnancy using islet transplantation. Islets were obtained from normal neonatal Wistars after pancreatic digestion with collagenase. Severely diabetic rats received an injection of 2000 islets into the portal vein at day 15 of gestation, sham-transplanted diabetic animals received the solution medium only.

Glycemia was normalized in the transplanted mothers from the day after transplantation and throughout further gestation and lactation.

At weaning (age 20 days) the weight of the pups from transplanted mothers was normal while it was seriously decreased in the sham group (32 ± 2 versus 18 g. ± 1.5), as it was in the previous untreated severely diabetic group.

In the adult offspring of transplanted mothers, insulin and glucose levels during glucose infusion were normal, however plasma insulin levels were increased in the offspring of sham-transplanted mothers (87 ± 14 uU/ml versus 187 ± 21 uU/ml) after a 3 hour glucose infusion. The values of the sham treated group were identical as previously shown in the offspring of untreated diabetic mothers.

385 PLASMA PROTEINS AND NUTRITIONAL STATUS IN PREGNANCY

JE Maher*, RL Goldenberg, T Tamura*, SP Cliver*, HJ Hoffman*
University of Alabama Hospitals, Birmingham, Alabama

Albumin (AL), prealbumin (PA), and retinol binding protein (RBP) are used as long, mecium and short-term markers for protein nutriture. Their serum half lives in the non-pregnant state are 18, 2, and 0.5 days, respectively. We measured the proteins at 18 and 30 weeks gestation and correlated the levels with birthweight and fetal growth retardation (FGR). We also assessed these protein levels in relation to maternal age, race, infant sex and various measures of nutrition status such as hematocrit, height, pre-pregnancy weight, body mass index (BMI), lean body mass, and weight gain. Serum samples were obtained from 289 indigent multiparous women, 29% of whom gave birth to a newborn with FGR. None of the protein levels correlated with FGR. AL levels correlated inversely with birthweight at 18 weeks gestation ($p=0.05$), but not at 30 weeks and neither of the other protein levels correlated with birthweight. At 18 and 30 weeks, there was an inverse association between AL and both pre-pregnancy weight and BMI ($p<.01$), but not with maternal weight gain during pregnancy. AL levels were not related to height or lean body mass. AL levels correlated positively with PA ($p<.0001$) and RBP ($p=.001$) at both 18 and 30 weeks. Hematocrit, infant sex, age, and race did not correlate with serum AL. PA, a protein which migrates during electrophoresis in front of AL but is otherwise not related, also correlated ($p<.01$) with pre-pregnancy weight and BMI at 18 weeks but not with any other factor. PA and RBP levels were highly correlated ($p<.0001$) since they are secreted in association with one another from the liver. RBP and AL levels decreased from 18 to 30 weeks, but for each protein, there was a positive correlation between the 18 and 30 week values ($p<.001$). RBP did not correlate with any of the factors studied except maternal weight gain ($p<.03$). During pregnancy, plasma protein concentrations are regulated by complex and incompletely understood factors. Extrapolating assumptions of nutritional status based upon normal nonpregnant levels of these proteins may not be valid for predicting nutritional status in pregnancy.

386 DOES THE PRESENCE OF TRACE PHOSPHATIDYL GLYCEROL (PG) INDICATE NEONATAL LUNG MATURITY?

Audrey Gassman,* Robert J. Stiller, Roberta H. de Regt
Dept. Ob/Gyn, Bridgeport Hospital, Bridgeport, CT

The presence of trace PG obtained on amniocentesis is usually an indication for further testing (Lecithin/Sphingomyelin-L/S). We questioned whether trace (tr) PG in any specific patient indicates lung maturity. 58 nondiabetic patients who underwent amniocentesis from August 1989 to March 1991, delivered within 72 hours of the test, and had L/S analysis were included. Lung maturity was examined by clinical diagnosis and by L/S >/= 2. All patients were < 36 weeks. 8 infants (14%) developed respiratory distress, 5 developed transient tachypnea (overall incidence 24%). 3/11 with L/S >/=2 required oxygen >6 hrs in NBICU (33,33,35 wks). The presence of tr PG predicted mature L/S in 76% (19/25) of patients over 34 wks, but only 52% (17/33) of patients under 34 wks. Conclusion: Tr PG is not a good predictor of pulmonary maturity regardless of gestational age.

387 THE EFFECT OF MATERNAL INTRAVENOUS GLUCOSE ADMINISTRATION ON FETAL ACTIVITY.

DP Eller, RB Newman, SL Stramm*. Medical University of South Carolina, Charleston, South Carolina.

Fetal hyperglycemia has been shown to cause marked stimulation of the fetal metabolic state, resulting in increased oxygen consumption. Bocking, et.al.demonstrated increased fetal breathing movements but no change in gross body movements after intravenous glucose injection (AJOG 1982; 142: 606-611). Others have suggested that increased fetal activity may play a role in this increased oxidative metabolism. The following study was designed to prospectively evaluate fetal activity during maternal intravenous glucose tolerance testing (IVGTT). Fourteen women, 30.7±3.0 weeks gestation, were evaluated continuously for fetal activity with a doppler fetal activity monitor (Toitu Model MT-320).Baseline monitoring began 10 minutes before a fasting blood sugar was obtained. A 25 g load of 50% dextrose was administered and maternal plasma glucose levels were drawn at 15, 30, 45 and 60 minutes via an in-dwelling venous catheter. Six control patients, 29.8±4.8 weeks gestation, were continuously monitored and corresponding plasma glucose levels drawn. However, controls did not receive intravenous dextrose. The plasma glucose levels remained stable in the control group and the corresponding fetal activity was random. Fetal activity in the IVGTT group increased over time and was best characterized by a polynomial regression curve ($y= 16.1 + 0.6X - .004X^2$; $p = .0001$). The increase in fetal activity in the IVGTT group corresponded to the initial rise in maternal plasma glucose levels. Glucose is the principle source of energy for the fetus and crosses the placenta rapidly via facilitated diffusion. Fetal glucose levels correlate well with maternal plasma glucose (100 mg/dl maternal concentration = 80 mg/dl fetal concentration). This study confirms that increased fetal activity is a likely consequence of hyperglycemia, suggesting an association between fetal metabolic state and activity.

388 FETAL BEHAVIORAL STATE AND SWALLOWING RESPONSES TO ORAL WATER. A. Dodd[X], C. Agnew, Y. Fujino, M.G. Ervin[X], M.G. Ross, Dept. of Ob/Gyn, Harbor-UCLA Med. Ctr., Torrance, CA.

Fetal swallowing is a major route of amniotic fluid resorption. Although absent swallowing may result in excess amniotic fluid, previous studies have suggested an increased rate of fluid exchange and fetal swallowing in polyhydramnios. To determine if fetal swallowing is influenced by increased accessibility of fluid, seven ovine fetuses (127±2 d) were chronically instrumented with vascular catheters, fetal electrocortical (ECoG) and esophageal electromyogram electrodes, an esophageal flow probe and a sublingual catheter. Following a 2 h control period, distilled water (22°C) was infused sublingually at 10 and 20 ml/kg/hr for 2 hours each. In response to the sublingual water infusions, fetal plasma NA (142±0.5 to 140.8±0.8 mEq/l) and osmolality (302±2 to 298±2 mOsm) decreased significantly while fetal low voltage ECoG (42±3 to 56±5%) increased. Fetal swallowing rate (47±9 swallows/hr), esophageal flow (19.2±4.2 ml/hr), arterial blood gases, blood pressure and heart rate did not change. These results suggest (1) fetal plasma may be affected by the composition of swallowed fluid and (2) exposure of the fetus to altered amniotic fluid composition and temperature may influence fetal behavioral state, though not swallowing activity.

389 NONINVASIVE CARDIAC OUTPUT IN NORMAL AND HYPERTENSIVE PREGNANCY. GJ Gilson, JF Smith, LB Curet, LA Izquierdo, MS Chatterjee, GO Del Valle[x], GM Joffe[x]. University of New Mexico Hospital, Albuquerque, New Mexico

The objective of the current study was to confirm or refute the hypothesis that the pathophysiology of preeclampsia (PIH) is abnormally high cardiac output (CO). Methodology entailed study of 16 women diagnosed as pure PIH and 22 women with normal pregnancy, all in the third trimester. Hemodynamic data were obtained by pulsed doppler and 2-D echocardiography. All were studied in left lateral decubitus, and hypertensive patients were studied prior to any therapeutic interventions.

Results: (mean+SE)	n	HR (bpm)	SV (ml/min)	CO (L/min)	MAP (mmHg)	TPR* (dynes/sec/cm-5)
Control	22	92±3	113±8	10.5±7	69±2	583±41
PIH	16					
PO	9	84±3	120±11	10.0±.8	103±3	883±85
P1+	7	79±7	121±9	8.9±.3	107±4	966±5
p		.019	NS	NS	.0001	.001

*Heart Rate (HR), Stroke Volume (SV), Mean Arterial Pressure (MAP), Total Peripheral Resistance (TPR), Nullipara (PO), Multipara (P1+)

Conclusions: Patients with normal pregnancy outcome and those with PIH both had elevated CO, which however were not significantly different. MAP was significantly elevated in PIH on the basis of elevated TPR. While this data is consistent with the classic theory of the pathophysiology of PIH, these patients were studied when they already had clinical manifestations of the disease and could have already crossed over into a state of elevated TPR.

390 EFFECT OF MODE OF DELIVERY ON LYMPHOCYTE SUBSETS IN FULL TERM NEONATES. R.Samelson, D.Larkey[X], K.S.Amankwah, P.McConnachie[X], Southern Ill School of Med., Springfield, Il.

With the aid of monoclonal antibodies, immunofluorescence, and flow cytometry, cord blood lymphocyte populations were studied in neonates, 6 delivered vaginally (V) and 6 by cesarean section without labor (C/S). These lymphocyte subsets, or phenotype frequencies (PF), were compared to normal adult values (A) and to each other (2 tail student t test, p less than 0.05). A statistically significant difference did occur in the PF of helper T cells (C) (CD4), more mature B C (CD21), Natural killer C (CD16), and Killer C (CD56). Total T C (CD2) were decreased in V when compared to C/S. The PF of common thymocyte (CD1) co-expressed with mature T C (CD2), suppressor cytotoxic C (CD8), B cells (Dr), early intermediate B C (CD19), and activated T C (CD3/Dr) were the same in all neonates regardless of mode of delivery and were no different from the PF in A. Thus a profile of elevated T and helper T C and depressed Natural killer C is characteristic of C/S; a profile of depressed T C and helper T C and elevated Natural killer C is characteristic of V. Depressed intermediate B C is common to all neonates compared to adult normal values.

391 THE FETUS DURING MATERNAL FEVER: BIOPHYSICAL EFFECTS ASSOCIATED WITH VIRAL SYNDROMES DIFFER FROM THOSE ASSOCIATED WITH PYLEONEPHRITIS. N. Wasserstrum, D.E. Patton Baylor College of Medicine, Dept OB/GYN, Houston, Texas.

We sought to determine if the marked suppresion of fetal breathing movements (FBM) and fetal body movements (FM) we previously reported during fever in pyelonephritis (PYL) depended on etiology. Gravida (GA=30+/-4wk) with viral syndromes (VS), were studied at least 24 hr. off antipyretics during fever T=102.9+/-0.8 C) and early convalescence (T=97.7+/-0.5 C) comparable to PYL.

	Temperature	% Time FBM	Total FM in 30 min
Fever	102.9+/-0.8	6.3+/-5.3	9.6+/-5.5
Convalescence	97.7+/-0.5	5.2+/-4.2	24.4+/-10.2
Control	97.3+/-0.3	36.6+/-8.4	19.5+/-2.2

1. In VS, FBM were depressed during fever, but much less severely and with greater variability [range: 0-15%] than in PYL [FBM = 0.9+/-1.1%; range: 0-3%] 2. In VS unlike PYL, FBM depression showed no recovery in convalescence. 3. In contrast, FM in VS were depressed during fever and recovered during convalescence as in PYL. 4. The fetal biophysical effects of febrile illness reflect more than fever per se, and depend on etiology.

392 UMBILICAL CORD BLOOD GAS SAMPLING AND AIR CONTAMINATION

Joe E. Gaskins,* MD, PhD, and John W. Goldkrand, MD, Department of Obstetrics and Gynecology, Memorial Medical Center, Savannah, Georgia 31404

Umbilical cord blood gas sampling at the time of delivery utilizing a double clamped closed loop of cord is becoming more of a routine procedure. The effect of air contamination on the accuracy of the sample results was studied in 21 patients. Utilizing 1 cc and 3 cc heparinized syringes, 0.5 cc of cord venous blood was obtained anaerobically, then 0.5 cc of air was drawn in and either removed or retained with the sample. Results: 1) In all samples, there was no difference in the pH, pCO_2, HCO_3 or BE. 2) pO_2 was elevated by air contamination only in the 3 cc syringe with 0.5 of retained air ($p<0.05$). No effect was seen in the 1 cc syringe. 3) Time from delivery until the results were obtained did not effect the results nor did the time from obtaining the first sample results to the last sample results. In a separate experiment with 15 patients using the 3 cc syringe, 0.5 cc of venous cord blood was contaminated with 0.1 cc, 0.2 cc, 0.3 cc, 0.4 cc and 0.5 cc of air. Significant increase in pO_2 occurred when greater than 0.2 cc of air was retained. pCO_2 appeared to decrease while pH and HCO_3 were stable with the increase in pO_2 with the other components being essentially unchanged, neonatal diagnosed and care will not be effected by the air contamination. RECOMMENDATION: Umbilical cord blood obtained for gas analysis at delivery would be best performed with either a 1 cc or 3 cc syringe. If a 3 cc syringe is used, less than 20% of retained air should contaminate the system so as not to confuse the actual pO_2 determination.

393 FETAL BLOOD SAMPLING IN HIV-SEROPOSITIVE PREGNANCIES PRIOR TO ELECTIVE TERMINATION OF PREGNANCY.

RR Viscarello, MT Cullen, NJ DeGennaro*, and JC Hobbins, Depts. of OB/GYN, Yale University, New Haven, CT. and University of South Florida, Jacksonville, FL.

Currently there is no specific immunologic, virologic, or serologic marker for the prenatal diagnosis of HIV-1 infection. We studied 18 HIV-seropositive women between 9 and 24 weeks of gestation prior to elective termination of pregnancy to investigate the transplacental transfer of HIV-1 antibody and p24 antigen and to explore the diagnostic potential of fetal blood sampling in the prenatal diagnosis of intrauterine HIV-1 infection. There were 7 Blacks, 6 Caucasians, and 5 Hispanics with a mean age of 27.2 years. Twelve of the women were CDC Group II, 5 were Group III, and 1 patient had AIDS (Group IV). Eleven patients acquired HIV-infection through IVDA, 6 via heterosexual contact, and 1 patient had no known risk factor. Fetal blood was obtained transabdominally via a single insertion into an anterior cord in 15 cases and transcervically using an embryoscope in 3 patients. HIV-1 antibody was detected by Western blot analysis in all samples of maternal serum, amniotic fluid, and fetal serum. Each mother/fetus pair displayed identical banding patterns. In contrast, p24 antigen was found in the maternal serum and amniotic fluid from only 5 of 18 patients, 3 of which also had p24 in the fetal serum. The finding that 2 of 5 fetal serum samples lacked p24 antigen argues against immediate procedure-related contamination of the fetal compartment. HIV p24 antigen was only found in fetuses of patients with CDC Stage III disease. Of note, p24 antigen was not detected in the 3 fetuses sampled in the first-trimester. Although the risk of iatrogenic infection of the fetus remains to be determined, we conclude that fetal blood sampling in conjunction with a positive p24 antigen result has the potential to provide the diagnosis in utero. (This research was partially supported by a grant from the American Foundation for AIDS Research and the Pediatric AIDS Foundation AmFAR/PAF #50034-7).

394 DOES AN ANTEPARTUM INVASIVE PROCEDURE INCREASE THE RISK OF PERINATAL TRANSMISSION OF HIV-1? RR Viscarello, NJ DeGennaro*, SM Griffith*, W Andiman*, JC Hobbins, Department of OB/GYN, Yale University School of Medicine, New Haven, CT.

Accurate prenatal diagnosis would facilitate more effective patient counseling regarding the risk of vertical transmission of HIV-1. However, the infectious potential of invasive diagnostic methods remains controversial. To determine if the risk of HIV transmission is increased after antepartum invasive procedures, we compared neonatal outcome in 2 groups. Group I consisted of 46 pregnancies in which amniocenteses, fetal blood samplings, fetal scalp samplings, or fetal scalp electrode placements were performed. There were a total of 32 amniocenteses (PTL-18; PROM-9; L/S & PG-5); 18 fetal scalp electrode placements; 10 fetal scalp samplings; and 3 fetal blood samplings (ITP-2; fetal distress-1). Group II included 93 pregnancies without invasive procedures. Both groups were matched for maternal age (27.0 vs. 27.6 yrs), HIV-status, racial breakdown, and HIV-risk behavior. The groups did not differ with respect to CD4 count (401 vs. 385/cc), HIV p24 antigen status, gestational age at delivery (36.2 vs. 36.4 wks), or birthweight (2426 vs. 2754g). No statistically significant difference was noted between the groups with respect to infant disease status with all invasive procedures (chi sq = 0.99), or with amniocentesis alone (chi sq = 1.37). Infant outcome did not differ significantly based on the number of invasive procedures performed during pregnancy (chi sq = 2.26). The mean time interval from invasive procedure to delivery was the same in infected infants and those who seroreverted (t = 0.49). Our data suggests that modern techniques of invasive prenatal diagnosis may predict which fetuses are truly infected with HIV-1 without increasing the risk of iatrogenic infection. (This research was partially supported by a grant from the American Foundation for AIDS Research and the Pediatric AIDS Foundation AmFAR/PAF #50034-7).

395 THE PREVALENCE AND PROGNOSTIC SIGNIFICANCE OF ANTICARDIOLIPIN ANTIBODIES IN PREGNANCIES COMPLICATED BY HIV-1 INFECTION.

RR Viscarello, CJ Williams*, NJ DeGennaro*, WA Andiman*, and JC Hobbins, Department of OB/GYN, Yale University, New Haven, CT.

Anticardiolipin antibodies (ACA) are estimated to occur in 2.2% of all pregnancies and are associated with adverse outcomes including thrombotic events, fetal wastage, IUGR, and preterm delivery. Recent studies suggest that maternal antibodies against specific epitopes of HIV-1 may prevent transmission to the fetus. We tested 23 HIV-positive gravidae for ACA to investigate the association with pregnancy outcome, disease status, and perinatal transmission. The racial breakdown included 16 Blacks, 5 Hispanics, and 2 Caucasians. Seventeen patients were IVDAs and 6 were heterosexual partners of IVDAs. Four patients were CDC Group IV; 5-Group III; and 14-Group II; with a mean age of 29.4 yrs. Two of 21 patients (9.5%) were positive for HIV p24 antigen. Thirty-two percent (7/23) were ACA-positive: 5 had IgM and 2 had IgG. All patients who were ACA-positive had CD4 cell counts below 500/cc. Six patients in the ACA-positive group delivered viable infants (mean gestational age 38 weeks and mean birth weight 3068g), and 1 elected TOP. All of the infants are currently CDC Stage P0. Of the 16 patients in the ACA-negative group, 11 delivered viable infants, including 2 sets of twins (mean gestational age 37.5 weeks and mean birth weight 2564g); 2 remain undelivered; and 3 elected TOP. Four infants have seroreverted, 7 are CDC Stage PO, and 2 are lost to follow-up. No peripartum complications were observed in either the ACA-positive or ACA-negative groups. Western blot patterns did not correlate with the presence of ACA and were not predictive of maternal or infant disease status. Of note, 16/20 patients lacked anti-p17 antibody. We conclude that there is a higher prevalence of ACA in HIV-positive patients, which is not associated with adverse perinatal outcome or maternal HIV status. IgM-ACA may recognize a novel epitope of the HIV-virion and therefore prevent perinatal transmission of HIV-1.

396 **PERINATAL EFFECTS OF *GARDNERELLA VAGINALIS* DECIDUITIS IN THE RABBIT.** N. Field,[x] E. Newton, K. Kagan-Hallet,[x] W. Peairs,[x] Dept. of Ob/Gyn, UTHSC, San Antonio, TX.

Gardnerella vaginalis in conjunction with anaerobic bacteria and genital mycoplasmas is associated with bacterial vaginosis and infection-induced preterm birth. However, minimal attention has been paid to the pathologic role of *Gardnerella vaginalis* alone in preterm labor and perinatal morbidity. We studied the effects of intrauterine infection with *Gardnerella vaginalis* on pregnancy outcome and fetal development in the rabbit. Both uterine horns of rabbits at 70% gestation were inoculated hysteroscopically with either 0.2 ml of 10^5 - 10^7 cfu/ml of *Gardnerella vaginalis* or saline. The animals were observed daily for fever, bleeding, or labor. Animals were sacrificed on day 4 or earlier if premature delivery was recognized. Aerobic and anaerobic cultures of blood, decidua, and peritoneal and amniotic fluid were performed. Maternal and fetal histology was examined in a blinded fashion (KK-H) for evidence of infection and/or injury. Severe brain injury was defined as ≥15% neuronal necrosis. Decidual and amniotic fluid cultures were positive for *Gardnerella vaginalis* in all of the study group animals.

Organism (n)	Fever	Preterm labor	Live births (%)	Fetal wt. (gm±SD)	Placental (gm±SD)	Brain injury (%)
Gardnerella vaginalis (17)	3	2	86/108 (80)*	12.8±3.3†	6.2±1.4†	60*
Placebo (14)	0	0	80/84 (95)	16.8±3.1	8.3±2.0	0

*p<0.03; †p<0.001

Gardnerella vaginalis deciduitis did not uniformly result in maternal illness and/or preterm labor. However, intrauterine infection with *Gardnerella vaginalis* had significant detrimental fetal effects, including death, growth retardation, decreased placental weight, and brain injury.

397 **SHOULD AN AMNIOCENTESIS BE PERFORMED BEFORE A CERCLAGE OPERATION IN PATIENTS PRESENTING WITH CERVICAL DILATATION IN THE MIDTRIMESTER OF PREGNANCY?** R. Romero, R. Gonzalez,[x] W. Sepulveda,[x] F. Brandt,[x] M. Ramirez,[x] M. Mazor, Depts. of Ob/Gyn, Yale Univ. School of Medicine, New Haven, CT; Wayne State Univ., Detroit, MI

Cervical cerclage is a management option for patients presenting with cervical dilatation in the midtrimester of pregnancy. Post-cerclage rupture of membranes and clinical chorioamnionitis are common complications often attributed to this procedure. However, these complications may result from a pre-existing ascending intraamniotic infection rather than from the procedure per se. This study was designed to determine whether microbial invasion of the amniotic cavity is present in patients presenting with cervical dilatation and effacement in the midtrimester of pregnancy. Materials and Methods: Amniocentesis was offered to patients presenting with cervical dilatation (>2 cm) in the midtrimester of pregnancy (gestational age ≤24 weeks) (n = 22). Amniotic fluid was cultured for aerobic, anaerobic bacteria and Mycoplasmas. Results: The prevalence of positive amniotic fluid cultures for microorganisms in women presenting with cervical dilatation and effacement was 59% (13/22). The most frequent isolates were Ureaplasma urealyticum (n = 3), Gardnerella vaginalis (n = 2) and Mycoplasma hominis. All patients who had an intraamniotic infection not detected by Gram stain and who underwent a cerclage operation had serious complications (rupture of membranes, chorioamnionitis or subsequent preterm delivery/abortion). Conclusions: 1) Microbial invasion of the amniotic cavity is present in 59% of patients presenting with cervical dilatation in the midtrimester. 2) Patients who had a cervical cerclage in the presence of microbial invasion ruptured their membranes, developed clinical signs of chorioamnionitis or delivered a preterm neonate. 3) Amniocentesis for microbiologic evaluation should be considered before performing a cerclage operation in patients presenting with cervical dilatation in the midtrimester.

398 **INTERLEUKIN-8; ASSOCIATION WITH AMNIOTIC FLUID LEUKOTAXIS AND CHORIOAMNIONITIS.** Peter H. Cherouny, Glenn A. Pankuch[X], Roberto Romero, John J. Botti, Peter C. Appelbaum[Y]. The Depts. of OB/GYN and Pathology, University Hospital, Penn State University, Hershey, PA and Dept of OB/GYN, Yale University School of Med, New Haven, CT. Supported by March of Dimes Research Grant #6-548

Interleukin-8 (IL-8) is a leukoattractant cytokine that has been shown to be elevated in amniotic fluid (AF) of patients with intraamniotic infection, defined by a positive AF culture. IL-8 also produces neutrophil leukotaxis in the AF-leukotaxis assay (AF LeuA), previously shown as a more accurate marker for histologic chorioamnionitis than AF culture. The purpose of this study was to determine if IL-8 is present in AF in which leukoattractants are detectable by the AF LeuA. AF collected from 32 patients within 48 hours of delivery was evaluated by AF culture, AF LeuA, and immunoassay for IL-8. Placentae were evaluated for histologic chorioamnionitis. 14 of 15 AFs negative for AF LeuA, culture and histology had IL-8 levels below the detection threshold of 1 ng/ml. All patients with detectable leukoattractants had histologic chorioamnionitis and detectable IL-8 and are grouped according to culture results. Conclusions: 1) IL-8 is present in AF with positive leukotaxis and, 2) IL-8 concentration increases significantly with extension of the tissue infection into the amniotic fluid. These data support the hypothesis that detection of amniotic fluid leukoattractants, including IL-8, identifies intrauterine infection before there are detectable amniotic fluid bacteria.

Group 1 (n=8)	Group 2 (n=9)
AF LeuA (+)	AF Leu (+)
AF culture(-)	AF culture(+)
Histology (+)	Histology (+)
IL-8 (18.5,2-36)*	IL-8(71.5,3-244)*

*p<0.05 (IL-8 ng/ml; median, range)

399 **THE IMPACT OF AMNIOINFUSION ON MATERNAL AND NEONATAL MORBIDITY IN PREGNANCIES COMPLICATED BY PRETERM PREMATURE RUPTURE OF MEMBRANES AND AMNIONITIS.**

C. A. Major, M. de Veciana[X] T. Asrat and M. P. Nageotte.
University of California, Irvine and Memorial Medical Center of Long Beach.

We evaluated 65 pregnancies complicated by both preterm premature rupture of membranes (PPROM) and amnionitis between 24 and 34 weeks of gestation. All patients were induced after the clinical diagnosis of amnionitis was made. Twenty-seven patients received i.v. antibiotics followed by prophylactic amnioinfusion (AI group); 38 patients received i.v. antibiotics only (non-AI group). Both groups were comparable for gestational age at ROM and at delivery, AFI on admission, latency periods from ROM until amnionitis developed, the time from the diagnosis of amnionitis to delivery and birthweight. In addition, there were similar incidences of variable decelerations and meconium staining in both groups. Only 1 of 27 patients in the AI group developed postpartum endometritis as compared to 18 of 38 patients in the non-AI group (P = 0.0003). The marked difference in the incidence of endometritis between the 2 groups was present regardless of the route of delivery (Vag. del. P = 0.018); (C/S P = 0.038). Delivery by C/S was necessary in only 5 of 27 in the AI group and 19 of 38 patients in the non-AI group (P = 0.0058). Although there was a trend towards an increased incidence of C/S for fetal distress in the non-AI group, this was not found to be statistically significant (P=0.079). No significant differences in perinatal depression/acidosis and neonatal sepsis were found between the 2 groups.

Conclusion: In pregnancies complicated by both PPROM and amnionitis, prophylactic amnioinfusion may significantly decrease maternal morbidity by limiting postpartum infections and the cesarean section rate. This study does not demonstrate improved neonatal outcome with amnioinfusion.

400 **PRENATAL DIAGNOSIS OF HIV INFECTION: THE USE OF CORDOCENTESIS, POLYMERASE CHAIN REACTION, AND P24 ANTIGEN ASSAY**

Mark T Cullen MD, Richard R Viscarello MD, Sharon Paryani MD*, L Sanchez-Ramos M.D, University of Florida Health Science Center, Jacksonville, FL. and Yale University School of Medicine, New Haven, CT.

Perinatal transmission of the Human Immunodeficiency Virus is thought to be between 25 to 30%. Neonatal infection is devastating with a 50% mortality in the first year. Antenatal knowledge of fetal infection would allow the option of pregnancy termination or fetal treatment with antiretroviral agents. Thirteen HIV-infected, pregnant women underwent cordocentesis for clinical indications. Two had AIDS (18%) and 11 were seropositive asymptomatic. A single insertion into an anterior cord was performed in all cases. Blood was sent for HCT, PCR, p24 antigen, T-cell phenotyping, and a Kleihauer-Betke. Gestational age ranged from 22 to 34 weeks (mean of 28.2 ± 5.4). Fetal CD4 counts were available in nine cases. There was no difference between the infected and uninfected groups. There was 1 fetal demise secondary to an abruption at term in a PCR-negative fetus. Three cordocentesis samples were positive for HIV-1 by PCR, 2 were indeterminate, and 7 negative. Of the three fetuses who had positive tests by PCR, 2 have developed AIDS, and one is asymptomatic and <15 months (P0). Both of these fetuses also had negative p24 antigen tests. One false negative PCR test was observed. **Conclusion**: HIV detected by PCR at cordocentesis appears to predict which fetus will develop HIV infection. A negative test is reassuring, but not absolute.

401 **HIV IN PREGNANCY: FACTORS PREDICTIVE OF MATERNAL AND FETAL OUTCOME:**

Mark T. Cullen MD, Issac Delke MD, Joseph Greenhaw MD*, Richard R. Viscarello MD, Sharon Paryani MD*, Luis Sanchez-Ramos MD, University of Florida, Jacksonville, FL. Yale University, New Haven, CT

In a 3 year study period, 7,596 pregnant women were screened for HIV-1. 82 (1.07%) were found to be HIV-seropositive and followed prospectively. The mean age at entry was 24.7 yrs. 23 were IVDAs, 10 admitted to prostitution; 25 had multiple heterosexual partners, 2 had received infected blood products, and 28 had no known risk factors. 71 were asymptomatic HIV-positive, 7 had AIDS, and 1 had ARC. 12 of 82 (14%) chose termination of pregnancy for the following reasons: 2 had hysterectomy for CIN3, 1 had new onset PCP pneumonia, and the rest were elective. To date, 64 deliveries have occurred. There were 56 vaginal deliveries and 8 cesarean sections. There was 1 third trimester stillbirth secondary to an abruption. 2 maternal deaths occurred in the peripartum period, which were HIV-related. 8 mothers experienced infectious morbidity. Mean CD4 nadir, while lower for this group did not reach statistical significance (314 vs 550 p=.06). Of the 63 infants, 13 are infected, 15 are seronegative, and 35 are P0. The perinatal transmission rate is currently 22.4%. Mean birthweight was 2,739g (936-4225) and gestation age was 37.7 weeks. 20% were premature deliveries. There were no differences in demographics, mode of delivery, length of ROM, or the use of a scalp clip between the infected and uninfected groups. Transmission rates were influenced by clinical status in the mother. Eight mothers were placed on AZT for CD4 counts<500/cc. There were no ill effects of the drug on either mother or fetus. **Conclusion:** Clinical status appears to be the best predictor of transmission and pregnancy course.

402 VIRULENCE FACTORS OF PYELONEPHRITIS ASSOCIATED E. COLI FROM PREGNANT WOMEN.

M. Martens*, A. Hart*, B. Nowicki*, S. Nowicki*, C. Peyton*, L. Schailer*, G. Anderson, Department of Obstetrics and Gynecology, University of Texas Medical Branch, Galveston, Texas

Pyelonephritis is a serious complication in pregnancy. E. coli is the most frequent organism associated with pyelonephritis. Virulence determinants such as P fimbriae have been determined to be associated with the pathogenesis of pyelonephritis in non-pregnant women. However, virulence factors have not been extensively characterized in pregnant women with pyelonephritis. Different fimbrial types on E. coli including P, Dr and type 1 were detected on E. coli isolates from 15 pregnant and 12 non-pregnant patients with pyelonephritis and 31 non infected individuals. E. coli strains were tested for the presence of P, Dr, and type 1 fimbriae (colonization factors) by agglutination with human pp, Dr (a-) erythrocytes or yeast cells (Table 1).

No./Patient	No. of E. coli	FIMBRIAE TYPE 1	P	Dr	p value*
Pregnant (15) <.002* with pyelonephritis	16	3 (19%)*	12 (75%)*	3 (19%)*	
Non-pregnant(12) <.01* with pyelonephritis	11	5 (45%)	9 (81%)*	3 (27%)*	
Healthy women NS	15	9 (60%)	8 (53%)	4 (27%)	

The results indicate that P fimbriae are expressed with higher frequency in pyelonenephritis - associated E. coli. Among cervical isolates of healthy non-infected fimbrial types are more distributed among all strains with type 1 fimbriae being the most frequent. Therefore, it appears that P fimbriae may be virulence factors associated with the development of pyelonephritis with the greatest risk associated with infection in pregnancy.

403 HORMONAL RECEPTORS AND ADHERENCE OF PYELONEPHRITIS ASSOCIATED ESCHERICHIA COLI IN PREGNANCY.

M. Martens*, B. Nowicki*, A. Hart*, B. Taylor*, S. Nowicki*, G.D. Anderson, Department of Obstetrics and Gynecology, University of Texas Medical Branch, Galveston, Texas

The incidence of pyelonephritis is increased in pregnancy, and has been attributed to various alterations of the human host. However an investigation of the changes which pregnancy has on bacteria has not been undertaken. Kinetics of various hormones in pregnancy and incidence of pyelonephritis was analyzed, and a correlation was noted for HCG. HCG and a control growth hormone (GH), were tested for possible receptor binding sites on pathogenic E. coli strains. GH or HCG were coated onto microtitre trays. E. coli, (type 1 pili positive and negative), and guinea pig RBC were added. Erythrocytes not trapped by bacteria-hormone complexes were removed by washing, and 0.001% Tryton X was added to lyse bound red cells. The amount of released hemoglobin was measured in an ELISA reader. Results indicate that pathogenic type 1 fimbriated *E. coli* bind to HCG in a dose dependent fashion. Saturation of *E. coli*-HCG binding occur at 4 ug (approximately 65,000 mIU) of HCG per well. Attachment of *E. coli* cells to HCG was inhibited by alpha- methyl-mannose, which is an inhibitor and receptor analog for type 1 pili adhesin. The alpha subunit of HCG, but not beta or GH, demonstrated dose dependent binding of *E. coli*. We conclude that E. coli via type 1 pili can bind to the mannose receptor on the alpha subunit of HCG. This phenomenon may be important in the pathogenesis of pyelonephritis in the early trimesters of pregnancy due to an increase in adherence to receptors found in genito-urinary tract tissues.

404 SUSCEPTABILITY PATTERNS OF RECENT PYELONEPHRITIS PREGANANCY ASSOCIATED PYELONERITIS BACTERIAL ISOLATES. Mark G. Martens, M.D.*, Rajender Syal, M.D.*, G. D. Anderson, M.D. Department of Obstetrics and Gynecology, University of Texas Medical Branch, Galveston, Texas 77550-2778

The incidence of pyelonephritis is increased in pregnancy and is directly related to the incidence of bacteriuria by pathogenic organisms. Treatment for pyelonephritis in pregnancy has changed over the years secondary to an alteration in the susceptibility patterns of the responsible uropathogen. Ampicillin has generally been replaced by first generation cephalosporins, such as cefazolin, due to the increased rate of ampicillin resistant Enterobacteriaceae, including *E. coli*. The current investigation identified the species and sensitivity pattern of recent pyelonephritis in pregnancy isolates. 129 patients and their microbiologic results were reviewed from 1988-91 with 136 organism recovered including *E. coli* (62%), Klebsiella pneumoniae (8%), Enterococcus (5%), Proteus mirabilis (4%), and Group B streptococci (3%). Susceptibility patterns to ampicillin, first generation cephalosporins (cefazolin), and advanced generation cephalosporins (cefotaxime) demonstrated a continued increase in resistance to beta-lactamase sensitive antibiotics.

		% Resistance		
Organism	n=	Ampicillin	Cefazole	Cefotaxime
E. coli	85	35 (41%)	6 (7%)	0
K. pneumonia	11	11 (100%)	1 (9%)	0
Enterococcus	7	0	7 (100%)	7 (100%)
Enterobacter	2	2 (100%)	2 (100%)	0
Total	105	48 (47%)	16 (15%)	7 (7%)

The organisms were significantly more resistant to ampicillin and cefazolin as compared to cefotaxime ($p < .001$, and $p < .01$ respectively). Clinically efficacy correlated with bacteriologic results. Therefore, it appears the resistance patterns affecting the effectiveness of ampicillin in the treatment of pyelonephritis in pregnancy have spread to the first generation cephalosporins, perhaps requiring the consideration of advanced generation cephalosporins such as cefotaxime as the initial empiric antibiotic of choice.

405 ACCEPTANCE OF HIV TESTING WITH AN ON-SITE PRENATAL CLINIC COUNSELOR. Neil S.Silverman, M.D., Susan M. Weiner, R.N.C., M.S.N.[X], Donna Weist, B.A.[X], Depts. of Ob/Gyn and Pediatrics, Jefferson Medical College, Philadelphia, PA

Background: Heterosexual transmission and drug-related acquisition of human immunodeficiency virus (HIV) have been recognized as major contributors to the rising rate of HIV infection in women of reproductive age. Pregnancy in these women is complicated by the potential for maternal-fetal transmission of the virus. This factor has created social and ethical dilemmas regarding HIV testing in this population, since it may not include appropriate explanation of the implications of HIV infection prior to testing. Objective: This study evaluated patient acceptance of confidential HIV testing in an inner-city prenatal clinic after the placement of an on-site HIV counselor. Methods: All patients registering for prenatal care received HIV counseling, after which they were offered confidential HIV testing. Those patients who consented to testing received a time for post-test counseling and release of results. The number of patients tested was compared to the number of HIV tests ordered in the prior six months via physician-consented, risk-directed testing at prenatal intake. Results:

	Pre-counselor	With Counselor
Pts counselled	814	839
Pts tested (% of counselled)	83 (10.2%)	549 (65%)
Positive results (% of tested)	0	3 (0.4%)
Post-test counselled (% of tested)	N/A	281 (34%)

Conclusions: Confidential HIV testing was well accepted in an inner-city pregnant population in conjunction with a full-time, on-site HIV counselor, with six times as many patients consenting to testing than before the current system was in place. This may result from both improved quality of education as well as separation of HIV testing as a medical directive.

406 HEPATITIS C VIRUS (HCV) IN PREGNANCY: SEROPREVALENCE AND RISK FACTORS FOR INFECTION. Neil S. Silverman, M.D., Brenda Jenkin, M.D.[X], Christine Wu, M.D.[X], Patricia McGillen, M.T. (ASCP)[X], Gerald Knee, M.S.[X], Jefferson Medical College, Phila., PA

Background: Though limited reports do exist describing the prevalence of specific anti-HCV antibodies in post-transfusion and other at-risk populations, none exist in prenatal populations. In order to address the vertical transmissibility of HCV, the prevalence of seropositivity in the population in question must first be determined. The Intents of this study were to: 1) anonymously compare the seroprevalence of anti-HCV in an inner-city prenatal clinic to that of a group of private patients; 2) to assess the use of risk factors to predict an increased rate of anti-HCV seropositivity; 3) to identify co-infection risks for HCV and other blood-borne agents. Methods: Blood samples were collected at the time of routine prenatal screening. They were then anonymously analyzed for HCV, HIV, HTLV-1 and RPR using commercially available assays. Results:

	Overall (n=599)	Clinic (n=444)	Private (n=155)
HCV+	26 (4.3%)	23 (5.2%)	3 (1.5%)
HTLV-1+	5 (0.8%)	4 (0.9%)	1 (0.6%)
HIV+	3 (0.5%)	3 (0.7%)	0 (0%)
HBsAg+	5 (0.8%)	4 (0.9%)	1 (0.6%)
RPR+	16 (2.7%)	14 (3.2%)	2 (1.3%)

Seropositivity for anti-HCV was significantly higher overall and in the clinic than for either HTLV-1 or HIV ($p<0.0001$), a statistic which did not hold for the private patients tested. In the clinic, only 52% of HCV-positive patients would have been predicted via targeting by risk factors; only 1 of 3 positive patients in the private offices would have been so identified. Conclusions: HCV infection may be of greater concern than previously thought in inner-city pregnant populations and, as with hepatitis B, not well-predicted by risk-factor identification. Further study is warranted to determine maternal-fetal transmissibility.

407 PENTAMIDINE PROPHYLAXIS IN PREGNANCY. D.Nanda[X], I Tannenbaum[X], S Landesman[X], H Mendez[X], G Moroso[X], H Minkoff. SUNY/Health science Center, Brooklyn NY. Pneumocystitis carini pneumonia (PCP) is one of the commonest opportunistic Infections (OI) among patients with AIDS. Prophylactic agents such as Aerosolized Pentamidine have substantially reduced the incidence of PCP among susceptible patients. At SUNY/HSCB and KCHC, a study was undertaken to assess the effects of Pentamidine use during pregnancy.

METHOD: Fifteen HIV infected patients with T4 counts <200/cmm or <20% of total lymphocytes were given PCP prophylaxis during pregnancy. Detailed history including that of STDs, drug use and other concomitant medications was taken & complete examination and full laboratory assessment was done on each patient. The patients were then administered 300 mg of Pentamidine via a respiragard nebulizer monthly, during II & III trimesters. Serum Pentamidine levels were drawn within an hour of inhalation & were frozen for HPLC assay. The patients were followed prospectively at prenatal clinics and delivered at the two study institutions.

RESULTS: Fifteen mothers received a total of 35 doses of pentamidine for an average of 2.3 doses per patient (range 1-5). One patient with a history of asthma received 60 mg bimonthly. Five patients received AZT concurrently. None of the patients reported any adverse effects of therapy or breakthrough PCP. Serum levels ranged from undetectable to 4.7ng/ml (reports among non pregnant patients have ranged from 0 to 30.91 ng/ml) . One patient discontinued prophylaxis and developed PCP about 70 days after the last dose. All patients delivered at term; All but one delivered vaginally. Mean birth weight was 3159.07± 380 gms (range 2500 - 3570) and head circumference was 33.9±1.1 (range 31-35mm). Average one and 5 minute apgar scores were 7.9± 1.3 and 8.7± 1.1 respectively. None of the babies developed any immediate problems in the neonatal period.

CONCLUSIONS: 1. Aerosolized pentamidine during pregnancy did not achieve high blood levels during pregnancy. 2. No breakthrough PCP was observed in any patient receiving prophylaxis. 3.Pregnant patients tolerated the drug well without any major side effects. 4. No significant effects on the course of pregnancy were observed. 5. Larger studies are needed to fully determine the efficacy and safety of pentamidine during pregnancy.

408 THE UTILITY OF LUMBAR PUNCTURE IN THE EVALUATION AND TREATMENT OF SYPHILIS. Brown,G*,LaSala AP,Anderson R*,Tose D*.Dept. of Ob/Gyn,Columbia University, New York, NY

Current recommendations for the evaluation of late latent syphilis or disease of unknown duration include cerebrospinal fluid (CSF) examination to rule out neurosyphilis. This assessment requires lumbar puncture (LP) which has the potential morbidity of meningitis and spinal headache. We examined the use of LP in a population of young pregnant women living in New York City. An evaluation of obstetrical patients with a positive rapid plasma reagin (RPR) screening test for syphilis was performed. Between Jan. 1, 1989 and Aug. 23, 1991, 253 of these women were followed at our center. They were evaluated for length of disease and given the appropriate therapy based on CDC guidelines. Twenty-three patients had disease present for less than 1 year and therefore did not require CSF examination. Two hundred-thirty women had disease of unknown duration or for greater than 1 year and were offered LP. Of this group, 12 tested positive for HIV. LP was performed in 70 women (30.4%), including 8 of the HIV positive group. One hundred fifty-five (67.4%) women refused LP, and 2 had unsuccessful taps. Four women came to the emergency room for treatment of spinal headache and several others reported milder headache. Three women had CSF that was positive for syphilis. Each of these patients was also HIV positive. The patients with negative CSF and those who declined LP were treated for presumed late latent syphilis. All of the women were followed with monthly RPR tests and showed the decline in values consistent with successful treatment. It is our conclusion that the potential morbidity of LP outweighs its' benefit in the routine evaluation of our young pregnant population with syphilis. All patients with syphilis should be offered HIV testing. CSF examination should be used for women with the additional risk factor of HIV infection which may hasten the progress of the disease. All treated women with syphilis should be followed with monthly RPR tests. Any evidence of persistent disease despite appropriate therapy may also warrant CSF examination.

409 FETAL SYPHILIS: CORRELATION OF SONOGRAPHIC FINDINGS AND RABBIT INFECTIVITY TESTING. L. Nathan[X], D.M. Twickler[X], M. Peters[X], P. Sanchez[X], G.D. Wendel, Dept. Ob/Gyn, U. Texas Southwestern Med Center., Dallas, TX

Fetal syphilis is the presumed diagnosis when the sonographic findings of fetal hydrops are found in the presence of maternal syphilis infection. In the absence of fetal hydrops, the diagnosis of fetal infection is problematic. Rabbit infectivity testing (RIT) is a specific, sensitive in vivo technique to identify Treponema pallidum in infected material. Amniocentesis and subsequent RIT to identify Treponema pallidum may be used to confirm amniotic fluid/fetal involvement. We sought to correlate antenatal sonographic findings from syphilitic gravidas with the results of amniotic fluid RIT. Twenty one gravidas with primary, secondary or early latent syphilis at 24 weeks or greater underwent real time sonography, including coronal liver measurements, and amniocentesis. Measurements which exceeded the 95th percentile for gestational age were considered abnormal. Fetal infection was confirmed by development of syphilis in rabbits after intratesticular inoculation of amniotic fluid. Eleven specimens had positive RITs and ten had negative RITS. The two groups were compared regarding sonographic findings:

	Positive RIT N=11	Negative RIT N=10	P
Hepatomegaly	9	2	<.01
Placental Thickening	7	6	NS
Ascites	2	0	NS
Enlarged Abdomen	1	0	NS
Hydrops Fetalis	1	0	NS

Conclusion: In over 50% of cases of maternal syphilis, fetal infection occurs. Sonographic hepatomegaly is significantly associated with amniotic fluid/fetal infection detected by RIT. Sonography, prior to maternal syphilis therapy, may identify these affected fetuses who are at risk for treatment failure.

410 CORRELATION BETWEEN THE PRESENCE OF HIV-1 mRNA IN THIRD TRIMESTER PLACENTA AND NEONATAL INFECTION.

J. Katz, C. Fox,[X] G. Eglinton, A. Firpo,[X] W. Meyer,[X] J.T. Queenan, Dept. of Ob/Gyn, Georgetown University, Washington, DC, and National Institutes of Health, Bethesda, MD

The purpose of this study was twofold: (1) to determine if 35S-mRNA *in situ* hybridization (ISH) can identify HIV-1 in paraffin embedded third trimester placentas from asymptomatic seropositive patients and (2) to determine if the presence of HIV-1 viral mRNA in placental tissue is associated with neonatal infection. The study population was seropositive from 1 to 36 months before delivery, had no history of opportunistic infection, depletion of CD4+ count or AZT exposure. Placentas from 3 of 9 patients demonstrated positive ISH. One infant is HIV-1 infected at 5 months of age based on clinical and laboratory findings. The other 2 infants have no evidence of HIV-1 infection at 6 months. None of the 6 infants with negative placental ISH have clinical or laboratory evidence of infection at 1 to 7 months after delivery. We conclude that the sensitive technique of 35S-mRNA *in situ* hybridization can successfully identify the presence of HIV-1 in paraffin embedded placental tissue, but the presence of viral mRNA does not consistently predict neonatal infection within the first 6 months of life.

411 PREDICTORS OF CESAREAN WOUND DISRUPTION/INFECTION. E.R. Newton, Dept. of Ob/Gyn, The University of Texas Health Science Center, San Antonio, Texas.

Parity, duration of internal monitoring and duration of ruptured membranes predict intraamniotic infection (IAI) and endometritis (ENDO). We examined the relationship between labor and operative characteristics that predict cesarean wound disruption/infection (WOUND). Six hundred fourteen consecutive cesarean sections were reviewed during the postpartum hospitalization for demographic, obstetric and operative characteristics as predictors of WOUND. WOUND was defined as any intentional or unintentional wound opening in the first 6 weeks postpartum. Thirty-two (5.2%) wound infections occurred and eight (25%) were associated with IAI or ENDO. Stepwise logistic regression was used to control for confounders and to identify the risk factors for WOUND. Possible predictors included concurrent infection, age, parity, labor duration, internal fetal monitoring, vaginal exams, duration of surgery, blood loss, weight, height, prophylactic antibiotics, gestational age, birthweight and diabetes.

Predictor	Incidence	Adjusted Odds Ratio	95th CI
Smoker	8.1%	6.67	1.2 - 2.49
Obesity (≥ 100 Kg)	17%	2.64	1.1 - 8.4

Unlike other obstetric infections, labor characteristics did not influence risk of WOUND. The etiology of wound infections after cesarean section appears to be similar to wound infections after gynecologic surgery.

412 **TREATED INTRAAMNIOTIC INFECTION AND OPERATIVE MORBIDITY.** E.R. Newton, Dept. of Ob/Gyn, The Univ. of Tx. HSC, San Antonio, TX.

Surgical manipulation in an infected field is associated with intraoperative and postoperative complications. We studied whether or not intraamniotic infection (IAI), which was treated intrapartum, was associated with more operative complications than cesarean deliveries in patients without IAI. Treated IAI and operative complications were identified in 614 consecut ve cesareans. Intraamniotic infection (IAI) was diagnosed by an intrapartum temperature ≥37.8° with 2 of 5 signs: maternal or fetal tachycardia, leukocytosis, tender uterus or foul lochia. Intrapartum ampicillin plus gentamicin was standard therapy at diagnosis of IAI. Clindamycin was added after the delivery of the fetus. The area under the fever curve (FEVER AREA) was calculated as the total C° - hours above 37° after delivery.

Complications	IAI (n=91)	No IAI (n=523)
Duration of surgery (min., range)	57 (111)	54 (178)
Estimated blood loss ≥ 1500 cc	11 (12%)*	23 (4%)
Uterine lacerations	4 (4%)*	4 (0.8%)
FEVER AREA (°C-hr, range)	42 (169)	43 (203)**
Wound infection	2 (2%)	32 (6%)
Septic pelvic thrombophlebitis	0	3
Pneumonia or urinary tract infection	0	7
Discharge from hospital ≥8 days	5 (5%)	43 (8%)

*P<0.05, **Endometritis (n=129) only

Cesarean section in the presence of treated IAI does not increase postoperative complications. Increased blood loss may be related to increased trauma and/or uterine atony associated with intramyometrial infecton.

413 **DOES GROUP B STREP(GBS) COLONIZATION SHORTEN THE LATENCY PHASE OF PATIENTS WITH PRETERM PREMATURE RUPTURE OF MEMBRANES (PPROM)?** Towers CV, Lewis DL, Asrat T, Haraguchi K[x], Perlow JH, Memorial Women's Hospital, Long Beach, CA, University of California, Irvine, CA.

A common premise in patients with PPROM is that GBS colonization will shorten the latency time (defined as time of rupture to time of delivery) when compared to patients who are not GBS colonized. Due to recent literature which emphasizes the impact of digital vaginal exam (DVE) on the latency phase in patients with PPROM, we looked at GBS colonization controlling for incidence of DVE. From 1/86 to 6/91, 577 patients with PPROM between 24 and 35 weeks were evaluated. Patients with multiple gestations, cerclage, advanced labor and indicated deliveries (i.e., pulmonary maturity, etc.) were excluded This left 332 patients for analysis. No patients received tocolysis after PPROM. 43 patients were GBS positive and 289 were negative. No differences were found in gravity, parity, gestational age at PPROM. incidence of DVE and antepartum antibiotic usage between the two groups. The latency in days for GBS positive patients was 6.9± 10.6 and for GBS negative patients was 6.5 ± 10.3. Both groups were then subanalyzed, excluding cases with DVE as shown below.

	GBS Positive	GBS Negative	p Value
Number	26	151	
Gravity	3.5±2.4	2.9±1.7	0.12
Parity	1.3±1.4	1.0±1.0	0.19
Gest.Age PPROM	29.2±2.6	29.6±3.0	0.21
Antibiotics	7	21	0.16
Latency (Days)	9.6±12.3	10.4±12.6	0.76

CONCLUSIONS: GBS colonization, by itself, does not appear to affect the latency phase in patients with PPROM. These data further emphasize the significant shortening of the latency period seen in patients with PPROM who experience a digital vaginal exam.

414 ROUTINE SCREENING OF PREGNANT WOMEN FOR LYME DISEASE IN AN ENDEMIC AREA "IS IT WORTH IT". R. Figueroa, U. Verma, M. Agüero[x], C. Smith[x], N. Tejani. NY Med., Coll., Valhalla, N Y.

Objective Screening for Lyme disease (LD) in pregnant women would detect asymptomatic women with the disease. **Study design** The sera of 485 asymptomatic pregnant women, who received prenatal care at our institution, were tested for LD utilizing the ELISA method (Lyme Stat Test Kit). The test was reported as positive (POS), equivocal (EQUIV), or negative (NEG). The sera of the patients who tested POS or EQUIV was further tested by a Western Blot (WB) for confirmation. The WB was reported as positive (pos) or negative (neg) depending on the appearance of specific (41, 34,31,20) IgG and IgM bands. **Results**

			WESTERN BLOT	
ELISA	#	(%)	Pos	Neg
POS	38	(7.8)	1 (2.6)	37 (97.4)
EQUIV	82	(16.9)	3 (3.6)	79 (96.4)
NEG	365	(75.3)	-	-

Ten patients who tested ELISA POS were found to have syphilis. One of these was the only pos WB. **Conclusions** 1) 25% of the patients had an abnormal ELISA. Only 3.3% of these were true positive to LD (See Above). 2) Routine screening by the ELISA test for LD is not productive or cost effective. ($70 per ELISA, $100 per WB).

415 IMPACT OF ASYMPTOMATIC GARDNERELLA VAGINALIS CARRIAGE ON PREGNANCY OUTCOME. Jean Ricci Goodman, Deidre Spelliscy Gifford[x], UCLA School of Medicine, Los Angeles, California.

This prospective study was conducted to determine whether asymptomatic carriage of gardnerella vaginalis, a component of bacterial vaginosis, is associated with an increased risk of premature labor, preterm premature rupture of membranes (PPROM), low birth weight, and/or maternal infectious morbidity. 176 consecutive asymptomatic obstetric patients had cervico-vaginal cultures for gonorrhea, chlamydia, ureaplasma, mycoplasma, group B streptococcus, gardnerella vaginalis, and other aerobic and anaerobic bacteria. The prevalence of asymptomatic gardnerella vaginalis carriage was 26.7% (47/176). All cultures were obtained prior to 24 weeks gestation (mean time of culture 14.00+/-4.00). Of the initial 176 patients, 32 were culture positive for only gardnerella vaginalis (Group A) and 85 were culture negative for all organisms (Group B). A comparison between these two groups revealed no difference in mean birthweight (Group A 3170+/-851 kg; Group B 3308+/-638 kg) or mean gestational age at delivery (Group A 39.01+/-3.44 wks; Group B 39.37+/-3.04 wks). Nor was the incidence of preterm labor, PPROM, amnionitis, endometritis, wound infection or episiotomy infection significantly different between the two groups. We conclude that asymptomatic carriage of only gardnerella vaginalis is not associated with an increased risk of poor pregnancy outcome. Therefore treatment of obstetric patients who are asymptomatic carriers of gardnerella vaginalis is not warranted.

416 ANTIRETROVIRAL THERAPY DURING PREGNANCY AND POSTPARTUM. U. Taylor and A. Bardeguez, Department of Obstetrics/Gynecology, UMDNJ-New Jersey Medical School, Newark, New Jersey.

The number of AIDS cases reported worldwide in women is rapidly increasing. In 1987 AIDS was the 8th leading cause of death for women of reproductive age in the U.S.A. Zidovudine (AZT) therapy in HIV infected individuals is known to prolong survival in patients with AIDS and to delay the progression of disease in those with CD_4 counts <500/mm³. The major toxicity of AZT is myelosuppression. Other minor adverse effects are nausea, headache and transaminase elevation. The available information on the use of AZT in pregnancy has focused on the lack of adverse effects in the fetus. This report details our experience with the use of AZT during pregnancy and postpartum. As of August, 1991, we have managed 20 patients (10 antepartum and 10 postpartum) with antiretroviral therapy. The mean duration of therapy was 14.1 ± 10 weeks. Ninety percent of our patients were black, 5% hispanic and 5% white. Seven patients were former IVDU's and 13 acquired the infection through heterosexual contact. There were 5 patients with AIDS; 6 with ARC and 9 asymptomatic patients. Mean maternal age was 26.1± 5.6 years. The CD_4 counts ranged from 13-500/mm³ with a mean value of 284.45 ± 187.35/mm³. Laboratory data showed mean value of WBC 7.8×10^3 ± 2.7, hemoglobin 8.9 ± 1.6g/dl, hematocrit 27.6% ± 3.2, GOT 35 ± 11.2; and GPT 39 ± 9.1 for that series. The obstetrical complications in the series were: preterm labor (3), PROM (1) and chorioamnionitis (1). Nineteen patients have delivered grossly normal infants with mean birth weight of 2299g. No fetal anomalies were noted. In patients with antepartum treatment, transaminase values were unchanged and CD_4 counts show an upward trend. We conclude that AZT has no immediate adverse effect on the pregnant woman or her neonate. Our findings support the use of AZT in pregnant women who are significantly immunocompromised or have advanced stage disease.

417 HIV-ASSOCIATED IMMUNE THROMBOCYTOPENIA IN PREGNANCY. U. Taylor, P. Gascon, J. Apuzzio and A. Bardeguez. Departments of Obstetrics/Gynecology and Hematology, UMDNJ-New Jersey Medical School, Newark, New Jersey.

Immune thrombocytopenia purpura (ITP) while relatively uncommon during pregnancy (<2%); occurs in 10 to 15% of asymptomatic HIV infected patients and is often the initial manifestation of the disease. Zidovudine (AZT) has been used effectively to treat HIV related thrombocytopenia. We sought to determine the prevalence of ITP in HIV infected pregnant women and to develop appropriate management guidelines for these cases. Between 1986 and 1990, we analyzed all HIV infected pregnant patients in our cohort with platelet counts <100,000/mm³. We evaluated a total of 112 cases and identified nine cases (8%) with thrombocytopenia. The HIV risk factors for these 9 cases with thrombocytopenia were IVDA (4/9) and heterosexual contact (5/9). There was 1 patient with AIDS, 6 with ARC; and 2 others were HIV positive but asymptomatic. The mean maternal age was 30.3 ± 3.9 years and the mean platelet count was 70,000 ± 21,000. Four patients had positive antiplatelet antibody. The CD_4 counts in these patients were 287.7 ± 106.7/mm³. The two patients treated with AZT for an average of 12 weeks during pregnancy, showed an increase in platelet count of 26%. These pregnancies were delivered at term. No IVH or other bleeding diathesis were noted in the neonates. Late postpartum hemorrhage was a complication in 2 patients. Thrombocytopenia was a common manifestation of HIV infection in our series. We recommend the inclusion of HIV testing in the diagnostic evaluation of thrombocytopenia for women of reproductive age. When other diseases have been ruled out intervention with antiretroviral therapy is beneficial to these patients.

418 **QUALITATIVE PHYSICAL AND CHEMICAL CHANGES OF INFECTED AMNIOTIC FLUID - AN IN VITRO STUDY.** W. Scorza, P. Lewis, A. Vintzileos, Mt Sinai Hosp., Univ. of CT Health Ctr, Farmington, CT

It has been a clinical observation that patients with ruptured membranes and subsequent infection fail to demonstrate arborization on the fern test. The purpose of this study was to determine if amniotic fluid inoculated with known pathogens differed in its arborization pattern and if qualitative changes (glucose, protein, nitrites, pH and leukocyte esterase) could be detected using a standard reagent strip. Sterile amniotic fluid was collected from 25 amniocenteses performed in the 2nd or 3rd trimesters. Patients with ruptured membranes, premature labor or signs of intraamniotic infection were excluded. Each specimen was divided into 5 cc aliquots consisting of a control and inoculated samples with either Group B *strep*, *E. coli*, or *B. fragilis*. The investigators who analyzed the amniotic fluid were blinded. The fluid was incubated at 38°C and examined at 48 and 96 hours for Gram stain, culture, and arborization and qualitative changes. Fifteen specimens were inoculated with each organism and compared to controls all of which had negative Gram stains and cultures. All inoculated samples had positive Gram stains and cultures. Inoculated specimens and controls demonstrated similar arborization patterns at 48 and 96 hours. No sample failed to "fern". All inoculated samples revealed "negative" readings for glucose (sensitivity of the reagent, 74 mg%) while controls were trace positive (sensitivity of the reagent, 100 mg%). There were no differences in protein (3+), nitrites (negative), pH (7.5 - 8.0), or leukocyte esterase (negative). The results were the same at 48 and 96 hours. This in vitro study confirms the usefulness of the fern test to diagnose ruptured membranes in the presence of infected amniotic fluid. This study also suggests that development of a reagent strip with high sensitivity for glucose may prove useful in the diagnosis of infected amniotic fluid. The qualitative analysis of other biochemical parameters did not seem to be useful at least in vitro.

419 COMPARISON OF GRAM STAIN, LEUKOCYTE ESTERASE, AND AMNIOTIC FLUID GLUCOSE IN PREDICTING CULTURE RESULTS IN PATIENTS WITH PREMATURE RUPTURE OF MEMBRANES. D. Gauthier,[X] W. Meyer,[X] A. Bieniarz. University of Illinois, Chicago, IL

Gram stain(GS), leukocyte esterase activity (LE), and amniotic fluid glucose(AFG) have been described as rapid predictors of amniotic fluid culture results. METHODS. A prospective study was performed on 90 patients with PROM ≤34 weeks EGA and no clinical evidence of infection. Aerobic, anaerobic, and mycoplasma cultures were done as well as GS, LE, and AFG on fluid obtained by amniocentesis. RESULTS. Cultures were positive in 47 patients(52%). The sensitivity, specificity, positive and negative predictive values of GS, LE 1+ or 2+, and AFG ≤16 mg/dl in predicting culture results are outlined below:

	SENS	SPEC	PPV	NPV
Gram st.	38(49)	95(95)	90(90)	59(68)
LE 1+/2+	68(81)*	84(84)	82(81)	71(83)
AFG ≤16	75(89)*	91(91)	90(89)	77(91)#

()=Exclusion of cultures + for Ureaplasma alone with no evidence of maternal/neonat. infection. In comparison to GS- * = $p < .01$, # = $p < .05$

CONCLUSION: AFG AND LE WERE SIGNIFICANTLY MORE SENSITIVE THAN GS IN DETECTING POSITIVE CULTURE RESULTS. OVERALL, AFG APPEARS TO BE THE MOST ACCURATE RAPID PREDICTOR OF CULTURE RESULTS.

420 FREQUENCY OF UTERINE CONTRACTIONS AFTER ANTIBIOTIC THERAPY FOR PYELONEPHRITIS: Graham JM*, Blanco JD, Oshiro BT, Magee KP: Department of Obstetrics, Gynecology and Reproductive Sciences, LBJ General Hospital, UTHSC-Houston, Texas.

Some pregnant women with acute pyelonephritis (Pyelo) present with uterine contractions (UCs). Presently, the relationship of UCs and antibiotic (AB) administration (with subsequent bacterial disruption) is unclear. We studied the relationship of AB therapy and UCs in pregnant patients with Pyelo. We recorded the number of UCs prior to and after initial AB therapy in 25 women. We compared the mean number of UCs at each hour after AB treatment to the mean number of UCs in the hour prior to AB administration. We also noted the number of patients who had an increase in UCs at each hour after AB initiation over the pre-AB hour. Inclusion criteria were: IUP ≥ 26 weeks gestation and clinical and laboratory evidence for Pyelo. We excluded any patients who had AB in the 7 days prior to admission. Statistical analysis was performed using ANOVA with a $p \leq 0.05$ as significant.

Hour	Mean Number of UCs	P value	Patients with Increased UCs
-1	7.8 ± 5.0		
Antibiotic administration			
+1	13.0 ± 6.7	0.003	21/25 (84.0%)
+2	14.0 ± 7.7	0.001	23/25 (92.0%)
+3	13.3 ± 7.9	0.005	20/25 (80.0%)
+4	13.0 ± 7.6	0.007	18/22 (81.8%)
+5	11.6 ± 6.3	0.029	13/20 (65.0%)

At study entry, 22 of 25 (88%) patients were < 37 weeks. Six of 25 patients (24%) required tocolysis after AB administration. Nineteen patients have delivered and 4 (21.1%) delivered at < 37 weeks gestation. We found a statistically significant increase in UCs over baseline in hours 1 through 5 after AB administration. Further studies are needed to elucidate the reason why UCs increase after AB administration in the pregnant patient with Pyelo.

421 IN VITRO STUDY OF AMNIOTIC FLUID GRAM STAIN: EFFECT OF CENTRIFUGATION. W. Torres,[X] D. Gauthier,[X] W. Meyer,[X] S. Warsof. University of Illinois at Chicago, Chicago, IL.

Amniotic fluid Gram stain (AF GS) has been used to assess for intraamniotic infection. It has been reported that centrifugation does not improve the sensitivity of AF GS. METHODS. AF obtained by amniocentesis from patients with preterm labor or preterm rupture of membranes was pooled. Individual AF samples as well as the pooled sample had negative GS and cultures. Using pure bacterial cultures, a 0.5 McFarland suspension was made and then diluted into the pooled AF to the concentrations outlined below. Concentrations were confirmed by colony counts. Prior to GS, each sample was divided into two portions, with one undergoing centrifugation. The slides were read in a blinded fashion by microbiology technicians.

	AF -NO CENTRIFUG.					AF-CENTRIFUG.				
BACT/CC	0	10^3	10^4	10^5	10^6	0	10^3	10^4	10^5	10^6
GS +	1	2	9	13	15	1	10	12	16	15
GS -	15	14	7	3	1	15	6	3	0	1
X^2 p-value vs no centrifug.							<.01	.14	NS	NS

CONCLUSIONS: CENTRIFUGATION OF AF PRIOR TO GS IMPROVED SENSITIVITY AT LOWER BACTERIAL CONCENTRATIONS. AT CONCENTRATIONS $\geq 10^5$, CENTRIFUGATION DID NOT IMPROVE ACCURACY OF GS.

422 BLOOD CULTURES ARE NOT COST-EFFECTIVE IN THE INITIAL EVALUATION OF POSTPARTUM ENDOMETRITIS. RD Jelsema[X], NB Isada. Divs Mat-Fetal Med and Reprod Genetics, Hutzel Hosp, Wayne St U, Detroit, Mi.

Objective: To assess the clinical impact and cost-effectiveness of blood cultures in the workup of uncomplicated postpartum endometritis. Design: Chart review of patients with a discharge diagnosis of postpartum endometritis. Setting: Public hospital postpartum ward. Patients: All patients with a discharge diagnosis of postpartum endometritis (n=83) in a 6 month period. Results: 67 patients had blood cultures, both aerobic and anaerobic (42 one set; 25 two sets; total 92 sets) obtained before starting antibiotic therapy. Three cultures were positive for Bacteroides fragilis, Streptococcus agalactiae, and Escherichia coli. The positive cultures did not change the therapy for any patient. The observed proportion of those individuals whose therapy was changed by blood culture results was 0%; binomial analysis shows an upper 95% confidence limit of ~4%. Discussion: The routine use of blood cultures in the initial workup of post-partum febrile patients with uncomplicated endometritis has been questioned because of the low specificity, low sensitivity and the high incidence of false-positive results (up to 50% in some series). This practice requires scrutiny because broad-spectrum or multi-agent antibiotic therapy is effective for such polymicrobial infections without blood culture results, with final identification often available only after the patient is considered cured. Furthermore, if the patient has not improved, evaluation is directed toward such diagnoses as wound infection, pelvic abscess or septic pelvic thrombophlebitis. Since results of blood cultures are unlikely to affect therapy (<4%) and their aggregate cost is substantial, we conclude that it is difficult to demonstrate their clinical utility or cost-effectiveness in the initial workup of uncomplicated postpartum endometritis in our patient population.

423 INCREASED AMNIOTIC FLUID TUMOR NECROSIS FACTOR-α & INTERLEUKIN-1B WITH SEVERITY OF CHORIOAMNIONITIS. Glenn A. Pankuch[X], Peter H. Cherouny, Douglas C. Kuhn[X], John J. Botti, Peter C. Appelbaum[X]. The Depts. of OB/GYN and Pathology, Penn State University, Hershey Med Center, Hershey, PA. Supported by March of Dimes Grant #6-548

Tumor necrosis factor-α (TNFα) and Interleukin-1β(IL1β) levels were determined in 28 amniotic fluids (AF) from patients in preterm labor with intact membranes. The purpose was to compare cytokine levels to results from the leukotaxis assay (LeuA) and microbiologic, histologic and clinical tests for chorioamnionitis. Cytokine levels were determined by ELISA. The fluids are grouped below according to LeuA result, presence of AF infection (positive Gram stain or culture) and clinical infection. AFs in groups 1, 2, and 3 were obtained from patients in idiopathic preterm labor. All patients in groups 2, 3, and 4 delivered within 48 hours of amniocentesis and all had histologic chorioamnionitis and detectable leukoattractants. Cytokines were not detected in AFs from group 1 despite significant cervical dilation. Results indicate; 1) TNF-α and IL-1β do not reach detectable levels in all LeuA (+) fluids and, 2) AF levels of IL-1β significantly increase following extension of the ascending infection into the amniotic cavity (Gp2 vs Gp3, $p<0.05$). TNF-α and IL-1β reach their highest levels in the presence of clinical infection (Gp3 vs Gp4, $p<0.01$).

	Gp 1 n=5	Gp 2 n=7	Gp 3 n=11	Gp 4 n=5
AF LeuA	(-)	(+)	(+)	(+)
AF Infection	(-)	(-)	(+)	(+)
Clinical Infx	(-)	(-)	(-)	(+)
TNFα	0[X]	3 (158±82)[*]	10 (394±112)	5 (1251±294)
IL1β	0[X]	6 (510±169)	11 (1141±217)	5 (2084±144)

424 **ICON STREP B^R: AN ENZYME IMMUNOASSAY FOR RAPID DETECTION OF GROUP B STREPTOCOCCUS.**

MJ Paidas[x+], DT Manhoff[x], S Kagan[x], G. Bender[x], J Earl[x], JC Dunn[x].
Mt Sinai School of Med., NY, NY and Pennsylvania Hospital, Philadelphia, PA.

A sensitive, reliable, and rapid test for detection of group B streptococcus (GBS) is still needed. Therefore, we evaluated an enzyme immunoassay Icon Strep B^R (Hybritech, San Diego, CA) for the detection of GBS in a population of 62 randomly selected pregnant patients presenting to Labor and Delivery at Pennsylvania Hospital. Three swabs from both the cervix and vagina were obtained per patient. One swab was tested with Icon Strep B^R without incubation. A second swab was placed in Lim Broth Enhancement Media^R (BBL, Baltimore, MD) incubated for 4 hrs at 37°C in a CO_2 rich enviroment followed by testing with Icon Strep B^R. The third swab, a control ,was placed in Lim Broth Enhancement Media^R, incubated for 4 hours at 37°C in a CO_2 rich environment and then plated on blood agar and incubated for 24 hours at 37°C in a CO_2 rich environment, and then read by a medical technologist. Colonies suspected of being positive for GBS were verified by a latex agglutination method.

RESULTS The prevalence of GBS by culture was 21.0% (13/62).

		+ Culture	-
Icon Strep B	+	1	0
	-	12	49

		+ Culture	-
Icon Strep B Lim Broth	+	7	0
	-	6	49

	Icon Strep B	Icon Strep B with Lim Broth
Sensitivity	7.7%	53.8%
Specificity	100%	100%
Positive Predictive Value	100%	100%
Negative Predictive Value	80.3%	89.1%

CONCLUSION In this preliminary study, Icon Strep B has poor sensitivity for rapid detection of GBS. However, its sensitivity is substantially improved with a short period of incubation with enhancement medium. More studies are necessary to confirm these results.

425 **THE EFFECT OF UNTREATED SYPHILIS ON THE MATERNAL CHARACTERISTICS OF LABOR AND DELIVERY**

Karen Lesser[x], Frances Marks, Carolyn Westhoff[x] Columbia Presbyterian Medical Center, NY, NY.
Brown Univ/Women & Infants Hospital, Providence, RI.

Syphilis is a significant cause of perinatal morbidity and mortality. A retrospective study of 79 women with positive serologic tests for syphilis who delivered between January 1, 1988 and December 31, 1990 was conducted to determine the intrapartum behavior of the fetus exposed to syphilis. Patients were grouped according to treatment status during pregnancy: group I (n=32) - no treatment, group II (n=12) - inadequate treatment, group III (n=25) adequate treatment, group IV (n=10) - appropriate treatment during the pregnancy but reinfected, and group V (n=25) - control population matched for gestational age and registration status. Infants were classified as to the certainty of the diagnosis of congenital syphilis by both Kaufman's criteria and the newer guidelines issued by the CDC in 1988. Diagnostic categories included probable, possible, unlikely (Kaufman) and compatible, unlikely (CDC). Neonatal diagnosis was found to be dependent on maternal treatment status ($p<0.001$). Intrapartum factors examined included: fetal heart rate tracing characteristics, presence or absence of meconium stained amniotic fluid, route of delivery, gestational age, weight at delivery, and Apgar score. Results were analyzed by analysis of variance and test for differences in proportions. There was no significant difference in the incidence of positive urine toxicology screens between study and control populations. Infants of untreated mothers, and those in the "probable" diagnostic category, had significantly fewer fetal heart rate accelerations, more late decelerations, more deliveries by cesarean section, more preterm deliveries and low birth weight infants. Infants in the "probable" category of congenital syphilis were also more likely to have meconium stained amniotic fluid. The fetal heart rate tracings of treated patients, and those "unlikely" to have congenital syphilis, did not show loss of reactivity or late decelerations. This suggests that maternal treatment of syphilis during pregnancy is beneficial and can prevent poor fetal outcome.

426 **HIV-1 INFECTION AMONG ADOLESCENT PARTURIENTS**

M. Lindsay, N. Johnson[x], S. Willis[x], H. Williams[x], L. Klein, Department Gynecology\Obstetrics, Emory University Atlanta, Georgia

Objective: To define the prevalence of HIV-1 infection and to characterize HIV risk behavior in adolescent parturients.
Methods: We performed a case-control study of 51 HIV-1 infected and 282 seronegative adolescent parturients (Ages 13-20) identified from a prenatal population undergoing routine voluntary HIV-1 antibody screening with self-reported risk behavior.
Results: From 7/87-3/91, we screened 10,794 adolescent parturients of which 51 (4.7 per 1000) were HIV-1 infected. The demographic characteristics of cases and controls were comparable, however 1/3 of cases were age 17 years or less. Significantly more cases than controls reported a history of crack cocaine use 10 (19.6%) vs. 23 (8.2%) (P=.03). Twenty-two (43%) of cases had no apparent risk factors for infection and 17 (33%) were presumed to be infected by heterosexual contact. Thirty-nine (14%) of controls had self identified risk factors for infection.
Conclusions: Adolescent parturients in our center are at risk for HIV-1 infection and should be targeted for HIV education and risk reduction counseling.

427 **HIV IN PREGNANCY: THE SWISS COLLABORATIVE STUDY**

O. Irion[x1], Ch. Rudin[x2], K. Biedermann[x3], F. Béguin[1] and the members of the Collaborative Group. Depts Ob/Gyn University Hospitals GENEVA[1] and ZURICH[3], Children Hospital University BASEL[2], Switzerland

Switzerland has the highest rate of AIDS cases in Europe: 1891 cases (283/million) until june 1991; 13511 HIV+ tests have been anonymously reported to the Federal Office for Public Health. Women represent a third of all cases. Many questions regarding HIV and pregnancy remain unanswered. Asymptomatic HIV infection is not a recognized risk for pregnancy complications. Vertical transmission rate is estimated 10 to 30%. It is not clear whether pregnancy influences HIV progression. Data are lacking on treatments during pregnancy. **Methods:** this multicentric prospective study was designed to collect epidemiological data, to study interactions between HIV and pregnancy, and to identify markers for vertical transmission. Pregnant women are included after informed consent. History, physical examination and laboratory are repeated at 3 months intervals, 1.5 and 6 months post-partum. When possible, women are then followed in the national cohort study. Neonates are included in the swiss neonatal study. **Results:** from may 1st 90 to aug. 20th 91, 96 HIV+ pregnant women were included: 39 (40.6%) obtained an abortion, 57 (59.4%) carried on their pregnancy, 44 have now delivered. We found no differences between women obtaining an abortion and those pursuing pregnancy for mean age (27.2 y, 19-35 vs 27, 21-35), way of infection (IVDU 68.4 vs 70.1%, sexually 28.9 vs 24.5%, p=NS) or CDC stage (II: 54.2 vs 73.6%, III: 37.1 vs 18.9%, IV: 8.6 vs 7.5%, p=NS). Six women seroconverted during pregnancy. In 78.7% of cases the first positive test was known before 1990. Twenty-eight sexual partners were also HIV+, mostly IVDUs. We have data on 40 deliveries of 42 newborns: 20 females, 22 males, 2 sets of twins. Mean gestational age is 37.8 weeks (27-41), mean birthweight 2860 g (900-4200); 23 deliveries (57.5%) were spontaneous, 4 instrumental (10%) , 13 by cesarean section (32.5%: 7 CS (17.5%) were electively performed in one center). **Conclusion:** after 16 months, we collected an unexpectedly high number of patients. Updated data will be presented. The study is ongoing and will help to improve the care of pregnant HIV+ women.

428 **PERINATAL HIV: OUTCOME AND MATERNAL FACTORS RELATING TO TRANSMISSION.** A Sison,[X] J Sever,[X] C Brandt,[X] T Rakusan,[X] M Chan,[X] J Campos,[X] D Fuccillo,[X] E Saxena,[X] M Young.[X] Georgetown, DC General and Children's Hospital, Washington DC.

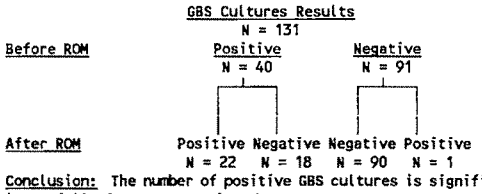
Through pregnancy and at delivery, 25 HIV infected women and their newborns were followed & tested for HIV & HTLV1 antibody, titer of HIV IgG and T cell subsets. Proviral HIV DNA by polymerase chain reaction (PCR) and virus by culture (VC) were also tested. **RESULTS: [MOTHER]** All but one were asymptomatic. Maternal IgG titers were high (mean=1:3450). CD4 counts were depressed (mean=615). Co-infection with HTLV1(=1) was rare. There was no difference between mothers of infected infants vs. those with indeterminate status regarding IgG titer, time to positivity of VC, or length of seropositivity. **[INFANT]** 20% were born < 36 wks. Known infected infants had mothers who were PCR+ and VC+ at delivery.

	Mother(n=20)	Neonate(n=20) HIV-Infected	Inderminate
PCR+	17/20	3/3	1/17
VC+	10/20	3/3	0/17

CONCLUSIONS: Most infected pregnant women (despite CD4 depression) and almost all infants of infected mothers are asymptomatic at birth. Prematurity appears increased in HIV+ pregnancies. Maternal HIV IgG titers are high but does not seem to protect against viral transmission.

429 THE ASSOCIATION OF CLINICAL INTRAAMNIOTIC INFECTION (IAI) AND MECONIUM. Wen IS*, Eriksen NL*, Graham JM*, Blanco JD, Oshiro BT*, Prieto JA. Dept Obstetrics, Gynecology, and Reproductive Sciences, LBJ Hospital, UTHSC, Houston, Texas.

Meconium has been shown to enhance bacterial growth. However, its role in IAI is undetermined. To determine the rate of IAI in patients with meconium and controls, we compared 100 pregnant women with meconium and 100 pregnant women without meconium between September 1 and December 31, 1990. Exclusion criteria were any active infection prior to labor or antibiotic use within the 7 days prior to delivery. We diagnosed clinical IAI in patients with rupture of membranes (ROM), maternal fever ≥ 100.4°F and any 2 of the following: maternal or fetal tachycardia, uterine tenderness, WBC ≥ 10,500mm^3 or foul amniotic fluid. We analyzed continuous variables by the Wilcoxon rank test and discrete variables by Chi-square or Fisher's Exact test as appropriate. All clinical characteristics are presented as the mean ± standard error.



Characteristics	Meconium (N=100)	No Meconium (N=100)	P
Age(yrs)	23.6 ± 0.5	24.1 ± 0.6	NS
Parity	1.1 ± 0.1	1.3 ± 0.1	NS
Length of Labor (hrs)	10.6 ± 0.8	10.5 ± 0.6	NS
Length of ROM (hrs)	5.0 ± 0.8	6.3 ± 1.2	NS
Vaginal exams (#)	4.1 ± 0.2	4.3 ± 0.2	NS

The percentage of patients with an intrauterine pressure catheter was similar between the meconium (17%) and no mecorium (21%) groups (P=NS). The rate of clinical IAI was significantly higher in women with meconium-stained amniotic fluid (8%) compared to women with no meconium (2%) (p=0.05). We conclude that the rate of clinical IAI is higher in patients with meconium-stained fluid compared to patients without meconium.

430 **GROUP B STREPTOCOCCUS CULTURES FOLLOWING RUPTURE OF AMNIOTIC MEMBRANES.** C.E. Henderson, H. Egre[X], G. Szilagyi[X], M.Y. Divon. Dept. of Ob/Gyn, Albert Einstein College of Medicine, Bronx, New York.

Amniotic fluid has been shown to exhibit specific antibacterial activity against group B Streptococcus (GBS). Therefore, genitourinary tract cultures used to identify women colonized with GBS before rupture of membranes (ROM) may have different results after ROM. To evaluate the effect of ROM on a rapid culture technique to identify GBS (sensitivity of 98.4% and specificity of 100%), we performed cultures on 131 women before and after ROM. Rayon tipped swabs were used to obtain samples from the vaginal introitus, the specimen was then incubated in selective broth medium to facilitate rapid bacterial growth. Samples positive for GBS were identified within 12 to 24 hours by slide co-agglutination.

Results: Before rupture of membranes 40/131 (30.5%) were GBS positive. After rupture of membranes only 22 of these 40 cultures (55%) remained positive. In contrast, only 1/91 (1%) culture which was initially negative became positive. The number of positive cultures before rupture of membranes 40/131 was significantly greater than the 23/131 seen after rupture of membranes (p = 0.02).

Conclusion: The number of positive GBS cultures is significantly lower following rupture of membranes.

431 **OUTCOME OF LYME DISEASE IN PREGNANCY.** Jodi F. Abbott, M.D.[X], Neil S. Silverman, M.D. Jefferson Medical College of Thomas Jefferson University Hospital, Philadelphia, PA.

The natural history of Lyme disease in pregnancy is not well understood, though the transplacental transmission of Borrelia burgdorferi has been documented. Case reports of cardiac malformations, fetal and neonatal deaths following maternal exposure have been published, though cause and effect have been difficult to establish. We sought to follow women with positive Lyme serology prospectively through pregnancy to help define fetal risks of in utero exposure. Materials and Methods: All patients were referred for consultation or management due to their history of possible Borrelia exposure. Six women have been followed with a clinical or laboratory diagnosis of Lyme disease. All had negative RPR's, eliminating cross reaction with other spirochetal antibodies.

Pt	Clin Sx	IgG	IgM	Trim Exp	Outcome
1	+	+	-	3rd	NI, term, AGA
2	+	+	-	2nd	NI, term, AGA
3	-	+	+	2nd	NI, term, AGA
4	+	+	-	1st	NI, term, AGA
5	+	+	-	1st	Ongoing
6	+	+	-	1st	Ongoing

Patients 1-3, with early Lyme disease received oral amoxicillin for at least three weeks. Patients 4-5, with systemic disease, received 1 mo. IV ceftriaxone, then ongoing oral amoxicillin. Patient 6 is receiving continuing IV ceftriaxone. All fetuses had normal cardiac ultrasounds in the second trimester. Cord blood was obtained on two newborns; #1 had +IgG -IgM; #2 had -IgG -IgM. Neither patient had evidence of spirochetes in their placentas. Discussion: To date, this is one of the larger prospective reports of fetal outcome in pregnancies exposed to Lyme disease. Although a limited series, the normal outcomes of these patients is reassuring, and may be helpful in patient counselling.

432 PETHIDINE COMPARED WITH DIAMORPHINE FOR PAIN RELIEF IN LABOUR. F.M.Fairlie, L. Marshall[X], J.J. Walker The Perinatal Centre, Glasgow Royal Maternity Hospital, Glasgow, Scotland. U.K.

Despite its proven inefficiency, intramuscular (IM) pethidine is widely selected for pain relief in labour. Diamorphine has been shown to be more effective but there has been a reluctance to use this powerful analgesic in labour. This study was designed to compare the analgesic properties and side effects of IM pethidine with IM diamorphine in active labour. **Method:** 50 nulliparous and 50 multiparous women in active labour (Bishop score ≥5) were randomly assigned to receive either IM pethidine or IM diamorphine. Nulliparous women received either 150 mg pethidine or 7.5mg diamorphine, multiparous women received either 100mg pethidine or 5mg diamorphine. Pain severity was assessed by a visual analogue score and a 5 point verbal scale. Assessments were made immediately before analgesia and at intervals of 30 minutes post analgesia until delivery or until additional analgesia (epidural blockade) was requested. **Results:** For each parity group there was no difference between those receiving pethidine compared with those receiving diamorphine with respect to bishop score at the time of drug administration, duration of labour or subsequent epidural analgesia. For the nulliparous group, pethidine was associated with a significant reduction in pain severity at 30 minute (p=0.03 Wilcoxon signed rank test) and 60 minutes (0.01) post drug administration. Reduction in pain severity was more marked in the diamorphine group (0.001 at 30 minutes and 0.008 at 60 minutes). The need for neonatal resuscitation was significantly less for the diamorphine group (p=0.03). The multiparous group showed similar differences. **Conclusion:** This data suggests that IM diamorphine is associated with less neonatal sedation compared with IM pethidine and there appeared to be a trend towards greater pain relief in the diamorphine group.

433 INDWELLING SPINAL CATHETERS AND POST DURAL PUNCTURE HEADACHE. S. Cohen,[X] N.Singer,[X] D. Amar,[X] M. Divon, Depts. of Anesthesia and Obstetrics/Gynecology, Albert Einstein College of Medicine, Bronx, NY.

Puncture of the dura mater for regional anesthesia is occasionally associated with post dural puncture headache (PDPH). It has been suggested that continuous spinal anesthesia (CSA) is associated with a low incidence of PDPH in non-obstetric patients. The purpose of this study was to determine the incidence of PDPH following inadvertent dural puncture in term pregnant patients and to assess the effect of continuous spinal anesthesia on PDPH. An epidural block (EB) was attempted in 65 patients. Three groups were identified: Group I (n=24) had a dural puncture on the first attempt of EB followed by a successful EB on the second attempt. Group II (n=26) had a dural puncture immediately converted to CSA with the catheter left in situ <24 hours. Group III (n=13) same as Group II, but the catheter left in situ >24 hours. Results:

	PDPH	Duration of Spinal Catheterization (hrs)
Group I	10/24	0
Group II	12/26*	8.3 ± 4.7 **
Group III	0	37 ± 9.7

* p<.01 Group III vs. Group I or II
** p<0.001 Group II vs. Group III.

In conclusion, continuous spinal catheterization following accidental dural puncture may be an adequate method of PDPH prophylaxis in pregnant patients.

434 THE EFFECTS OF CONTINUOUS BUPIVACAINE/FENTANYL EPIDURAL ON FETAL HEART RATE CHARACTERISTICS. E.R. Newton, B. Schroeder,[x] K. Higby[x] and B. Bennett,[x] Dept. of Ob/Gyn, The Univ. of Tx. HSC, San Antonio, Tx.

The effects of epidural analgesia on fetal heart rate patterns (FHR) are controversial. The differences in maternal and fetal conditions between patients obscure the direct effect of epidurals on FHR. We evaluated the effects of epidural analgesia on FHR using each fetus as its own control. Thirty-seven successful continuous labor epidurals using bupivacaine and fentanyl were matched with the next two consecutive patients of the same parity who delivered without epidural analgesia. Fetal heart tracings, one hour before and after epidural placement, or at a corresponding cervical dilation in the control patients were evaluated by in a blinded fashion. Six (16%) epidural patients required ephedrine for hypotension and epidural patients received more I.V. fluids than controls (2075 vs. 952 cc, P <0.01). FHR characteristics within fetuses in the presence or absence of epidural analgesia, were compared.

	Mean change between periods		
Characteristics	Epidural		Control
Baseline heart rate (BPM)	1.4		−1.1
Variability (BPM)	−0.9		−1.7
Maximum oscillation (BPM)	0.32		−1.3
Accelerations	−0.81	p=ns	−1.88
Moderate variables	0.81		0.82
Severe variables	0.00		0.47
Late decelerations	0.20		0.54

Deterioration or improvement in FHR characteristics are not related to continuous bupivacaine/fentanyl labor epidurals.

435 ANONYMOUS URINE TOXICOLOGY SCREEN IN A RURAL STATE

RA Wright[X], F Byford[X], S Carter[X], MA Morgan, KM Parker[X], PC Toubas[X], D Blouse[X], Oklahoma Univ. Health Sciences Center, Oklahoma State Health Dept., Indian Health Services, Oklahoma City, OK and Univ. of California, Irvine, Orange, CA.

Although substance abuse in inner-city pregnant populations is reported to be high, the frequency of abuse in a rural state remains unknown. The purpose of this study was to anonymously screen urine specimens of consecutive deliveries during one month from three hospitals, in different cities and geographic areas of a rural state and determine perinatal outcomes. Specimens were collected on admission from 435 patients in labor (57% teaching hospital, 25% public hospital and 19% private hospital) and tested at a NIDA certified laboratory for amphetamine, barbiturate, benzodiazepine, marijuana, cocaine, opiate and phencyclidine. Positive screens were observed in 90 patients (86% one substance; 12% two; 2% three). Babriturate(51%) was most frequently seen, followed by opiate (19%), amphetamine (14%), marijuana (13%), benzodiazepine (2%) and cocaine (0.9%). However, the barbiturate positives were prescribed. The patients with positive and negative results were similar in age, parity, race, delivery gestational age, mode of delivery, neonatal birthweight, apgar scores, low birth weight and perinatal mortality. The three different participating hospitals had similar positive results. However, those positive for opiates were observed to deliver at a significantly earlier gestational age than negatives (37.9±3.6 vs. 39.2±2.3, p<0.025). Although these hospitals in a rural state have a similar frequency of positive toxicology screens at delivery as reported for inner-city hospitals, the distribution of substances is drastically different, with a low frequency of cocaine. Similar studies from other rural settings are needed to determine where to concentrate therapy efforts for substance abuse during perinatal period.

436 **ASYNCHRONOUS MULTIPLE BIRTH SYNDROME**

J.P. Lavery, M.D., R.J. Austin, M.D.
D.S. Schaefer, M.D.*, S. Aladjem, M.D.
Bronson Methodist Hospital
Kalamazoo, Michigan

Extending the interval between the births of members of a multiple gestation is uncommon. Prolongation of time in utero may allow for survival of the later delivering fetus(es) and also lower the long term morbidity of prematurity. We report four cases in which aggressive tocolysis, antibiotic therapy, liberal hospitalization and cerclage (3 cases) achieved a dramatic extension of the pregnancy after the primary delivery. Although all first delivered fetuses died, 4 of 5 of the remaining infants survived and are without major complications. Aggressive therapy has a place in selective cases of asynchronous births in multiple gestations.

CASE	GESTATION (WEEKS) 1ST.....2ND BIRTH		TIME GAINED	2ND DEL OUTCOME
1.	21	24	21 DAYS	NND
2.*	18 2/7	34 1/7	111 "	TWINS-A&W
3.**	26 3/7	29 4/7	20 "	A&W
4.	21 5/7	33 3/7	82 "	A&W

*Pregnancy began as a triplett gestation
**Stillbirth with first birth, no cerclage.
NND=Neonatal death; A&W=Alive and well without major complications.

437 PREDICTING SUCCESS IN A TRIAL OF LABOR. L.R. Troyer, V.M. Parisi. Dept. Ob/Gyn, University of Texas HSC, Houston, TX.

Increasing experience with vaginal birth after cesarean delivery (VBAC) attests to its overall success, but has also raised controversy as to its universal safety. The purpose of this study is to identify factors predicting success and/or failure in a trial of labor (TOL) and to determine if a subset of patients at high risk to fail a TOL consequently suffer greater morbidity. In a retrospective chart review from Jan. 1990 - Jan. 1991, 264 labors with documented transverse lower uterine segment scars were analyzed. Previous birth weight, diabetic status, and current estimated fetal weight did not affect the outcome of a TOL. Success of a TOL was significantly influenced by (1) previous dysfunctional labor, (2) no prior vaginal delivery (PVD), (3) nonreassuring admission fetal heart tracing (NR FHT), and (4) induction of labor (Table 1). A scoring system was then constructed to predict VBAC success rates, with one point assigned for each variable present at admission (Table 2).

TABLE 1

Variables	VBAC	C/S
Prev. dys. labor	63.4%*	36.6%
No PVD	67.4%*	32.6%
NR FHT	43.6%*	56.3%
Induction	52.9%*	47.1%

(*p < .05 compared to overall VBAC rate of 72.7%)

TABLE 2

Score	N	VBAC
0	59	91.5%
1	92	73.9%
2	87	66.7%
3-4	26	46.1%

The incidence of uterine rupture was 1.1% (n = 3), all in the C/S group. There was no increased maternal or fetal morbidity between VBAC and C/S in those patients scoring 3-4 points. We conclude: (1) based on the additive presence of each variable, we have identified subsets of patients undergoing a TOL who have high rates of success and high rates of failure; (2) a TOL in the subpopulation of patients with the lowest percentage for success (score 3-4) does not increase maternal morbidity; and (3) this scoring system may influence the counselling of patients who desire a TOL.

438 **VAGINAL BREECH DELIVERY IN THE 1980s-*PRETERM GESTATION.*** C.Weiner and L.Estle*, Univ Ia College of Med, Iowa City, Ia 52242

Vaginal delivery (VagD) of the selected breech remains clinically controversial. Criticisms have included, sample size, the % of patients allowed a trial, delivery prior to widespread use of epidural anesthesia, fetal monitors, and umbilical blood gases. To resolve many of these issues, we examined the mother/child hospital records of 850 breech and 1611 vertex singleton deliveries between 1981 to 1990. This abstract focuses on the 223 with completed records <36w. 19 (8.6%) had lethal and 41 (20%) nonlethal abnormalities; each higher than the matched vertex neonates (each $p<0.05$). Excluding neonates with lethal defects, 55% (112/204) had a trial of labor. 69% of these were either frank or complete. Selection criteria were staff dependent and included a flat plate, pelvimetry, a Zatucchni-Andros score and an ultrasound weight estimate. 71% delivered vaginally (40% overall, 90% by resident staff). The PNM rate appeared higher for all VagD (V:173/1000; CS: 82/1000, $p=.08$) and after exclusion of 7 neonates <25w (V:147/1000; CS:67/1000, $p=.11$). Neither GA at delivery (V:30±4w; CS:31±3w), the GA of those that died (V:26±2w; CS:27±3w), the incidence of significant trauma nor metabolic or respiratory acidoses varied significantly by route. *Because of the large sample, GA could be stratified. PNM did not differ by route from 32 to 36w (V: 0/1000; CS: 19/1000,p=.83). It was higher for VagD <32w (V:275/1000; CS:106/1000, p=0.05). RDS was less frequent after VagD (V:46%; CS:62%, p=0.05), a benefit not confined to any particular GA. The incidence of IVH was increased by VagD, but the increase was confined to those < 32w (V:31%; CS:11.8%, p=0.02).* **CONCLUSION: The breech ≥ 32w does not benefit from routine caesarean delivery and is at greater risk of RDS if delivered by caesarean. Therefore, routine caesarean delivery of the breech ≥ 32 w cannot be medically justified. In contrast, caesarean delivery of the breech < 32 w reduces the PNM predominantly by a reduction in IVH.**

439 **VAGINAL BREECH DELIVERY IN THE 1980s- *TERM GESTATION.*** C.Weiner and L.Estle*. Univ Ia College of Med, Iowa City, Ia 52242.

Vaginal delivery (VagD) of the selected term breech remains clinically controversial despite 2 randomized trials and several large retrospective studies confirming safety. Criticisms have included sample size, the % of patients allowed a trial, and delivery prior to widespread use of epidural anesthesia, fetal monitors and umbilical blood gases. To resolve many of these issues, we examined the mother/child hospital records of 850 breech and 1611 vertex singleton deliveries between 1981 to 1990. This abstract focuses on the 462 breeches ≥36w. 4 (.9%) had lethal and 110 (24%) nonlethal anomalies; each higher than the matched vertex deliveries ($p<0.05$). After excluding neonates with lethal defects, 69% (316/458) had a trial of labor. Selection criteria were staff dependent and included a flat plate, pelvimetry, a Zatucchni-Andros score and an ultrasound weight estimate. X-ray pelvimetry was done in only 35% and altered the plan in 19% of those. 63% delivered vaginally (43% overall, 84% by resident staff) (3153±401g, range 2060-4350). ***There was only 1 perinatal death -a patient who presented with the fetus on the perineum without a heart rate (corrected PNM 0/1000).*** Though a metabolic acidosis was more common after labor and VagD (V:6.3%; CS:1.1%, $p=.02$), there were no clinical sequellae. Neonatal trauma (includes bruising and laceration) was greater after VagD (45 vs 8%, $p<0.0001$) and a nuchal arm (6.1%) was seen only with VagD. *However, the incidence of significant trauma (fractures, nerve palsies, etc) did not vary by route (V:2.1%; CS:3.3%, p=NS).* Further, among VagD patients, an epidural was associated with a decrease in total (50 vs 38%) but not significant trauma. The incidence of trapped head did not vary by route (V:2.6; CS:.8, $p=.3$). VagD was unassociated with NICU admission or RDS (V:1.5%; CS:4.2%). However, maternal morbidity and hospital days were each increased by CS ($p<0.001$). **CONCLUSIONS: *Routine* caesarean delivery of the term breech is not medically justifiable.**

440 **ACTIVE MANAGEMENT OF LATENT LABOR WITH UNKNOWN UTERINE SCAR INCREASES RISK OF UTERINE RUPTURE.** D.K. Grubb,[X] S.L. Kjos, R.H. Paul. University of Southern California, Los Angeles, CA

Trial of labor is now frequently undertaken after prior cesarean birth. The term patient with an unknown uterine scar and persistent uterine contractions presents an unknown risk of uterine rupture. A prospective, randomized study was undertaken to determine if prolonged labor and operative delivery could be minimized by outpatient observation until labor was confirmed. Uncomplicated, term patients with one or two prior cesarean births were randomly assigned to active inpatient management, with oxytocin augmentation for persistent contractions, or to outpatient evaluation and observation until labor was ruled in. Of 197 patients enrolled, 8 failed to return for delivery, and were excluded from analysis. Four initially requesting trial of labor elected repeat cesarean section after enrolling.

	Expectant (94)	Active (95)	p
2 prior cesarean births	20 (21%)	16 (17%)	NS
Prior vaginal birth	31 (33%)	31 (33%)	NS
Cesarean delivery	17 (18%)	15 (16%)	NS
Oxytocin used	49 (52%)	76 (80%)	0.0001
Hours active labor (median)	4.25	4	NS
Uterine scar disruption	0 (0%)	5 (5%)	0.03

Four cases of asymptomatic low transverse uterine scar dehiscence and one case of vertical uterine scar rupture requiring hysterectomy occurred. All five were in the inpatient active management group, and all had received oxytocin augmentation. We conclude that, in term gravidas with unknown uterine scars exhibiting persistent uterine contractions, expectant management did not reduce the rate of cesarean delivery or prolonged labor. Second, expectant management was associated with a decreased usage of oxytocin. Finally, the risk of uterine scar dehiscence or rupture was increased significantly by active inpatient management compared to expectant outpatient management.

441 **CLINICAL CHARACTERISTICS AND NEONATAL OUTCOME IN PATIENTS WITH PRETERM PREMATURE RUPTURED MEMBRANES WHO DELIVER WITHIN 72 HOURS.** S.J.Carlan,J.V.Parker*,U of S FL,Tampa,FL,ORMC,Orlando,FL

Over a two-year period 386 patients with preterm premature ruptured membranes (rupture of membranes prior to labor < 37 weeks gestation) delivered at Tampa General Hospital. Of these, 19 terminated electively and 14 resealed. Of the remaining 335, 205 (61%) delivered within 72 hours. No patient was tocolyzed. The group that delivered within 72 hours was similar in GTPAL, racial makeup, incidence of smoking, and positive cervical cultures for Gc and GBBHS to the group that delivered after 72 hours. The incidence of multiple gestations, breech presentations, abruptios and fetal distress in labor was also not significantly different between the groups. Neonatal outcomes were similar in incidence of NEC, IVH, and positive blood cultures.

CLINICAL CHARACTERISTICS AND OUTCOME PARAMETERS (MEAN ±1SD)

	Delivery <72 hrs N=205	Delivery >72 hrs N=130	P
Age (yrs)	24.1 ± 6.6	23.5 ± 5.5	NS
EGA at rupture (wks)	32.5 ± 3.5	30.9 ± 3.7	<.05
Cx Clamydia + (%)	5.3	13.8	<.05
Initial US deepest pocket (cm)	2.6 ± 1.6 (N=156)	3.1 ± 1.6 (N=126)	<.05
Amnio + gr stain;#(%)	11/36 (30)	6/59 (10)	<.05
Clinical chorio (%)	14	18	NS
Pit induction (%)	8.2	12.3	NS
C-Section (%)	19.5	25	NS
Newborn wt. (grs)	1999 ± 661	1879 ± 714	NS
ROM to delivery (d)	1.07 ± 0.7	11.9 ± 14.1	<.05
Cord pH	7.29 ± 0.08	7.31 ± 0.09	NS
Newborn Respirator (d)	1.9 ± 6.3	3.9 ± 12.3	.05
NICU (d)	10.7 ± 19.3	17.4 ± 28.7	<.05

We conclude that women with earlier gestational ages, deeper amniotic fluid pockets, and a lower incidence of positive amniotic fluid bacterial studies are likely to delay delivery > 72 hrs. Inspite of a mean latent period of almost 12 days and similar gestational ages at delivery, the neonates in the delayed delivery group had more ventilator and NICU days.

442 **THE FISCAL IMPACT OF THE MEDICAID ABORTION FUNDING BAN IN MICHIGAN.** MI Evans, E Gleicher, MP Johnson, RJ Sokol, Dept Ob/Gyn, Wayne State University/Hutzel Hospital, Detroit, MI

Attacks upon the availability of abortion have occurred in many states. In Michigan after several attempts, a 'no Medicaid funding of abortion law' went into effect in December, 1988, prior to which the number of abortions per year in Michigan and the number of abortions per 1000 residents remained relatively steady.

Year	# Abortions Reported	# Abortions/ 1000 Livebirths	Deliveries
1987	49,098	340.4	140,466
1988	46,747	331.2	139,635
1989	36,557	248.4	148,164
1990	36,183	236.0	153,304

Following the change in the law the number of abortions decreased by about 10,000 which was closely reflected in increased births. Such an increase was not seen in surrounding states. At Hutzel Hospital, the largest delivery service in Michigan, deliveries rose 10% in 1989 and 7% in 1990. However, while the overall percentage of Medicaid patients remained steady at approximately 50% in our hospital (an increase of 600 Medicaid deliveries), the percentage of NICU Medicaid volume rose from 64 to 68%. These findings are consistent with the supposition that unwanted pregnancies result in neglected prenatal care. Poor care gives rise to prenatal complications and NICU admissions which may have been avoided had freedom of access to abortion services been an option for these women. It is unknown just how many of these pregnancies would have continued, but using the cohort of an additional 13,669 Michigan babies born in 1990 over 1988 numbers at an average medical cost of $3708 (Medicaid estimate) for the first year, the overall cost will be $54,748,620. There have been no increased appropriations by the Michigan legislature to care for these babies.

443 **EARLY REPAIR OF EPISIOTOMY DEHISCENCE ASSOCIATED WITH INFECTION.** R. Ramus[X], S. Ramin, B. Little[X], L. Gilstrap, Dept. Ob/Gyn, Univ. Texas Southwestern Med. Ctr., Dallas, TX

The traditional approach to episiotomy dehiscence has been delayed repair. Recently, early repair of episiotomy dehiscence has been examined in a military population. The purpose of the present study was to examine early repair in a city-county hospital setting serving predominantly an indigent population. The incidence of episiotomy breakdown at our institution was 0.5%. Our policy, since September 1, 1989, has been to proceed with early repair in the immediate postpartum period. Medical records were reviewed on 34 of 35 patients who have undergone early repair. Of these, 21 (62%) had midline and 13 (38%) had mediolateral episiotomies. Twenty of the former and 8 of the latter group had a third-degree or fourth-degree extension. Dehiscence was associated with episiotomy infection in 27 (79%) of the 34 patients -- 18 (86%) in the midline and 9 (69%) in the mediolateral group. All patients received antibiotic therapy and wound care prior to repair. In addition, those with fourth-degree episiotomy breakdowns received a go-lytely bowel prep. Repair was accomplished from 3 to 13 days ($\bar{x}$=6.4) following dehiscence. Successful repairs were accomplished in 32 of 34 (94%) patients. Two patients (6%), with an initial third-degree episiotomy, had a subsequent breakdown of their repair and were allowed to heal by secondary intention. In conclusion, most dehiscences in our population are associated with infection. Unlike previous reports, infection was as common in midline as in mediolateral episiotomy dehiscences. Early repair of episiotomy dehiscence in this population is associated with a satisfactory outcome in the vast majority of patients.

444 **TRANSVERSE UTERINE INCISION CLOSURE: ONE VERSUS TWO LAYERS**

J.C. Hauth, J. Owen, R.O. Davis, T. Lincoln[x], J. Piazza[x]
University of Alabama Hospitals, Birmingham

In 1926, Munro Kerr described the transverse lower uterine segment incision and recommended a two layer closure. Theoretically, a one layer closure should disrupt less tissue, introduce less foreign material, require less operative time, and perhaps achieve hemostasis more rapidly. To test this hypothesis, we prospectively randomized 761 women to closure with either one continuous layer of a locking #1 chromic gut suture using a CTX needle (#384) or two continuous layers of #1 chromic gut with the first layer locked (#377). Both groups had similar demographic and intrapartum risk factors. Women who had a one layer closure required less operative time, 39 versus 45 minutes, (p=.004) and fewer uterine hemostatic sutures, a mean of 0.65 versus 0.82 for one and two layers respectively (p=0.03). Endometritis (excluding patients with chorioamnionitis) was similar in both groups (21 vs. 16% p=0.34) and a Hct decrease of ≥ 8% from the pre- to postoperative day one occurred in 11.7% (one) vs. 15.5% (two) p=.14. In no outcome assessment was the two layer closure of more benefit than the one layer. We recommend that a transverse incision be placed in the true lower uterine segment and that a one layer closure be used when anatomically feasible.

445 **SOCIOBEHAVIORAL CHARACTERISTICS AND INTRAUTERINE GROWTH RETARDATION: A MULTIVARIATE ANALYSIS.** L.C. Castro, C. Hobel, L. Platt. Dept OB-GYN, Cedars-Sinai Med Ctr. LA, CA.

The purpose of this study was to determine the prevalence rates for tobacco use (TU) & substance abuse (SA) in a broad spectrum of pregnant women & to evaluate the individual & interactive effects of TU, SA & sociodemographic characteristics on intrauterine growth retardation (IUGR). **Methods:** 8,914 women delivering in a university affiliated hospital from 1986-90 were studied. Information on TU, SA (use of alcohol, marijuana and other illicit drugs) & sociodemographics was obtained antenatally. IUGR was a birthwt < 10th% for gestational age (GA). Univariate logistic regression was used to assess the association between each sociobehavioral factor & IUGR. Stepwise multivariate analysis was used to determine their interactive effects on IUGR. **Results:** Prevalence Rates

Race-ethnicity	White	Black	Asian	Hispanic	p-value
Tobacco use	17%	13%	8%	5%	<.0001
Substance abuse	7%	7%	5%	3%	<.0001
Insurance status	Uninsured	HMO	Private	p-value	
Tobacco use	14%	8%	5%	<.001	
Substance abuse	6%	5%	4%	<.01	
Marital status	Single	Married	p-value		
Tobacco use	17%	8%	<.0001		
Substance abuse	9%	4%	<.0001		

TU & SA were lowest in 30-39 year old women (6% & 4%) vs other ages (p<.001). Univariate analysis showed that TU, alcohol, marijuana, race & non-private insurance were significantly associated with IUGR. Multivariate analysis showed that TU (odds ratio= 1.96, p<.0001), marijuana use (odds ratio=1.69, p<.03) & race (odds ratio= 1.66 for blacks, p<.001) were most strongly associated with IUGR. For the categories SA, TU, & SA plus TU the prevalence of IUGR progressively increased (p<.0001) & this increase was greatest in black women. **Conclusions:** There are significant interactive effects of TU, SA & race on IUGR. Supp. by UCTRDRP.

446 **PREDICTORS OF SUCCESS IN THE EMERGENT CERCLAGE.** T.F.Kelly MD,[x] L.R.Troyer MD, K.M.Piacquadio MD,[x] C.J.Cantrell MD, V.M.Parisi MD,MPH, T.R.Moore MD. *From the Divisions of Maternal Fetal Medicine of the University of California, San Diego and the University of Texas at Houston and the Department of Obstetrics and Gynecology, Balboa Naval Hospital, San Diego.*

It is difficult to counsel the mid trimester patient who presents with advanced cervical dilatation. Available literature does not delineate the variables most prognostic for the success of emergent cerclage. We retrospectively reviewed charts of 20 patients (21 fetuses) who presented within the last 6 years with advanced cervical dilatation and visible or prolapsing membranes, in the second trimester. The average gestational age (GA) on admission was 20.9 ± 3 (SD) weeks (wks), weeks gained were 8.9 ± 7.4 wks and GA at delivery was 30 ± 7.7 wks. Neonatal survival correlated negatively with cervical dilatation on admission (R=0.46, P<0.04). If cervical dilatation was > 3.5 cm, survival was 0% (n=3); if ≤ 3.5 cm survival was 83% (n=18) (P=0.015). Cervical effacement and membrane prolapse on admission were not predictive of weeks gained. Of 8 who had prolapsing membranes, 80% went greater than 50 days from cerclage to delivery. There was no significant relationship between time from admission to surgery or the time on tocolytics to weeks gained. We conclude that (1) cervical dilatation > 3.5 cm is prognostic of poor outcome in the performance of emergent cerclage, (2) neither cervical effacement nor evidence of membrane prolapse were predictive of successful outcome, and (3) use of tocolytics prior to cerclage appears not to improve outcome.

447 **THE MANAGEMENT OF BREECH PRESENTATION: CESAREAN SECTION VERSUS VAGINAL DELIVERY**

Tracy L. Wells[x], Luis Sanchez-Ramos, M.D., M.D., Mark T. Cullen, M.D. Division of Maternal-Fetal Medicine, University of Florida, Jacksonville, FL

The management and perinatal outcome of 451 cases of singleton breech presentation occurring at 34 or more weeks' gestation and with a fetal weight greater than 2000 grams are reviewed. Beginning in 1986 a trial of labor was offered if the breech was frank or complete, had an estimated weight between 2000 and 4000 grams, adequate pelvimetry, and a non-extended fetal head. Three hundred-thirty patients underwent a cesarean section without a trial of labor; most of these cesarean deliveries were for patients' "choice". The incidence of elective cesareans because of this indication decreased from 62% to 6% in a five year period. Of the 121 patients who qualified for a trial of labor, 22 had a cesarean section, and 99 had a successful vaginal delivery. Approximately 80% of patients who met protocol criteria delivered vaginally. Comparing the 330 patients with an elective cesarean delivery to the 99 who delivered vaginally revealed no difference in several outcome parameters including: NICU admissions, Apgar scores less than 7 at 1 and 5 minutes, umbilical cord gases, and birth trauma. There was a significant increase in maternal morbidity and length of hospital stay in the cesarean section group. We conclude that a trial of labor in selected patients can be achieved without an increase in perinatal or maternal morbidity and mortality.

448 CHOICE OF DELIVERY METHOD AFTER CESAREAN SECTION. A Stek* MD, R Jacobson MD, J Khoury*, Department of Obstetrics and Gynecology, University of Cincinnati, Cincinnati, Ohio

Despite recent recommendations, vaginal birth after cesarean section (VBAC) is still not completely accepted as a desirable option by many patients and physicians. Our study was therefore designed to determine the factors which may influence patients' decisions regarding method of delivery after a previous cesarean section (C/S). 55 patients with a previous low transverse C/S were interviewed with respect to choice for method of delivery (trial of labor [TOL] versus repeat C/S) for the current pregnancy and the reasons for this choice. Spontaneously mentioned reasons were noted, after which the patients indicated the factors in their decision from a standardized list. 42 patients (76%) preferred TOL whereas 13 (24%) desired a repeat cesarean section. These two groups were similar in age, race, gravidity and parity. Patient reasons for preferring TOL were: (a) comfort and convenience (52%), (b) desire to experience a normal birth (43%); and (c) physician/midwife advice (24%). Using Fisher's Exact Test and Chi-Square analysis, specific factors which were statistically significant for TOL choice included: decreased postpartum pain, shorter recovery and hospitalization, current and previous physician's advice, desire to experience a normal birth and avoid surgery, remain in control of the birth process, decreased anesthetic and medication use and decreased risk of infection or surgical trauma, as well as history of a previous vaginal delivery, and problems experienced with a previous C/S. Patient reasons for preferring repeat C/S were: (a) comfort and convenience (100%), (b) safety for mother and infant (75%), and (c) experience with C/S and lack of familiarity with vaginal birth (42%). Educational level, insurance status and the partner's opinion were not statistically significant factors. In summary, the strictly medical and financial benefits of VBAC were not of major significance in the patients' decision making process. The current and previous physicians' advice however, did significantly influence the patients choice of method of delivery. We propose that physician counseling at the time of the original C/S and subsequently can contribute towards further lowering of the rate of repeat cesarean sections.

449 **MID-TRIMESTER PREGNANCY TERMINATION: A RANDOMIZED TRIAL OF PROSTAGLANDIN E2 VERSUS CONCENTRATED OXYTOCIN**

J Owen, JC Hauth, CL Winkler, SE Gray*, T Lincoln*, J Piazza*
The University of Alabama Hospitals, Birmingham

Concentrated oxytocin infusion was compared with prostaglandin E2 (PGE2) vaginal suppositories for indicated mid-trimester (17-24 weeks) abortion in a prospective, randomized analysis. **Methods**: 72 patients received either PGE2 (N=36) or concentrated oxytocin (N=36). The uterine size was ≤ 24 cm in all patients. Treatment consisted of six PGE2 suppositories (one q4h) or six cycles of an escalating concentration of oxytocin (50X units in 500 cc of normal saline q4h - X represents the cycle number). Unless delivery was imminent at 24 hrs, the agent was considered to have failed, and patients were crossed to the other method. **Results**: Indications were similar between the two methods (p=0.38) and included fetal anomalies (N=36), fetal death (N=17), PROM (N=14), and maternal indications (N=5). The patients were of a similar age, parity, race, gestational age, uterine size, and initial cervical dilatation. There were 12 first-round failures: 5 (14%) with PGE2 and 7 (19%) with oxytocin, p=0.53. Of these, 11 were delivered during the second 24 hrs, and one patient required treatment beyond 48 hrs. Failures were significantly related to gestational age (mean 18.5 weeks in failures versus 19.8 weeks in the successes, p=.001) and anencephaly (3 of 6 vs. 4 of 66, p=.01). Considering the failures and subsequent crossovers, a total of 85 patient-trials were completed. Maternal side effects were more frequent with PGE2: fever (p<.001), nausea (p=.004), vomiting (p<.001), and diarrhea (p<.001). No patients experienced neurologic symptoms related to hyponatremia. Pre- and post-treatment electrolyte values were similar in 14 patients. **Conclusions**: Concentrated oxytocin is a satisfactory alternative to PGE2 for indicated mid-second trimester abortions.

450 **VACUUM EXTRACTION IN PRETERM INFANTS: A CASE CONTROL STUDY**

LUIS SANCHEZ-RAMOS, M.D., ROBERTO MORALES, M.D.*, MARK T. CULLEN, M.D. UNIVERSITY OF FLORIDA, JACKSONVILLE, FL.

The vacuum extractor is now an established instrument in the practice of obstetrics. However, there is paucity of data on the application of vacuum extraction in preterm deliveries. This study was designed to determine perinatal and developmental outcomes in preterm infants (34.2 ± 1.9 weeks; 2080 ± 387 gm). delivered by vacuum extraction compared to spontaneously delivered controls (33.6 ± 2.3 weeks; 2071 ± 357 gm) From January 1989 to June 1991, 47 infants were delivered by vacuum extraction. Ninety-eight well matched controls were selected for comparison. During the study period there were approximately 13,104 deliveries at this institution. Both groups were matched for: maternal and neonatal demographics, indications for delivery, and labor characteristics. No statistically signficant difference was noted in Apgar scores, umbilical cord gases, length of NICU stay, length of hospital stay, number of NICU admissions, and incidence of retinal and intraventricular hemorrhages. Developmental outcome was evaluated and did not appear to be affected by instrumental deliveries. Our data support the indicated use of vacuum assisted delivery in preterm infants.

451 **COUNSELING BASED ON OBSTETRICAL HISTORY: RECURRENCE RATES FOR ABNORMALITIES OF BIRTH WEIGHT, GROWTH, AND GESTATIONAL AGE.**

MC Treadwell, and SF Bottoms. Wayne State Univ., Hutzel Hospital, Detroit, MI.

There is often little information to guide counseling based on obstetrical history. Many of the available studies calculate recurrence retrospectively using multiple/single occurence ratios, which imprecisely estimate both followup rates and the number of cases at risk. This report addresses the lack of recurrence studies for macrosomic, postterm, and large for gestational age births. We analyzed 4349 women with more than one singleton live birth at our hospital from 1984-1990 and calculated the frequencies, odds ratios, and 95% confidence intervals (CI) tabulated below.

	Incidence	Recurrence	Odds(CI)
>4000 gm	5.1%	30.6%	8.2(6.0-11.3)
<2500 gm	15.7%	47.7%	4.9(4.1-5.8)
≥42 wks	6.6%	12.3%	2.0(1.4-2.9)
<37 wks	13.1%	42.9%	5.0(4.1-6.0)
LGA	8.4%	33.8%	1.5(1.1-2.1)
SGA	8.9%	20.3%	1.5(1.1-2.0)

We believe the high recurrence rate for prematurity and low birth weight may be in part a reflection of our referral pattern. Recurrence rates for macrosomia and posterm gestation are subject to variation in obstetrical management; these rates would be higher without intervention. Clinicians should consider individual and institutional practice patterns as well as the above rates when counseling patients.

452 ANTEPARTUM AUTOLOGOUS BLOOD DONATION: COST/BENEFIT ANALYSIS. CA Combs MD PhD*, EL Murphy MD MPH*, RK Laros, Jr., MD. University of California, San Francisco

To minimize the risk of infection after homologous blood transfusion (TX), autologous blood donation (AuBD) has been recommended before procedures with a high risk of TX. Antepartum AuBD has been shown to be safe for mother and fetus in patients with "traditional" risk factors for obstetric TX. However, the majority of units so donated are not needed for TX, except in patients with placenta previa. We attempted to develop rational recommendations for antepartum AuBD based on actual risk factors for TX. We reviewed the TX experience in 14,267 consecutive term deliveries from 1978-88. Women with placenta previa were excluded. Preterm deliveries were excluded because these women could not have completed an AuBD program. Ten risk factors that could have been known in advance were studied. On multiple logistic regression, four factors were significantly (P<0.05) associated with TX: preeclampsia (odds ratio=3.7), multiple gestation (OR=2.8), elective cesarean (OR=1.7), and nulliparity (OR=1.5). There was no association between TX and ethnic group, prior abortions, prior cesarean section, or prior postpartum hemorrhage. In a cost/benefit analysis, we assumed that the cost of a 2-unit AuBD was $100, the risk of hepatitis 1 in 20 homologous units, and the risk of HIV infection 1 in 40,000 homologous units. Lower infection rates would result in higher costs per case prevented by AuBD.

# of Risk Factors	# of Pts. Transfused	Cost of AuBD to Prevent One Case of: Homologous TX	Hepatitis	HIV
0	43/6218 (0.7%)	$23.0K	$161.8K	$300.0M
1	83/7187 (1.1%)	11.6K	88.0K	136.9M
2	24/810 (3.0%)	4.3K	35.2K	73.6M
3 or 4	4/52 (8.0%)	1.3K	13.3K	26.0M

CONCLUSION: In obstetric patients without placenta previa, the probability of TX or TX-related infection is too low for antepartum AuBD to be cost-effective.

453 **OUTPATIENT PROSTAGLANDIN E2 SUPPOSITORIES IN POSTDATES PREGNANCIES.** SK Sawal, WF O'Brien, MS Mastrogiannis, MG Mastry*, GW Porter*, L Johnson*. University of South Florida, Tampa, Florida

Although the safety of low dose outpatient PGE2 for postdate pregnancy has been established (Obstet Gynecol 78:19, 1991), the efficacy and advantages remain unknown. We investigated daily self-administered 2 mg PGE2 vaginal suppositories in accelerating cervical ripening in this double blind, placebo controlled study. 72 patients with uncomplicated pregnancies ≥ 41 weeks gestation and a Bishop score of < 9 received either 2 mg PGE2 placebo or vaginal suppositories. The groups were comparable in age, parity, EGA, and Bishop score. Patients were admitted for labor induction if the Bishop score was ≥ 9, for unfavorable antepartum test results, or other obstetrical complications. There were no cases of stimulation of regular uterine contractions or reports of other side effects. The results were

as follows	CONTROL(40)	PGE2(32)	p
Bishop score on L&D admission	11	10	NS
EGA on L&D admission (days)	298	295	<.05
No. of suppositories	8	2	<.05
Total oxytocin used (mU)	2192	484	<.05
Time in L & D (hrs)	12.2	8.4	<.05
C-sections	5	2	NS
Antepartum testing costs ($)	664	506	<.01

CONCLUSIONS: 1. Daily 2 mg PGE2 suppositories accelerate cervical ripening resulting in earlier spontaneous or scheduled admission for labor 2. Low dose PGE2 may decrease intrapartum cervical resistance as reflected by shortened labor course & decreased requirement for oxytocin, not necessarily reflected in the Bishop score.

454 **CESAREAN BIRTH SOLELY TO PREVENT MECONIUM ASPIRATION SYNDROME UNWARRANTED.**
YR Renfroe*, and SF Bottoms. Wayne State Univ., Hutzel Hospital, Detroit, MI.

The persistence of meconium aspiration syndrome (MAS) with meconium staining despite intrapartum suction has led some clinicians to perform cesarean birth to prevent gasping in cases with little evidence of fetal distress. To investigate the relationship between mode of delivery and MAS, we studied 2,523 consecutive singleton, vertex, live births complicated by meconium stained fluid delivered in 1987-89. Of these, 172 had a final clinical diagnosis of MAS. MAS was associated with Apgar score of 0-3 at 1 minute ($p<0.001$), fetal scalp pH < 7.20, ($p<0.01$) and primary, repeat, and elective repeat cesarean delivery ($p<0.01$ in each case). Discriminant function analysis revealed no relationship to mode of delivery in the absence of a low Apgar score or scalp pH. Dysfunctional labor, abnormal fetal heart rate patterns, and the duration of labor were not significantly related to MAS. There was a 6.8% incidence of MAS with meconium staining that increased to 28.4% with an Apgar score of 0-3 or scalp pH < 7.20. This is in sharp contrast to the reported 4% frequency of aspiration among meconium stained stillbirths, and suggests MAS is linked mainly to acidosis at the time of birth rather than before birth. We conclude that cesarean birth to prevent intrauterine gasping is unwarranted; severe acidosis should be avoided irrespective of the presence of meconium.

455 **A PROSPECTIVE STUDY OF THE 30 MINUTE RULE IN THE TIMING OF CESAREAN DELIVERY FOR FETAL DISTRESS.** T.R. Moore M.D., W.M. Gilbert M.D., R. Resnik M.D., R.C. Stevenson M.D.* *Division of Perinatal Medicine, University of California San Diego, CA.*

A limit of 30 minutes from the recognition of fetal distress until delivery is a commonly recognized standard, yet supporting data are lacking. We prospectively studied the effect of timing of cesarean section (decision-to-delivery time (DDT) and OR-to-delivery time) on neonatal outcome in 261 consecutive cesarean sections performed for fetal distress (FD) from 12/85 to 2/88. The time of onset of labor, the time of recognition of fetal distress, the FHR abnormality/scalp pH, time to OR , time of delivery, umbilical gases (UBG), and Apgars were recorded on a data sheet validated by independent review the following day. The mean DDT was 31 ± 27 (SD) minutes. FD deliveries were divided into DDT<30' (66%) and >30' (34.%). The mean arterial UBG pH (7.23 ± .09 vs 7.25 ± .08, $p<.02$), venous pH (7.28 ± .08 vs 7.31 ± .07, $p<.004$) were statistically but not clinically different. Fetal acidemia (arterial pH<7.15, venous pH<7.20), was more frequent in the DDT<30' group (16% vs 7%, $p<.001$), but the incidence of Apgar 5'<7 (3% vs 1%) and admission to NICU (20% vs 21%) was similar. This study suggests that, utilizing traditionally accepted indicators of fetal distress, immediate neonatal outcome is not influenced by the decision to delivery time.

456 SUBSTANCE ABUSE IN PREGNANCY, A RURAL PERSPECTIVE. S.C. Fee, P. Meier, Dept. Ob/Gyn, Marshfield Clinic, Marshfield, WI.

Substance abuse in pregnancy is a well documented problem and has been associated with numerous perinatal problems. Most studies have noted a prevalence of 11-15%, but these studies have all relied on urban populations. We have attempted to address the problem of substance abuse in rural pregnant women by conducting urine toxicology screens on 714 pregnant patients in a rural obstetrical clinic. In the first 4 months of this ongoing clinical study we obtained anonymous urine toxicology screens from 301 consecutive women seen for their initial prenatal visit and from 413 consecutive women admitted to the labor/delivery suite. All urines were screened for cocaine, cannabinoids, opiates, barbiturates, benzodiazepams and amphetamines. All positive screens underwent confirmatory testing. The presence of secobarbitol in labor/delivery patients (n=4) was considered iatrogenic and was not included in the calculations. The prevalence of positive urine screens was 1.7%. Of patients presenting for prenatal care, 1.3% were positive. Labor/delivery patients had a prevalence of 1.4%. The substances found were as follows: opiates 1.3%, barbiturates 0.1%, cocaine 0.3%, cannabinoids 0.3%, 3 screens were positive for more than one substance. No screens were positive for amphetamines or benzodiazepams. Our findings suggest that substance abuse in pregnancy may not be as wide spread as suggested by previous studies and that the concept of universal screening for substance abuse in pregnancy may not be a cost effective measure in all populations.

457 POSTPARTUM MORBIDITY AFTER FOURTH DEGREE PERINEAL REPAIR. Kenneth G. Goldaber,[X] Paul J. Wendel,[X] George D. Wendel, Jr. Department of Obstetrics and Gynecology, University of Texas Southwestern Medical Center, Dallas, TX

Fourth degree extension of episiotomies and perineal lacerations can have serious sequelae. However, there is little data regarding the incidence of fourth degree repair morbidity: infection and dehiscence. We sought to investigate the frequency of puerperal complications in women with fourth degree perineal lacerations and episiotomy extensions. The hospital records of 389 women (2% of vaginal deliveries) in 1989 and 1990 who had fourth degree perineal repair were reviewed. The delivery room surgical technique involved layered closure with 00 and 000 chromic catgut suture. Twenty women (5.1%) had infection and/or dehiscence. Thirteen women (3.3%) had infected perineal repairs, and 10 of the repairs (77%) subsequently became dehiscences. Seven women (1.8%) had perineal dehiscence without infection. Overall, 17 dehiscences (4.4%) occurred, accounting for 85% of the postpartum morbidity. Seventeen of the women (85%) were primiparas, and 19 (95%) had episiotomy extensions. The mean birth weight in the group with morbidity was 3500 grams. When compared to the 369 women without repair complications, there were no significant differences between maternal age, race, parity, weight, smoking or human papilloma virus infection. Similarly there was no difference regarding duration of second stage of labor, occiput positions, forceps delivery, blood loss, macrosomia, or birthweight. The only significant association was with shoulder dystocia which occurred in 19 of 369 women (5.1%) without morbidity and 4 of 20 women (20%) with morbidity (P= 0.02). Conclusion: Postpartum morbidity after fourth degree perineal repair is an uncommon event, usually accompanied by perineal dehiscence. Unfortunately, fourth degree complications are not predicted by readily preventable antepartum or intrapartum factors.

458 **PERIPARTUM HYSTERECTOMY: A RETROSPECTIVE REVIEW**
Lorraine Stanco[X], M.D., David Schrimmer, M.D. Richard Paul, M.D.
University of Southern California, Los Angeles, CA

From January 1, 1985 to July 1, 1990 at LAC+USC Women's Hospital, there were 85,841 births (71,845 vaginal and 13,996 cesarean). Retrospective review of medical records and departmental statistics revealed 125 cases of either cesarean or immediate post partum hysterectomy, with 60 being total and 65 subtotal. The incidence of peripartum hysterectomy was 1.5/1000 births, with an incidence following vaginal delivery of .097/1000 whereas the incidence associated with cesarean birth was 8.4/1000 or one hundred times greater. Median parity was 2 and median gestational age was 38 weeks. In 81 cases (65%), there was a history of prior cesarean delivery. Delivery was by cesarean section in 118 pts., while 7 delivered vaginally. Placenta previa was the indication for cesarean in 58/118 (49%) pts. Of the 7 pts. delivered vaginally, the 4 with prior cesarean delivery had uterine rupture requiring hysterectomy, despite the fact that 3 of them had undergone prior successful VBAC. Indication for hysterectomy was the diagnosis of placenta accreta in 55 pts, uterine atony in 25 pts, unspecified uterine bleeding in 19 pts, uterine rupture in 14 pts, placenta percreta in 6 pts, fibroids in 5 pts and infection in 1 pt. The pathological diagnosis of accreta or percreta was confirmed in 26/61 cases (43%). In 108/125 cases (86.4%) estimated blood loss was at least 2000 cc (range 900-21000) and blood transfusion occurred in 102/125 pts (82%). Fifty-seven pts. were transfused more than 2 units and of these 27 received more than 10 units. There were no significant differences in blood loss or replacement products with respect to type or indication for hysterectomy. Maternal complications included 11 cases of infectious morbidity, 11 wound complications, 7 cases of coagulopathy, and 4 cases of profound hemorrhage with one resultant maternal death. Median birthweight was 3120 grams and 13/126 (10%) infants had a 5 minute Apgar score of less than 7. There were 2 intrapartum and 2 neonatal deaths, the latter being attributed to prematurity. Median discharge for mothers and infants was the fourth hospital day. Previous cesarean section, placenta previa and blood loss of 2000cc or more were identified risk factors leading to hysterectomy. For 37/125 (29.6%) pts., all three factors were identified.

459 INTRAPARTUM MANAGEMENT OF THE NONVERTEX SECOND TWIN. S.J. Sherman, B.W. Kovacs, Dept. Ob/Gyn, University of Southern California School of Medicine, Los Angeles, CA

The intrapartum management of twin gestations in the vertex-nonvertex presentation is controversial. The purpose of this study was to compare the following delivery methods of the nonvertex second twin with regard to neonatal outcome: assisted breech, breech extraction, external version, and cesarean section. From 1/89 to 1/90, 236 sets of twins were delivered: 109 vertex-vertex, 67 vertex-nonvertex, 59 nonvertex, and 1 unspecified. Among the 67 vertex-nonvertex, the findings were:

Second twin	Assisted breech	Breech extraction	External version	Cesarean section
N (%)	13 (20%)	26 (39%)	3 (4%)	25 (37%)
Birth weight	2314g	2387g	3140g	2399g
Apgar 5 min	8.3	8.3	8.2	8.6
NICU admit	0%	17%	0%	18%

In conclusion, there is no statistically significant increased neonatal morbidity for these specified methods of vaginal delivery of the nonvertex second twin compared to delivery by cesarean section.

460 THE EFFECT OF PLACENTAL MANAGEMENT AT CESAREAN DELIVERY ON BLOOD LOSS. C. M. McCurdy,Jr., [X]E. Magann,[X] C.J.McCurdy,[X] A. Saltzman,[X]Dept. Ob/Gyn, Naval Hospital Camp LeJeune, Jacksonville, NC.

The effect of alternative methods of placental delivery at cesarean section on blood loss has not been studied. We randomized and prospectively compared 62 gravidas with respect to manual or spontaneous placental delivery at cesarean section. Duration of the third stage of labor, duration of surgery, and antibiotic prophylaxis did not differ between the study groups ($p > .05$). Blood loss measured at cesarean delivery was greater in the manually delivered group, 967 ml ± 248 ml(n=31), compared with the spontaneously delivered group, 666 ml ± 271 ml, n=31, ($p < .0001$). The incidence of postpartum endometritis was 7-fold greater in the manual vs. the spontaneous group, 23 % vs. 3 % respectively ($p < .05$). We conclude that spontaneous delivery of the placenta through the uterine incision at cesarean delivery can result in less operative blood loss and a lower incidence of postoperative endometritis.

461 **CORRELATION OF CHORIOAMNIONITIS AND PLACENTAL ABRUPTION IN THE TERM GESTATION** Fadi Bsat, MD[X], Dept. Ob/Gyn, Eastern Virginia Medical School, Norfolk, VA

An association has been established between placental abruption in the preterm gestation and histologic chorioamnionitis. To determine if a similar association is present at term, forty-two pregnancies at ≥37 weeks gestation with clinically diagnosed placental abruption were compared to a control group of forty-two term pregnancies with no evidence of abruption. Pathological examination of the placentae was done on all the cases, specifically looking for findings of chorioamnionitis. Each case was then classified in one of three groups, depending on the severity of abruption, as determined by gross examination of the placenta (Table I). Mild and severe abruption were defined as <50% or >50% placental separation, respectively. Cases with no abruption (group 1) or mild abruption (group 2) had a similar incidence of histologic chorioamnionitis ($p=0.66$). Patients with severe placental abruption (group 3) had a higher incidence of chorioamnionitis than either group 1 or group 2 ($p<0.01$). Chorioamnionitis and placental abruption are correlated in the term gestation, but the chronological nature of this relation remains unclear.

TABLE I: Chorioamnionitis and abruption severity.

Group	Abruption severity	# patients	# Chorio-amnionitis	% Chorio-amnionitis
1	None	42	4	10
2	Mild	32	5	16
3	Severe	10	7	70*

* $p<0.01$ when compared to either group 1 or group 2.

462 CT PELVIMETRY IN MANAGING BREECH LABOR. M. Gimovsky, J. P. O'Grady, B. Morris[X], R. Petrie, Dept. of Ob/Gyn, Baystate Medical Center/Tufts University School of Medicine, Springfield, MA

Previous experience suggests that CT pelvimetry offers distinct advantages over conventional radiographic studies including less fetal/maternal irradiation, ease of interpretation, and greater accuracy. In a three year experience with 55 breech labors in which CT pelvimetry was utilized, 37/55 (67%) fetuses were delivered per vagina in an uneventful manner when adequate maternal pelvic measurements were noted. 15/55 (27%) had "borderline" measurements and were delivered by C/S for that indication. 2/55 (4%) labors had failure of descent followed by C/S delivery. One fetus (2%) evidenced hyperextension of the fetal head and was delivered by C/S. We conclude: CT pelvimetry was easy for the radiologist to interpret, added no additional expense to the patient, and provided the clinician with an improved radiographic estimation of pelvic dimension and architecture.

463 A COMPARISON OF THE STANDARD PAPANICOLAOU TEST AND THE *CERVEX BRUSH* IN PREGNANCY. P.A. Cook,[X] J. Wormsbaker,[X] J.E. Hamous,[X] V.D. Castracane,[X] Dept. Ob/Gyn, Texas Tech University Health Sciences Center, Amarillo, TX.

The Papanicolaou (PAP) smear is a widely used technique for cervical cancer screening. The presence of endocervical cells is a criteria for considering the cervical cytology sample adequate. This study was designed to compare the *Cervex-Brush* (Unimar) with the standard PAP smear during pregnancy. Cervical smears were obtained from each of 144 pregnant women (8-37 weeks gestation). Q-tip and Ayre spatula samples were obtained in our usual fashion and placed on a single slide. *Cervex-Brush* samples were obtained by placing the middle lines of the brush into the cervical os and rotating the brush in a clockwise fashion five times and placed on a separate slide. All slides were then evaluated by the same pathologist. Samples were obtained in a alternating fashion so that roughly one-half of the patients had the *Cervex-Brush* sample collected first and the other half had a standard PAP smear obtained first. Contemporary statistics from a separate group of 229 obstetrical patients, 50 (21.8%) had no endocervical cells. Of 144 initial smears, 88 (61.1%) of the smears obtained with the *Cervex-Brush* retrieved more endocervical cells than did the routine smear in the same patient. Only 18 (12.5%) of the routine smears retrieved more endocervical cells than did the *Cervex-Brush*. Twenty-nine smears (20.1%) had equal amounts of endocervical cells and in 9 (6.3%) there were no endocervical cells retrieved with either method. There seemed to be no increase in cervical bleeding associated with this procedure. Patients continue to be enrolled to reach a total of 200 subjects. This data indicates an improved method of endocervical cell retrieval during pregnancy with the *Cervex-Brush* and may become the method of choice for obtaining PAP smears in pregnancy.

464 PERINATAL SEPSIS AND DEATH ASSOCIATED WITH RETAINED CERCLAGE IN PATIENTS WITH PREMATURE RUPTURE OF MEMBRANES

J Ludmir MD, T Bader MD[X], L Chen MD[X], P Samuels MD
University of Pennsylvania School of Medicine, Philadelphia, PA

The timing for cerclage removal in patients with preterm premature rupture of the membranes (PPROM) is controversial. Early removal has been advocated due to concerns for perinatal infection. Recently, Yeast and Garite (AJOG 1988) found that early cerclage removal was not associated with an increased risk for immediate delivery or infection, however, the possible sequelae of retained cerclage were not addressed. We have, therefore, assessed the effect of removing or retaining cerclage in cases of PPROM. Prophylactic cerclages were performed in 246 patients at our institution over a 12-year period for a history consistent with cervical incompetence. Patients having cerclage placed for cervical change detected during the index pregnancy were excluded. Thirty-one singleton pregnancies associated with PPROM without labor between 24 and 32 weeks of gestation were identified. Four women were delivered upon presentation for overt chorioamnionitis. The remaining 27 patients were entered into an expectant protocol. Of the 27 patients, 21 (78%) had immediate cerclage removal (Group A); six women (22%) opted to retain the cerclage (Group B). There were no statistically significant differences between the two groups regarding gestational age at time of cerclage (15.3±1.9 weeks vs. 15.1±2.4 weeks, p=0.8); gestational age at PPROM (28.3±2.2 weeks vs. 27.7±2.8 weeks, p=0.5); birthweight at delivery (1320.76±495.25 gm vs. 1440.33±872.69 gm., p=0.6); the latency period (5 days vs. 3 days, 50th percentile), and maternal febrile morbidity (6/21 vs. 4/6, p=0.27). Immediate neonatal death occurred in 2 babies in group A (9%) compared to 5 in group B (83%) (p=0.006). All deaths were secondary to sepsis. We conclude that retaining cervical cerclage in cases of PPROM does not increase the latency period to delivery or birthweight but is associated with a dramatic increase in neonatal morbidity and mortality.

465 MATERNAL TRANSPORT OF PATIENTS WITH ADVANCED CERVICAL DILATATION -- TO FLY OR NOT TO FLY

John P. Elliott, M.D., Tamara L. Sipp, R.N.*, Kendra T. Balazs, R.N.*, Phoenix Perinatal Associates, Good Samaritan Regional Medical Center, Samaritan Air Evac Services, Phoenix, Arizona

Emergency maternal transport of patients in advanced preterm labor often involves difficult decisions about whether to transport or not. Numerous studies have documented an increased survival rate, decreased short and long term morbidity, and decreased cost of hospitalization for infants transported in utero and delivered at a tertiary care facility. A retrospective review of maternal transports performed in Northern Arizona by Samaritan Air Evac Services was performed covering a 21 month period. Fifty-four (5%) of 1,080 patients transported for preterm labor were in advanced stages of labor (≥ 7 cm dilated) at the time of call for transport. Five patients were delivered at the referring hospital and 49 were transported to a tertiary center in Phoenix. There were no deliveries en route and only 30% delivered in the first hour after arrival at the tertiary hospital. Transport of these patients was mostly by rotor wing aircraft (40) with 8 in fixed wing, and 1 ground transport. Almost 50% of these patients were 10 cm dilated at the time of call for transport. The Air Evac transport team consists of maternal flight nurses and neonatal flight nurses. These nurses have had a minimum of 2 years nursing experience in tertiary care L&D units and an extensive didactic course with an extended preceptorship. This study supports the concept that maternal transport can be accomplished despite advanced cervical dilatation. The experienced judgment of the maternal flight nurse is critical to these decisions to fly or not to fly.

466 QUADRUPLET PREGNANCY - CONTEMPORARY MANAGEMENT AND OUTCOME

John P. Elliott, M.D. and Tari Radin, R.N., Ph.D.*
Phoenix Perinatal Associates, Good Samaritan Regional Medical Center, Phoenix, Arizona

Quadruplet pregnancies are occurring more frequently as assisted reproductive techniques improve fertility in couples previously unable to conceive. Recommendation for selective reduction of quads to twins due to the "excessive" risk of quad pregnancies is not acceptable to all patients. This report describes 10 quadruplet pregnancies cared for in one perinatal practice over a 5 year period of time. This is the largest number of quad pregnancies ever reported from one center. These are compared to 57 consecutive quad pregnancies enrolled prospectively on home uterine activity monitoring nationwide by the Tokos Medical Corporation from October, 1986 to January, 1990. The mean gestational age at delivery for the Phoenix quads was 32.5 weeks compared to 30.2 weeks from the national quad group (sig p <0.001). All 40 babies in Phoenix survived without morbidity compared to a perinatal mortality rate of 127/1000 in the Tokos group (morbidity unknown). Of interest, 9 of 10 patients developed PIH in our series and 7 of 10 were delivered for worsening PIH, 2 of 10 for fetal distress, and only 1 of 10 for preterm labor. Maternal age does not impact outcome, but PMR for parous patients is lower than for nulliparas (p <.001). Our data reveals two gestational ages that are associated with an increased delivery rate: 29 to 30 weeks and unexpectedly 21-22 weeks. A team approach directed by an experienced perinatologist is vital to the improved outcome achieved in our series.

467 PRETERM PREMATURE RUPTURE OF MEMBRANES: IS OUTPATIENT MANAGEMENT APPROPRIATE?

D. Hoffman[X], G. Hansen[X], C. Ingardia, E. Philipson, Div Mat/Fet Med, Hartford Hospital, Hartford, Ct.

Preterm premature rupture of the membranes (PPROM) has traditionally been managed by prolonged hospitalization with delivery if infection or labor occur. For patients with PPROM who do not labor or demonstrate clinical signs of infection, outpatient management may be acceptable. The purpose of this study is to report the maternal and neonatal outcomes of patients with PPROM remote from term who, after 1 week of PPROM, remain undelivered and are followed as outpatients. Of 11,007 deliveries from January 1989 through April 1991, 82 patients (0.8%) with singleton pregnancies between 20-30 weeks were admitted with documented PPROM. Of the 21 patients (26%) who remained undelivered after 1 week, 12 (57%) were discharged and delivered at term. None of these patients had chorioamnionitis and all infants remained in the hospital for less than 4 days. One patient developed postpartum endometritis which was successfully treated with IV antibiotics. Nine patients (43%) delivered prematurely (range 26-34 weeks) and all reported increased leaking of amniotic fluid for days or hours prior to delivery. While 5 of these patients had clinical or laboratory evidence of infection, all neonates had five minute Apgar scores >7. Admission to the NICU for all the preterm neonates ranged from 12 to 72 days. In conclusion, the results of our study indicate that the majority of patients with PPROM will deliver within 1 week of admission. However, there appears to be a subset of patients with PPROM, (1 of every 7), characterized by the absence of labor or infection for 1 week, that may be managed as outpatients and deliver at term if adequate amniotic fluid volume is demonstrated by ultrasound and further leaking of amniotic fluid is minimal or absent.

468 FETAL LUNG MATURITY TESTING PROTOCOL: SURFACTANT/ALBUMIN RATIO. L.A. Bayer-Zwirello, B.A. Morris*, C.M. Kanaan, M.L. Gimovsky, J.P. O'Grady. Dept. of Ob/Gyn, Baystate Medical Center, Springfield, MA

An automated amniotic fluid surfactant-albumin ratio test (SAR) was performed for lung maturity on 137 pregnancies delivered within ≤3 days. 20/137 (15.6%) of neonates developed respiratory distress syndrome (RDS); 6/37 (4.9%) had transient tachypnea (TTN); the remaining 111/137 (78.8%) were clinically normal. The SAR had a sensitivity of 96.0%, a specificity of 75%; positive predictive value 46.1%; negative predictive value of 98.7%; interassay coefficient of variability 3.5%. Conclusion: The SAR for lung maturity is automated, rapid (≤ 1 hr), inexpensive, precise, and uses ≤ 1 cc fluid. Our protocol uses the SAR as our initial, rapid screening test for fetal lung maturity. The L/S ratio follows the SAR only if the initial study is immature. This protocol has reduced the number of L/S ratios required in our high risk population while retaining clinical accuracy and reducing cost.

469 NONFRANK BREECH PRESENTATION: EFFECT OF MANAGEMENT ON OUTCOME. D. Gauthier,[X] S. Warsof. University of Illinois at Chicago, Chicago, IL.

Nonfrank(NF) breech presentation is considered by many as an indication for C-section(CS). The purpose of this study was to assess the effect of intrapartum management on neonatal outcome. METHODS. Retrospective analysis of singleton NF breech deliveries ≥ 34 weeks EGA during a 10 year period was performed. Different managment plans included selective vaginal delivery(SVD) in which route of delivery was determined after evaluation of fetal weight, head position, and maternal pelvis, unselected vaginal delivery(UVD), elective CS for NF breech (ECS), and CS for other indication(OCS). RESULTS. Neonatal outcome for 290 NF deliveries is summarized as follows:

MANAGEMENT	SVD			UVD	ECS	OCS
	VD	CS-NTOL	CS-TOL			
NUMBER	86	53	14	24	95	18
5" APGAR <7	5(2)	0	1(0)	5(2)	6(2)	2(0)
BIRTH TRAUMA	1	2	0	1	2	0
MORTALITY	2(0)	0	1(0)	2(0)	2(0)	2(0)

VD=Vaginal delivery, CS-NTOL=CS-no trial of labor, CS-TOL=CS after trial of labor, ( )= corrected for congenital anomalies. CONCLUSIONS: (1) THERE WAS NO DIFFERENCE IN NEONATAL OUTCOME IN SVD VERSUS ECS, (2) CONGENITAL ANOMALIES WERE THE LEADING CAUSE OF MORTALITY.

470 ANTEPARTUM MANAGEMENT OF TRIPLET GESTATIONS. AM Peaceman, SL Dooley, RK Tamura, ML Socol. Department of Obstetrics and Gynecology, Northwestern University Medical School, Chicago, Il.

Recent improvement in perinatal outcome for triplet gestations has been attributed to the use of routine antepartum hospitalization, home uterine contraction monitoring, tocolytic therapy, and cervical cerclage, but the value of these interventions has yet to be established. Furthermore, published series continue to report preterm delivery rates of 82-100%. We evaluated an alternative approach to the management of triplet gestations to determine its efficacy in the early diagnosis of preterm labor (PTL) and reduction of preterm birth. This approach included patient education regarding signs and symptoms of PTL, weekly prenatal visits with cervical examination after 24 weeks' gestation, and increased rest in an outpatient setting. Tocolytic therapy was restricted to gestations < 34 weeks in which progressive cervical change was documented in association with uterine contractions. Fifteen patients with triplet gestations were managed by this protocol over a 3 year period. Ten patients were hospitalized in the antepartum period for the following indications: PTL (4), advancing cervical dilation or effacement without contractions (5), and preeclampsia (1). Five patients received tocolytic therapy with $MgSO_4$, as one patient hospitalized for cervical dilation subsequently developed PTL; the interval from tocolysis to delivery was 37 ± 15 days (range 27-63). No patient was delivered because of failure to detect PTL in sufficient time to initiate successful tocolysis. The mean gestational age at delivery was 34.7 ± 2.6 weeks; 10 of 15 (67%) patients achieved 34 completed weeks' of gestation, and 6 (40%) completed 37 weeks. Indications for preterm delivery included labor at ≥ 34 weeks (4), premature rupture of membranes followed by labor (3), suspected placental abruption (1), and worsening preeclampsia (1). Mean birth weight was 1957 ± 488 grams, and 29 of 45 (64%) neonates did not require admission to the intensive care nursery. One neonatal death occurred secondary to necrotizing enterocolitis. We conclude that this management scheme for triplet gestations allowed for appropriate recognition of preterm labor and was as successful as protocols utilizing more expensive or invasive technologies in reducing the preterm delivery rate.

471 INCIDENCE OF MATURE L/S RATIO IN THE PRESENCE OF AN IMMATURE FOAM STABILITY INDEX (FSI). Asrat T, Towers CV, Lewis DL, Ogburn A[X], Nageotte MP, Women's Memorial Hospital, Long Beach, CA, University of California, Irvine, CA.

A commonly employed scheme of ascertaining fetal pulmonary maturity involves the use of the "maturity cascade" which consists of the "shake" test, followed by the FSI and finally the Lecithin Sphingomyelin (L/S) ratio if the first two tests indicate pulmonary immaturity. We conducted this study in order to determine the distribution of L/S values following an immature FSI, across various gestational ages. An immature FSI is defined as ≤0.46. From 1/86 to 12/89 857 samples of amniotic fluid were evaluated by an FSI. 259 of these samples had an FSI of <0.46 and 136 had an FSI equal to 0.46.

%Mature L/S (No.of Samples)

GA(Wks)	N	FSI≤0.46	N	FSI=0.46
28-29	4	0%(0)	1	0%(0)
29-30	7	0%(0)	2	0%(0)
30-31	12	0%(0)	4	0%(0)
31-32	25	0%(0)	8	12.5%(1)
32-33	45	4.4%(2)	18	5.5%(1)
33-34	36	8.3%(3)	26	30.7%(8)
34-35	59	8.4%(5)	32	28.7%(9)
35-36	42	7.1%(3)	24	46.0%(11)
36-37	29	31.0%(9)	21	62.0%(13)

%Mature L/S (95% CI)

GA(Wks)	FSI≤0.46	FSI=0.46	Total
<32	0/48	1/15	1/63-1.6%(0-4.6)
≥32	22/211	42/121	64/332 19.2%(15.0-23.5)

CONCLUSION: The above data indicate that at gestational ages below 32 weeks, if the FSI is ≤0.46 there appears to be no need to move on to an L/S. Furthermore, between 32 and 35 completed weeks, if the FSI is only <0.46 the rate of a mature L/S is less than 10%, and the routine assay for L/S may not be cost effective.

472 THE FAILURE OF ROUTINE AMNIOINFUSION IN PATIENTS WITH THICK MECONIUM TO ELIMINATE THE OCCURRENCE OF MECONIUM ASPIRATION SYNDROME. M.T. Parsons, A.K. Parsons,[X] and J.L. Angel. University of South Florida College of Medicine, Tampa, Florida.

The use of amnioinfusion in patients with thick meconium stained amniotic fluid (MSAF) to reduce complications of meconium to the fetus was first reported in 1988. The practice has become widespread but no data have been reported of a beneficial effect of routine use in a large patient population. We compared the incidence and complications of MSAF in 1987 (before amnioinfusion was used) to Jan.-Sept. 1990, (when amnioinfusion was routine for patients with thick meconium stained amniotic fluid). Patients' and babies' charts were reviewed for complications during labor, abnormal fetal heart rate tracings, use of amnioinfusion, and infant outcome, especially meconium aspiration syndrome. Results: The incidence of MSAF was 16.1% (1012 of 6275 deliveries) in 1987 compared to 16.9% (937 of 5537 deliveries) in 1990 (NS). Thirty-two infants were admitted to the NICU with meconium aspiration syndrome in 1987 which represented 3.2% of patients with MSAF, compared to 31 infants admitted to the NICU with meconium aspiration syndrome in 1990, 3.4% of patients with MSAF (NS). The mean stay in NICU in 1987 was 9.3 days and in 1990 8.8 days (NS). Of the 31 patients whose infants had meconium aspiration syndrome in 1990, only 6 had amnioinfusion performed and all 6 of these had abnormal fetal heart rate tracings. The reasons that the other 25 patients whose infants had meconium aspiration syndrome did not have amnioinfusion included: no suspicion of thick meconium (20), advanced labor (2), fetal distress necessitating delivery (2), and other (1). We conclude that routine amnioinfusion for suspected thick meconium does not eliminate meconium aspiration syndrome. Improvements may be made by 1) accurate and continued observation for the presence of thick meconium stained fluid, and 2) not falsely assuming amnioinfusion will always protect the fetus with thick meconium and an abnormal heart rate tracing.

473 CHANGES IN SUBSTANCE ABUSE OVER SUCCESSIVE PREGNANCIES: A LONGITUDINAL ANALYSIS. R.J. Sokol, S.S. Martier,[X] J.W. Ager, Dept. Ob/Gyn, Wayne State Univ./Hutzel Hosp., Detroit, MI

Though substance abuse is well recognized as a major pregnancy risk, there have been no longitudinal studies of maternal substance abuse in successive pregnancies. In this longitudinal study, prenatal risk factors were observed in two consecutive pregnancies for 388 black patients in an inner city prenatal clinic. Of particular interest were changes over time in substance abuse. For this sample, the age at the first pregnancy was 21.9 and mean inter-pregnancy interval was 23 months. Mean gestational age at first visit was about 22 weeks for both pregnancies. Differences between means for successive pregnancies were assessed using the matched t test for continuous measures and the McNemar significance of change test for the dichotomous outcomes in both cases using alpha = .01. Of the substance abuse factors, cigarette smoking showed a significant increase, ($p<.001$) whereas use of cocaine, cannabis and narcotics ($n=305$) showed no difference for the two pregnancies. For alcohol use, results depended on the period assessed. Periconceptional drinking, as measured by ounces of absolute alcohol per day (aad), amount per drinking day (aadd) and proportion drinking days (ppd), did not differ for the two pregnancies. However, for drinking at time of initial visit, the same three measures—aad, aadd and pdd—showed large and significant increases for the second pregnancy. A measure of alcohol-related life problems, the Michigan Alcohol Screening Test (MAST) score of ≥ 5 showed no differences between pregnancies (about 10% in each). Results reinforce the need for post-partum interventions designed to reduce maternal drinking before and during subsequent pregnancies.

474 PLACENTAL "LAKES" AND ANTICARDIOLIPIN ANTIBODIES (ACA). C. Hatjis, J. Graham[X], S. Wheeler[X], J. Gadd[X], K. Reed[X], Div. Maternal/Fetal Med., Dept. OB/GYN, Riverside Methodist Hospitals, Columbus, Ohio

ACA and lupus anticoagulant (LA) have been associated with significant obstetrical complications. Question: Does the sonographic detection of placental "lakes" correlate with the presence of ACA or LA in maternal blood? Methods: Placental lakes were seen in 23 pregnant women examined by ultrasound in the 2nd trimester. Transplacental lakes (TPL) spanned the entire width or a significant portion of the placenta and measured at least 2 cm in diameter. Subchorionic lakes (SCL) were located near the subchorionic plate. ACA and LA were measured by established methods. Results: 13 of 14 patients with TPL were positive for ACA (5/13 medium positive, 8/13 low positive); 1/13 was also positive for LA. In patients with SCL only 2/9 had low-positive ACA ($p < 0.001$). 10/14 patients with TPL, but only 3/9 with SCL had pregnancy related complications ($p < 0.06$). Conclusions: The presence of TPL strongly correlates with a positive maternal ACA panel and may serve as a marker for pregnancies at risk for complications. Intensive surveillance of patients with TPL and positive ACA is recommended.

475 PREVIOUS VERTICAL CESAREAN SECTION; UTERINE RUPTURE RATE

Jacquin P. Matthews[X], Jeffrey J. Knickerbocker[X], Mark A. Morgan, Dept. Ob/Gyn, Univ. Oklahoma Health Sciences Center, Oklahoma City, OK and Dept. Ob/Gyn, Univ. of California, Irvine Medical Center, Orange, CA

Although the uterine rupture in patients undergoing a labor trial with a previous low transverse cesarean section is reported to be acceptably low, uterine rupture in patients with a previous vertical cesarean section is believed to be unacceptably high. However, studies of patients with previous vertical cesarean section labor trials have not represented all of these patients having a labor trial. The purpose of this study was to determine the frequency of clinically significant uterine ruptures in all baboons with previous vertical cesarean section. The reproductive histories of baboons from our colony between 1966 and 1991 were reviewed and those animals (n=29) who had undergone at least one labor trial after vertical cesarean section (VBAC) comprised the study group. A total of 188 deliveries occurred, 75 vertical cesarean sections, 104 VBAC (gestational age at least >100 days at delivery, term 175 days) and 9 uterine ruptures. The overall frequency of uterine rupture in these animals all having had a labor trial was 8.0% (9/113). The uterine rupture frequency increased with the number of previous vertical cesarean sections: one, 5.2% (3/58); two, 11.4% (4/35); three or more, 10.0% (2/20). The maternal mortality associated with uterine rupture was 38% (3/8) and the perinatal mortality 100%. Interestingly, the baboons in whom uterine rupture occurred tended to be older. Based on these experimental animal data, the frequency of uterine ruptures in nonhuman primates with a previous vertical scar having all had a labor trial is unacceptably high. Therefore, we would not recommend a labor trial for a patient with a previous vertical cesarean section.

476 **ELECTIVE CESAREAN HYSTERECTOMY IN RESIDENCY TRAINING.** M. Yancey,[X] F. Harlass, W. Benson, K. Brady, Madigan Army Medical Center, Tacoma, WA and William Beaumont Army Medical Center, El Paso, TX.

The utilization of elective cesarean hysterectomy (ECH) in select patients could eliminate the need for two seperate procedures and provide valuable resident experience. A survey of graduates from military residency programs demonstrated that 30% had no experience with cesarean hysterectomy during residency and only 45% had experience with peripartum hysterectomy as a primary surgeon. We studied the morbidity associated with ECH through a retrospective review of 45 patients that had undergone a scheduled procedure in a military training hospital between 1979 and 1989. We compared these findings to the combined morbidity of a scheduled cesarean delivery and subsequent abdominal hysterectomy in a control population of similar patients. Study patients were assigned two control patients matched for age, parity, number of previous cesarean deliveries, and indications for procedures. The number of women receiving transfusions following ECH was greater than the control population (39.5% vs 20.9% $P < 0.05$). However, the number of patients with major morbidity was significantly increased in the control population (44%) compared to patients with ECH (16%, $P < 0.01$). We conclude that patients undergoing ECH are less likely to have major perioperative morbidity, excluding the need for transfusion, than similar patients undergoing separate cesarean delivery and hysterectomy. Current residency training in elective or emergent peripartal hysterectomy is limited and could be increased through greater utilization of ECH.

477 **UMBILICAL ACID-BASE STATUS IN NEONATES AT HIGH ALTITUDE** M. Yancey[X], J. Moore[X], K. Brady, D. Milligan, W. Strampel[X], Evans Army Hospital, Ft. Carson, CO.

The analysis of umbilical cord blood acid-base status has proven useful in the immediate care and rescusitation of the newborn and provides an objective measure of the intrapartum fetal environment. The effect of an increase in altitude upon umbilical cord acid-base status has not been previously described. We studied the acid-base status of neonates delivered at a relatively high altitude of 6000 ft. (N=150) and infants delivered at 100 ft. (N=150). All patients had singleton pregnancies with an uncomplicated labor and vaginal delivery. Continuous electronic fetal monitoring was utilized and reviewed for evidence of impaired fetal perfusion. Exclusion criteria included fetal distress, hypertensive disease, diabetes, suspected intrauterine growth retardation, meconium stained amniotic fluid, or chorioamnionitis. Cord arterial and venous blood samples were collected and analyzed within 30 minutes of delivery. Statistical analysis was performed with the unpaired t test. Results are presented as mean values and * denotes $P<0.05$.

	pH	pCO_2	HCO_3	pO_2	O_2%
Venous					
6000 ft	7.392	33.4	20.2	29.2	57.5
100 ft	7.362*	37.8*	20.8*	28.0	54.8
Arterial					
6000 ft	7.322	44.7	22.9	18.1	27.0
100 ft	7.296*	46.3*	21.8*	17.3	26.3

We conclude that maternal adaptive measures to high altitude result in significant alterations in the umbilical blood acid-base status.

478 **THE FORCES CREATED BY THE OBSTETRIC BONNET ON THE FETAL HEAD: LABORATORY EVALUATION OF AN EXPERIMENTAL DELIVERY DEVICE.** B. Elliott,[X] L. Ridgway, E. Newton, M. Berkus, W. Peairs,[X] Univ. Texas Health Science Cen. at San Antonio, Texas.

The decline in the use of instrumental delivery is due, in part, to the concern regarding the forces vacuum extraction or forceps apply to the fetal head (30-60 cmHg vacuum and 5-20 lbs/in^2 compression, respectively). The obstetric bonnet is a disposable, dome-shaped, latex device. It resembles a large condom, and is rolled, placed on the fetal occiput and manually unrolled over the fetal head within the mother's vagina. Its elastic properties create an airtight seal on the fetal head, and a handle at its apex is used to manually apply traction. This study was undertaken to determine the forces this device creates on a laboratory model and to test its adherence during traction. A domed polypropylene cylinder with a 33cm circumference simulated the fetal head. An open port at the dome's apex measured the vacuum created and a closed bladder placed circumferencially around the cylinder measured lateral compression. Standard bourdon gauges were used to measure vacuum in cmHg and compression in lbs/in^2. A force gauge was attached to the handle of the device to measure the traction being experimentally applied. The devices were tested to a maximum traction force of 60 lbs in increments of 10 lbs. A significant relationship existed by simple regression between the traction applied and the vacuum and compression created as indicated below:

Traction Applied (lbs)	Vacuum (cmHg)*	Compression (lbs/in^2)**
10	10 ± 3	0.5 ± .3
20	18 ± 5	0.6 ± .3
30	23 ± 5	0.7 ± .3
40	27 ± 5	0.9 ± .4
50	31 ± 6	1.1 ± .5
60	33 ± 7	1.2 ± .3

n = 18 Mean ± SD *r^2 = .85, $p < .00001$ **r^2 = .42, $p < .0004$

The data from this model indicate that this device: 1) provides adequate adherence to allow traction forces commonly used in instrumental delivery; 2) creates vacuum and compression forces that compare favorably to those created by other instruments; and 3) creates graded vacuum and compression determined by the traction applied. This is an encouraging preliminary evaluation of this new device.

479 PERIMORTEM CESAREAN SECTION IN MICHIGAN: "ARE WE GETTING BETTER?" Chang Y. Lee, M.D., Elaine M. Mills,[X] Maternal Mortality Committee, Michigan State Medical Society, Center for Health Promotion, Michigan Department of Public Health, Lansing, Michigan.

Eight (25%) infants survived from 32 perimortem Cesarean sections performed for 15 years, from 1972 to 1986 in the State of Michigan. The overall survival rate was not significantly improved compared to that of postmortem sections performed from 1950 to 1957 (25% vs. 15.3% $P < 0.05$). In 19 cases, the time of delivery and maternal death was recorded. No infants survived from six cases when the procedure was performed after maternal death. Six (46%) infants survived from 13 cases when the procedure was performed before death of the mother. This is clearly less than the 70% survival rate when the procedure was performed within five minutes after maternal death in reported series. It is apparent from the study that the procedure should be performed before the death of the mother to ensure the best chance of the infant's survival.

480 **ADOLESCENT PREGNANCY OUTCOME.** J.L. Davis, A. Pisani,[X] B.R. Morgan,[X] F. Wall,[X] J Greenspoon, Cedars-Sinai Med Ctr. LA, CA.

To determine whether maternal age influenced obstetrical outcome, we compared a group of young adolescents (age ≤ 17 yrs) to a group of older women (ages 21-24 yrs). All were patients of a health maintenance organization (HMO) who delivered between 1985 and 1990. The mean (SD) age was 16.1 (0.97) for adolescent and 22.6 (1.1) for the older group. Black race was more common among adolescent (63.1%) than the elder group (48.1%). Logistic regression was used to examine the relationship of obstetrical outcome variables to race and subsequently to maternal age. After accounting for race, we found that adolescent pregnancies differed statistically but not clinically from those of the older women with respect to birthweight (Table). The adolescents were 2.5 times more likely to develop preeclampsia than the older women ($p < 0.001$). Conversely, older women were twice as likely to develop gestational diabetes ($p < 0.05$) as the adolescents. During the time interval studied, 59 (7.5%) of the adolescents and 282 (8.8%) of the older group delivered a second pregnancy. The time interval between pregnancies did not differ (Table). Young maternal age had a limited and predictable effect on obstetrical outcome in women receiving care through a HMO.

Table

	Adolescents N=786	Control N=3198	P*
Gest age (wks)	39.2±2.53	39.4±2.34	NS
Birthwt. (gms)	3175±557	3290±564	<0.001
5 min Apgar	9±1	9±1	NS
Cesarean delivery	17%	18.8%	NS
Preterm delivery	13%	9.3%	0.0079
Posterm delivery	21%	21%	NS
Interval between preg (days)	632±660	568±229	0.0620

*NS= not significant

Values are means ± standard deviations or percentages.

481 **SUBCUTANEOUS TISSUE: TO CLOSE OR NOT TO CLOSE AT CESAREAN SECTION** V.R. Bohman MD[X], L. Gilstrap MD, K. Leveno MD, S. Ramin MD[X], R. Santos-Ramos MD[X], K. Goldaber MD[X], B. Little PHD[X], J. Dax RN[X]. University of Texas Southwestern Medical Center, Dallas, Texas.

There is no unanimity of opinion regarding suture closure of Scarpa's and Camper's fascia at time of c-section. Over a 4 month period, all cesarean section patients had their subcutaneous tissues sutured closed with interrupted 000 plain cat gut suture or left open on alternating months. Suspected risk factors of subsequent wound separation were rigorously sought in each patient. This study included 871 patients, 457 with subcutaneous tissues closed and 414 left open. Labor was present in 57.5%, 13.7% had ruptured membranes for >24 hours, 7.3% had amnionitis, and 4.5% had diabetes. These factors failed to differ in these two groups. At c-section, 85% had a vertical skin incision, 11.6% of the cases took >1 hour to complete and 4.9% had a decrease in hematocrit by 10 percentage points. The overall wound separation rate was 7.2% (62 of 871), 6.6% (30 of 457) of the suture closed group and 7.7% (32 of 414) of the non-closed group ($P = 0.504$; $OR = 0.838$). Culture proven wound infections were present in 23 (2.6%) women and 2 (0.2%) had a fascial dehiscence. We were unable to identify any risk factors for wound separation including whether the subcutaneous tissues were sutured together or not in this study population. Our data suggests that the surgeon's personal preference is appropriate to determine whether the subcutaneous tissues should be closed with suture or not.

482 **STANDARDS FOR FETAL GROWTH IN ADVANCED MATERNAL AGE PATIENTS.** J. Williams III, B.T. Wang[X], R. Willis-Hassan[X], The Prenatal Diagnostic Ctr. of S. CA, Beverly Hills, CA

Published standards for fetal growth are derived from general patient populations (GP) which consist of patients of all maternal ages but are skewed toward younger patients. We hypothesize that infants delivered to advanced maternal age (AMA) patients have larger birthweights (BW) than infants delivered to GP patients and that published BW standards may not be appropriate for use with AMA patients. To test this hypothesis, BW and delivery data were obtained from 2473 liveborn, singleton, cytogenetically normal infants delivered to AMA (age ≥ 35 at EDC) patients. Gestational age (GA) at delivery was based on completed weeks (WKS) from LMP. All GA's were confirmed by a 1st or 2nd trimester sonogram. The racial distribution was 86% white and 14% non-white. The 10th, 50th and 90th percentiles were calculated for each GA and compared with published standards for singleton births near sea level (Brenner, Williams). The BW in our series were comparable at GA < 35 WKS and were consistently greater at all percentile ranks than published standards at GA ≥ 35 WKS. This suggests that BW curves derived from AMA patients should be used to evaluate fetal growth in AMA patients.

483 **THE CERVICAL CAP DOES NOT PREVENT PULMONARY HYPOPLASIA IN SECOND TRIMESTER RUPTURE OF MEMBRANES.** B.V. Parilla, R.K. Tamura, M.L. Socol, Division of Maternal-Fetal Medicine, Northwestern University Medical School, Chicago, Il

Premature rupture of the membranes (PROM) is one of the most common causes of preterm delivery and neonatal morbidity. Particularly in the second trimester, PROM is associated with a high incidence of pulmonary hypoplasia, compression deformities, and neonatal death. Recent evidence suggests that residual amniotic fluid volume may be an important factor in affecting outcome. To test the hypothesis that reaccumulation of amniotic fluid would improve perinatal outcome, we have applied a cervical cap as part of an ongoing study in 2 pregnancies complicated by PROM <23 weeks with oligohydramnios to recreate a seal and thereby reaccumulate amniotic fluid. The first cap was placed at 21 4/7 weeks' gestation, 72 hours after ROM (Amniotic fluid index (AFI):0). Amniotic fluid reaccumulated within 48 hours. The patient remained stable for 4 weeks with a mean AFI of 9.6 cm (range 5-10). At 25 6/7 weeks' gestation, a low lying placenta with bleeding necessitated removal of the cap and this was followed by the immediate loss of all fluid. Labor ensued within 2 days and a neonate with pulmonary hypoplasia (birth weight 1015 gm, lung weight 14.8 gm) was delivered and expired. The second cap was placed at 20 1/7 weeks' gestation, 84 hours after ROM (AFI 0). Again, amniotic fluid reaccumulated over 48 hours. The patient remained stable for 7 weeks with a mean AFI of 5.0 cm (range 3-6). At 27 4/7 weeks spontaneous labor ensued and again the neonate had pulmonary hypoplasia and expired (weight 1013 gm, autopsy denied). These observations disappointingly suggest that the reaccumulation of amniotic fluid after PROM may not prevent pulmonary hypoplasia.

484 EFFECT OF ANGULAR TRACTION ON THE PERFORMANCE OF MODERN VACUUM EXTRACTORS, Kevin Muise, M.D.· Method A. Duchon, M.D., Richard H. Brown, Ph.D.[X], Departments of Repro. Biol., University MacDonald Womens Hospital and Surgical Research St. Luke's Hospital, Cleveland, Ohio.

A baffling array of vacuum extractors exists for operative vaginal delivery. The purpose of the present study was to describe the effect of off-axis traction on the performance of modern vacuum extractors. Eight vacuum extractors were examined in the laboratory using a force indicator and fetal cephalic model. Devices evaluated included the 6 cm. Malmstrom, Mity-Vac, M-Type, O'Neil, 5 cm. Posterior, Silc, Tender-Touch, and Silastic. Maximal tractive (pop-off) force was measured for each device in increments of ten degrees from the vertical. Results revealed the best fitting model to be Force = Constant+Angle+Vacuum. Each device was described by a unique regression plane, where the regression coefficient for angle was negative in all devices except the Posterior cup. At increasing angles of traction, maximal force decreased in the following order: Silastic, Silc, Tender-Tough· M-Type, Mity-Vac. O'Neil, Malmstrom, and Posterior. These results suggest that an understanding of performance may allow tailoring of cup selection to the clinical situation.

485 **THE SIGNIFICANCE OF FETAL HEART RATE (FHR) BASELINE IN THE POSTDATES PATIENT.** D.N. Platek[X], M.I.G Morel[X], A.D. Marks[X], H.W. Hsu[X], M.Y. Divon. Dept. Ob/Gyn, Albert Einstein College of Medicine, Bronx, N.Y.

It has been noted that the resting FHR baseline in some postdates patients is lower than that previously defined as normal (120-160 bpm). The purpose of this study was duo-fold: (1) To determine the normal range of FHR baseline in the postdates patient, (2) To evaluate the association between FHR baseline and outcome in the postdates patient. The study population consisted of 196 consecutive patients evaluated by non-stress testing who met the following entry criteria: no medical or obstetrical complications other than being postdates, certain EDC based on LMP and confirmed by early ultrasound and a minimum of two postdates NSTs. Intrapartum FHR tracings and outcome data was also reviewed for these patients. Adverse outcome was defined as the presence of thick meconium, 5 minute apgar score <7, fetal acidosis (scalp or cord artery pH <7.2), or NICU admission. The mean gestational age at the first postdates visit was 41.2 ± .4 weeks (mean ± S.D.), with a mean FHR baseline of 133.9 ± 9.3 bpm and a range of 110-160 bpm. The gestational age at last visit was 42.1 ± .5 weeks, with a mean FHR baseline of 133.2 ± 9.4 bpm and a range of 110-158 bpm. 10% of patients had a resting FHR baseline of 120 bpm or lower on non-stress testing. Longitudinal trends of FHR baseline were evaluated by Wilcoxon and standard regression analyses and revealed no significant decrease in FHR baseline as a function of advancing gestational age. In addition, there was no relation between either antepartum or intrapartum FHR baseline <120 or >150, and adverse fetal outcome in this patient population. In conclusion, the range of antepartum FHR baseline in our postdates patient was found to be 110-160 bpm with a mean of 133 bpm and a FHR baseline within this range is associated with favorable outcome.

486 PROPHYLACTIC CERCLAGE IN TRIPLET PREGNANCY.

J.M. Hulson, C. Creatura,[X] T.G. Edersheim. New York Hospital - Cornell University Medical College, New York, New York.

Prophylactic cerclage was performed in 12 triplet pregnancies. Pregnancy outcomes were compared to 15 triplet pregnancies managed without cerclage placement. All gestational dates were confirmed by knowledge of date of conception by assisted reproduction technology or by first trimester ultrasound measurement. All cerclages were performed at 11 to 15 weeks and no complications occurred. Home uterine activity monitoring, tocolysis, bedrest, and hospital admission were utilized as needed in both groups. Results:

	Cerclage		No Cerclage
Mean Gest Age (wks)	34.8		33.5
Range	32.1 - 36.3		27.7 - 38.2
Mean Birthwt (gms)	2081		1899
Range	1525 - 2770		910 - 3020
Mean # NICU Days	8.4	p<.02	18.8
Range	0 - 23		0 - 85

Prophylactic cerclage placement in triplet pregnancy was associated with a significant reduction is length of stay in the neonatal ICU and a prolongation of gestation by 10 days. No incidences of infants less than 1500 grams or less than 32 weeks gestation occurred in the cerclage group. Cerclage placement may allow more consistent outcome in triplet gestations.

487 **TRIAL OF LABOR AFTER A ONE OR TWO LAYER CLOSURE OF A LOW TRANSVERSE UTERINE INCISION**

J. Martin Tucker, John C. Hauth, Pam Hodgkins[X], John Owen, Mary DuBard[X], Carey L. Winkler
The University of Alabama Hospitals, Birmingham

There is little documentation of the safety of a subsequent trial of labor following a one or two layer uterine incision closure. We reviewed the charts of 258 women who had a low transverse cesarean section with no vertical extensions and who had a subsequent labor and either a vaginal or cesarean delivery in our unit. In 123 women the uterine incision was closed in one continuous layer of a locking #1 chromic gut suture and in 135 it was closed in two continuous layers of #1 chromic gut with the first layer locked. Maternal morbidity, specifically endometritis, post partum blood loss, intra-operative complications, post-operative atelectasis and ileus were similar in both groups during the subsequent pregnancy and delivery. Three women in each group had an asymptomatic scar separation confirmed at repeat c-section. No symptomatic uterine rupture or adverse perinatal outcome occurred in these 258 women. We conclude that closure of a lower uterine transverse incision in one continuous layer should not preclude a trial of labor after one prior cesarean section.

488 **DOES NONCLOSURE OF BLADDER FLAP AT CESAREAN SECTION DECREASE FLUID COLLECTION AND INFECTIOUS MORBIDITY?** J.D. Jacobson[X], G.N. Gregerson[X], G.J. Valenzuela. Department Obstet Gynecol, San Bernardino County Medical Center, San Bernardino, CA.

The re-approximation of visceral peritoneum over the lower uterine segment at cesarean section has been shown to be associated with significant bladder flap fluid collections in up to 30% of patients studied, and has also been shown to be a site of pelvic abscess. We hypothesized that nonclosure of peritoneum would decrease fluid collection and decrease infectious morbidity. To study this question, we randomized a group of 61 patients to have either the bladder flap closed, or left open. In all patients parietal peritoneum was not sutured and prophylactic antibiotics were used. An ultrasound was done on the third post-op day to assess bladder flap fluid collection. A data base was prospectively collected on all study patients. 30 patients were randomized to the "closed" group, and 31 patients to the "open" group. Outcomes, including fluid collection, paraendometritis, and post-operative fever were similar between the two groups. Nonclosure of the bladder flap at cesarean section is not associated with decreased fluid collection or infectious morbidity.

489 ANTEPARTUM HOME CARE FOR HIGH-RISK PATIENTS: AN ALTERNATIVE TO HOSPITALIZATION R. Kempfer-Kline,[X] T.Lubart Spector,[X] R.J. Wapner, G.H. Davis, Dept. of Ob/Gyn, Jefferson Medical College of Thomas Jefferson Univ. Hosp., Philadelphia, PA

The management of high-risk pregnancies frequently involves bedrest and prolonged costly hospitalization which separates the woman from her environment. We evaluated the hypothesis that high-risk pregnancy management could be safely provided at home. Materials and Methods: From 1/1/90 - 7/1/91, 80 high-risk pregnant women (102 fetuses: 8 triplets, 6 twins) were managed by a home high-risk management protocol. Patients were admitted following either an antepartum hospitalization (64%) or from the physician's office (36%). In lieu of prolonged hospitalization, patients had, at least, 1 home visit per week by a nurse trained in perinatal care. Visits included FHT's, measurement of fundal height, urine dip stick, cervical examination, NST's, limited ultrasound, childbirth and nutritional counseling, phlebotomy, and subQ or IV fluids. NST's were faxed for evaluation by the perinatal physician. Services were performed by a nurse with the exception of ultrasound, which was provided by a home visit from an MFM specialist. Patients were readmitted to the hospital for acute changes in their condition. Results: Program patients included: preterm labor 58%; incompetent cervix 16%; hypertensive disease 7.5%; antepartum hemorrhage 5%; intrauterine growth retardation 4%; PROM 4%; polyhydramnios 2.5%; other 3%. Thirteen (16%) required, at least, one further antepartum admission and 35 (44%) were admitted to the hospital for a change in their condition or delivery requiring discharge from home care services. Of the 76 completed pregnancies there were 4 losses: 2 from PROM <22 weeks; 2 from twin-twin transfusion. Thirty-seven (49%) delivered at $\geq$ 37 weeks; 28 (37%) delivered 33-36 weeks; 8 (10%) between 28-32 weeks, and 3 (4%) $\leq$ 27 weeks. These statistics compare favorably with patients managed in hospital. Conclusion: High-risk pregnant women can be safely managed at home in lieu of prolonged antepartum admission.

490 **COMPARISON OF POSTPARTUM PAIN AND HEALING WITH REPAIR OF PERINEAL DISRUPTIONS USING CHROMIC CATGUT OR POLYGLYCOLIC ACID SUTURE.** C.L. Wikoff MD[X], T.J. Kuehl PhD[X], A.T. Cooney RN[X], A.B. Knight MD, Scott & White Memorial Hospital & Clinic, Texas A&M University College of Medicine, Temple, Texas.

Studies, primarily in the English literature, suggest that repair of perineal disruptions is less painful if accomplished with polyglycolic acid (PA) rather than chromic catgut (CG) suture. In this study 431 patients were prospectively randomized to repair with PA or CG. 345 required repair. Postpartum pain was assessed by the ACCS (Analog Chromatic Continuous Scale, range 0 to 100 mm) and amount of prn medications requested. Perineal healing was evaluated by the REEDA scale (redness, edema, ecchymosis, discharge and skin approximation; each characteristic score was 0-3 and total scores 0-15). Perineal disruptions were divided into 3 groups: no episiotomy or laceration (I), 1st and 2nd degree (II), and 3rd and 4th degree disruptions (III).

Group	N	ACCS (x±SE)	REEDA (x±SE)	Comps
I	86	9.9 + 1.5	0.80 + 0.14	0
II+CG	125	17.3 + 1.6	1.51 + 0.22	1
II+PA	149	16.5 + 1.4	1.40 + 0.15	1
III+CG	42	29.6 + 3.5	3.34 + 0.45	1
III+PA	29	33.5 + 3.7	2.91 + 0.35	0

Pain and perineal appearance increased significantly with extent of disruption but not with suture type. No differences in pain medications nor length of hospital stay were found between groups or sutures.

491 **A PRACTICAL AND COST EFFICIENT APPROACH TO UMBILICAL ARTERY pH AND BLOOD GAS DETERMINATIONS.** Norman B. Duerbeck,* David G. Chaffin,* John W. Seeds, Arizona Health Sciences Center, Tucson, Arizona

The purpose of this study was to assess a simplified method of umbilical artery pH sampling and to determine the effect of delay of sampling upon umbilical artery pH, pCO_2, and pO_2. Twenty-five umbilical cords were sampled at time of delivery and every fifteen minutes thereafter up to one hour postpartum from umbilical cord segments left at room temperature. The blood samples were collected in non-heparinized and non-iced plastic syringes. Sixty minutes after delivery, the average change in pH was 0.01 (range 0-0.08). None of the changes in pH, pCO2, or pO2 were statistically significant by paired Students's t test ($p>0.05$). Further analysis of pH data using multivariate analysis of variance (MANOVA) demonstrated no significant change up to one hour after delivery ($p=0.698$). Our results indicate that umbilical artery blood gas determinations can be obtained from umbilical cords left at room temperature for up to one hour after delivery and collected with non-heparinized, non-iced syringes without a significant change in pH.

492 THE USE OF THE NONSTRESS TEST AND THE FETAL BIOPHYSICAL PROFILE IN THE EXPECTANT MANAGEMENT OF PATIENTS WITH PROLONGED PRETERM PREMATURE RUPTURE OF THE MEMBRANES.
G.O. Del Valle, G.M. Joffe, J.F. Smith, G.J. Gilson, L.A. Izquierdo, O. Kushnir[x], M.S. Chatterjee, L. Papile[x], and L.B. Curet, Dept. of OB/GYN, University of New Mexico, Albuquerque, NM

The role of the nonstress test and the fetal biophysical profile in the management of prolonged preterm PROM was evaluated in 68 consecutive patients who had a latency period of more than 48 hours. Fetal surveillance consisted of daily nonstress tests and biophysical profiles every two to three days. Patients were delivered due to spontaneous labor, clinical chorioamnionitis, fetal distress, or upon reaching 37 weeks gestation. We found a statistically significant association between an abnormal nonstress test and overall infectious complications (chorioamnionitis plus neonatal infections), neonatal infections (sepsis and pneumonia), and fetal distress. A biophysical profile score ≤ 6 was associated with fetal distress, as was the combination of absent fetal breathing movements and nonreactive nonstress test. The association between a low biophysical profile (≤ 6) or the combination of absent fetal breathing movements plus a nonreactive NST and the development of chorioamnionitis or neonatal infectious complications did not reach statistical significance. This study suggests a role for the use of the NST in the management of patients with prolonged preterm PROM, but is less encouraging in terms of defining a role for the biophysical profile as the main tool for fetal surveillance in cases of prolonged preterm PROM.

493 **NORMAL MATERNAL BODY MASS INDEX IS ASSOCIATED WITH GOOD PERINATAL OUTCOME IN POSTDATES PATIENTS.**
C. O'Reilly-Green[x], M. Divon, Albert Einstein College of Medicine, Bronx, NY.

Body mass index (BMI), defined as weight divided by height squared, is used as a measure of obesity. Various recommendations have been made regarding the optimal pregnancy weight gain. However, paucity of data exists regarding the optimal BMI in pregnancy. Purpose: To evaluate the association between pregnancy outcome in postdates patients and maternal BMI. Postdates patients are interesting in this regard because IUGR and macrosomia can be studied after the exclusion of hypertension and diabetes. The BMI was evaluated prospectively in 158 postdates patients (over 41 weeks by accurate dates). An adjusted BMI (aBMI) was calculated by subtracting the maternal mass attributable to pregnancy from the calculated BMI and was correlated with the incidence of C/S, macrosomia, small for gestational age (SGA), oligohydramnios, low Apgar score at 5 minutes, acidosis and NICU admission. A normal aBMI was defined as less than 23.5 Kg/m^2. Results:

	Normal aBMI	High aBMI	p value
Cesarean section	1/27	53/131	.0006
Macrosomia	0/27	26/131	.03
Small for gestational age (wt <2800gm)	2/27	5/131	NS
Oligohydramnios	5/24	32/127	NS
Low Apgar or pH	0/24	16/127	NS
NICU admission	0/24	5/127	NS

In conclusion, normal maternal weight for height (aBMI) in postdates pregnancy is associated with a lower incidence of cesarean section and macrosomia. Normal aBMI is not associated with increased perinatal morbidity despite the fact that this group contains individuals who may actually be underweight.

494 **DOES UNEXPLAINED SECOND-TRIMESTER MATERNAL SERUM HUMAN CHORIONIC GONADOTROPIN ELEVATION PREDICT PERINATAL COMPLICATIONS?**
R. Gonen MD.[x], R. Perez BSc.[x], M. David PhD[x], H. Dar PhD[x], M. Sharf MD.[x] Departments of Obstetrics & Gynecology and Genetics, Bnai Zion Hospital, Faculty of Medicine, Tehnion, Haifa, Israel.

This cohort analytic study was undertaken in order to examine whether women with unexplained human chorionic gonadotropin (HCG) elevation at 16 to 20 weeks gestation are at increased risk for perinatal complications as has been shown for women with unexplained elevation of maternal serum alpha-feto protein (MSAFP). We searched the data base of our laboratory for all cases of unexplained HCG levels > 2.5 MOM (with normal MSAFP) during the year 1990. We then assessed the delivery records of these patients for various maternal and perinatal complications and compared them to a group of randomly selected controls whose HCG as well as MSAFP were normal. Delivery records were available for 262 (91%) patients with elevated HCG and 265 (92%) of the controls. Elevated HCG was found to be associated with a significantly increased risk for IUGR - odds ratio 2.75 (95% CI 1.08 - 7.02) and for hypertension - odds ratio 4.35 (95% CI 1.88 - 10.06). The risk for the various perinatal complications was computed with multiple logistic regression to adjust for the effects of risk factors such as maternal age and obstetrical history. The risks associated with high HCG were unchanged by adjustment for these factors. We conclude that women with unexplained elevated HCG are at increased risk for hypertension and IUGR.

495 AMNIOTIC FLUID INDEX (AFI) AS A PREDICTOR OF LATENCY AFTER PRE-TERM PROM
William MacMillan, M.D.,
Stephanie Mann M.D.[x], Susan Shmoys, M.D. and Daniel Saltzman, M.D.
Department of Obstetrics and Gynecology
Suny-Stony Brook, Stony Brook, New York

Patient records were reviewed to identify patients admitted with a diagnosis of pre-term PROM. 51 patients with initial evaluation within 48 hours of rupture and gestational age 26-34 weeks were identified. AFI was evaluated along with a Biophysical Profile, these were followed serially until delivery. Delivery was accomplished because of spontaneous labor, chorioamnionitis or fetal compromise. Tocolytics were not used. AFI at initial evaluation was stratified into 3 groups: Low (AFI<5), Reduced (5.0-7.9) and Normal (≥8.0). Latency in days from PROM to delivery was evaluated for these groups. A significant ($P<0.01$) difference was noted using the Kruskal-Wallis test. Wilcoxon two-sample (Rank-Sum) test scores showed that latency was significantly longer in the group with Normal AFI vs Low ($P<0.005$) or Reduced ($P<0.05$) AFI groups. This knowledge should allow better patient selection for various intervention strategies, such as corticosteroid administration or antibiotic amnioinfusion. This striking result makes the AFI a powerful tool for predicting latency after PROM.

496 ANTENATAL TESTING USING THE AMNIOTIC FLUID INDEX (AFI) BEYOND 280 DAYS GESTATION

William MacMillan, M.D., Susan Shmoys, M.D. Corinne Dermont, R.N.* and Daniel Saltzman, M.D.
Department of Obstetrics and Gynecology
SUNY-Stony Brook, Stony Brook, New York

500 patients were referred for antenatal testing beyond 280 days EGA. AFI and Biophysical Profiles (BPP) were evaluated twice weekly. Adverse labor events and neonatal outcomes were analyzed according to the AFI using Receiver Operating Characteristic (ROC) analyses. Spontaneous and induced labors were included. Clinicians were not blinded to the AFI or BPP scores. The ROC curve for all EGAs shows only a modest effect for AFIs<12.5, above this true positives and false positives are equal. Below this level the ROC curve is quite shallow indicating minimal effectiveness. From 281-287 days the ROC curve indicates better predictive ability; an AFI cur-off of 9.0 yields sensitivity of 100% and specificity of 57%. At more advanced gestational ages the utility reverts to that seen overall; for example and AFI cutoff of 9.0 yields 44% sensitivity and 65% specificity. This lack of prediction of pathology mirrors the known downward trend of AFI in normal pregnancies beyond 40 weeks and makes it imperative to interpret "oligohydramnios" cautiously at advanced gestational age. AFI norms at greater EGAs are needed, but we have shown that between 281-287 days an AFI<9.0 is a predictor of adverse events or outcomes.

497 OLIGOHYDRAMNIOS FOLLOWING PROM; IS THE AMNIOTIC FLUID INDEX (AFI) PREDICTIVE OF OUTCOME?

William MacMillan, M.D.
Stephanie Mann, M.D.*, Susan Shmoys, M.D. and Daniel Saltzman, M.D.
Department of Obstetrics and Gynecology
SUNY-Stony Brook, Stony Brook, New York

To test whether oligohydramnios following PROM is predictive of adverse labor or neonatal outcomes the records of 193 patients serially tested in the Fetal Diagnostic Unit were reviewed. The last AFI before delivery was subjected to Receiver Operating Characteristic (ROC) analyses. Patients either labored spontaneously or were delivered for indications other than oligohydramnios. Patients had been managed expectantly without tocolytics. AFI was virtually non-predictive at delivery≥36 weeks; the ROC curve was flat with true positives and false positives essentially equal. For patients with EGA at delivery <36 weeks the ROC curve shows modest prediction of adverse outcomes (other than those related simply to prematurity). Two operating points are suggested by the shape of the ROC curve; a strict cut-off of AFI <4.0 gives sensitivity of 64% and specificity of 72%, a liberal cut-off of AFI <6.0 gives sensitivity of 84% but only a specificity of 43%. Thus AFI is not useful in near-term PROM but should influence the decision of whether to intervene or manage pre-term PROM expectantly. Oligohydramnios <36 weeks may reflect placental insufficiency along with mechanical leakage.

498 FETAL HEART RATE MONITORING FOLLOWING ANTENATAL BLEEDING.

A. Samueloff,* B. Rubinoff,* D. Weinstein.* Dept. OB/GYN, Hadassah Medical Center, Jerusalem, Israel.

Antepartum bleeding is associated with fetal stress and increased perinatal morbidity and mortality. It is proposed that as a result of the stress, central nervous system maturation will be accelerated in the fetus. It is assumed that bleeding will result in specific fetal heart rate (FHR) changes reflecting this process (sympathetic). Our hypothesis was that early antenatal bleeding will result in accelerated sympathetic maturation expressed by matured FHR patterns in the preterm infant. 91 patients with severe antenatal bleeding and 91 controls with uncomplicated normal pregnancies participated in the study. All women were not in labor and were hospitalized in the High-Risk Pregnancy Unit at 24-37 gestational weeks. Excluded were patients with premature rupture of membranes, intrauterine growth retardation, diabetes, hypertension and twins. FHR tracings were analyzed during the first week from the initial episode of bleeding and compared to the control group. FHR tracings were analyzed for basal heart rate, long-term variability, number and amplitude of accelerations in the best 20 min segment.

Gest. Age	*24-29 wks*		*30-33 wks*		*34-37 wks*	
Group	*Bleeding*	*Control*	*Bleeding*	*Control*	*Bleeding*	*Control*
Mean GA	27.6	27.2	31.4	31.3	35.9	35.4
Baseline HR	142.5	142.7	139.4	140.7	136.7	137.4
# Accelerations in 20 min	4.4**	1.0**	5.5**	3.9**	7.7**	5.3**
Amplitude of acceleration	20.7**	18.5**	21.7**	18.7**	22.7*	21.6*
% of reactive monitors	89**	37**	95**	71**	100**	87**

*p<0.05 **p<0.001

The study also revealed: 1) both placenta previa and abruptio placenta had significantly larger numbers of accelerations with a higher acceleration amplitude when compared to the control group; 2) no significant differences were found in the FHR characteristics between these two causes of antenatal bleeding. Our data suggest that accelerated sympathetic maturation expressed by reactive FHR tracing is prominent in pregnancies complicated by antenatal bleeding due to abruptio placenta and placenta previa.

499 LONGITUDINAL AMNIOTIC FLUID INDEX IN POSTDATES PREGNANCIES AND ITS ASSOCIATION WITH FETAL OUTCOME.

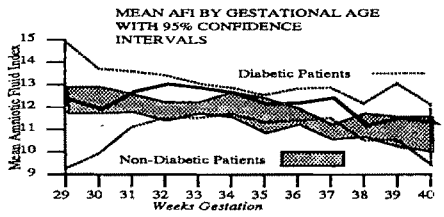
Michael Y. Divon, M.D., Ariel D. Marks*, M.S., Cassandra E. Henderson M.D. Albert Einstein College of Medicine, Bronx, New York.

Due to the known association between oligohydramnios and adverse fetal outcome, sonographic evaluation of amniotic fluid index (AFI) is extensively used for fetal testing in postdates pregnancies. However, the relationship between dynamic changes in AFI and fetal outcome is unknown. Purpose: To study the dynamic changes in AFI measurements and their association with adverse fetal outcome in postdates pregnancies. Serial AFIs were obtained semi-weekly in 139 reliably dated (certain LMP consistent with early sonographic exam) pregnancies > 41 weeks' gestation. Each patient was evaluated on 2 - 6 separate occasions and a total of 331 tests were performed. Indications for delivery included poor fetal testing, oligohydramnios (i.e. AFI≤5.0cm) or a favorable cervix. Adverse fetal outcome was defined by the presence of moderate or thick meconium, FHR decelerations, C/S for fetal distress or NICU admission. The AFI increased in 43 patients (a mean increase of 2.5 cm ± 2.7, ±SD), did not change in 2 patients and decreased in 96 patients (a mean decrease of 3.7 cm ± 2.7). Fourteen of these patients had a final AFI ≤ 5.0cm. Prominent changes in AFI (i.e.± 66%) had no association with adverse fetal outcome. A significant association with the outcome variables was only detected in patients whose final AFI was ≤5.0 cm (p=0.00001). Mean birth weight was significantly lower in those patients who had a final AFI ≤ 5.0cm. The mean gestational age for patients with a normal AFI was 42 weeks + 3 days and for those with oligohydramnios was 42 weeks + 1 day (p=NS). Neither birth weight nor gestational age were predictive of fetal outcome. There was no significant association between oligohydramnios and gestational age. Thus, there was a significant increase in adverse fetal outcome when the final AFI ≤ 5.0cm, irrespective of the rate of change in AFI. Fetal outcome was not predictably associated with either gestational age or birth weight in these patients.

500 **A LONGITUDINAL STUDY EVALUATING THE EFFECT OF GESTATIONAL AGE ON ANTENATAL ASSESSMENT TESTS.** S.J. Carlan, M. Gore*, S. VanMeter*, D Mastrogiannis,U of S FL,Depts Ob/Gyn Tampa,FL, ORMC,Orlando,FL

The purpose of this study was to evaluate the effect of gestational age on antenatal assessment tests using the same group of patients throughout their pregnancy. Fourteen normal pregnant women with normal fetuses were studied every two weeks from 20 wks until delivery. Gestational ages were confirmed by early exam and ultrasound. A biophysical profile (BPP) and non-stress test (NST) were performed in the standard manner at each visit. Umbilical artery S/D ratios (S/D) were obtained using a continuous wave doppler and were recorded during fetal apnea. A startle reflex was considered positive if a quiet fetus was demonstrated to startle on real time ultrasound within one second of a three second application of sound using the standard artificial larynx. A vibrocoustic stimulation (VAS) was considered positive if a similar sound challenge resulted in a >15 beat per minute increase in fetal heart rate for >15 seconds. All maternal and neonatal outcomes were normal. The mean birth weight was 3569 ± 169 grams.

WKS	BPP	SD	NST	VAS	STARTLE
	%>6	Mean ±1SD	(% reac)	(% reac)	(%+)
20	21	4.1 ± .7	0	0	0
22	14	4.0 ± .7	0	14	0
24	36	3.8 ± 1.0	7	14	0
26	86	3.4 ± .7	57	29	0
28	92	3.5 ± .8	62	92	85
30	91	3.2 ± .8	85	85	92
32	100	2.8 ± .8	100	92	92
34	92	2.7 ± .5	85	85	85
36	100	2.6 ± .4	85	92	92
38	78	2.3 ± .4	88	100	100
40	75	2.3 ± .5	67	100	66



We conclude that, like previously reported cross-sectional studies, antenatal surveillance is highly gestational age dependent, and in fetuses less than 26 wks associated with a high false non-reassuring rate.

501 **WHAT IS THE INTERVENTION RATE IN PATIENTS IN ANTEPARTUM TESTING FOR A PRIOR STILLBORN?** Dena Towner MD*, Richard Paul MD University of Southern California Los Angeles, California

In the era prior to antepartum evaluation and intervention for fetal indications, the Collaborative Perinatal Study published in 1972 that the perinatal mortality was 73 per 1000 in the pregnancy subsequent to a stillborn(SB). In contrast, our current institutional SB rate in women undergoing antepartum testing is 2/1000. The women at greatest risk of repeat SB are those with another known risk factor; ie, hypertension, diabetes and current IUGR. However this leaves a significant population with no other known risk factors. The purpose of this study is to determine if a significant number of antepartum tests (APT) led to intervention in patients with a prior SB and no other indication for testing, compared to patients with other indications for APT. From 1/87 through 4/91 there were 355 patients tested that had a prior SB with no additional risk factors. Of these, 299 delivered prior to 41 weeks and 56 had gestations that exceeded 41 weeks. Onset of testing ranged from 28 wks to 42 wks, with a median of 35 wks. The earliest intervention occurred at 35 weeks, with the majority occurring after 37 completed weeks(39/42). The comparison group was 979 consecutive patients being tested for postdates(PD), diabetes(DM), IUGR, HTN or decreased fetal movement(DFM). Patients were tested once or twice weekly with NST & AFI or biophysical profile. Significant variable decelerations (FHR fall >30 bpm & up to 15 sec or any fall lasting >1 min), late decelerations, or AFI < 5cm led to further evaluation on L&D for delivery. Significantly less intervention occurred for abnormal testing in patients with prior SB delivering prior to 41 weeks 24/299 (8%) than PD 118/497 (24%) $p < 0.00001$ or DM 46/232 (20%) $p < 0.0001$. Intervention rate was not different than DFM 6/121 (5%) $p < 0.37$, HNT 4/19 (21%) $p < 0.24$, or IUGR 15/110 (13.6%) $p < 0.13$. The intervention rate in patients with prior SB & PD 18/56 (32%) was not different than those with only PD 118/497 (24%) $p < 0.2$. This data shows that patients with a prior SB as the only indication for APT have significantly less intervention than patients with DM or postdates, and an intervention rate similar to patients tested for IUGR, HTN and decreased fetal movement. Patients with a prior SB whose gestation exceeds 41 weeks have a similar intervention rate as those patients whose only risk factor is postdates.

502 **MEAN AMNIOTIC FLUID INDEX BY GESTATIONAL AGE IN DIABETIC AND NON-DIABETIC PREGNANCY.** Montgomery DM*, Perlow JH*, Morgan MA, Nageotte MP, Garite TJ. Long Beach Memorial Womens Hospital. Long Beach, California University of California, Irvine Med. Center, Orange, California

The amniotic fluid index (AFI) has become an integral part of antenatal fetal assessment. However, presently there are no published data regarding the mean AFI at varying gestational ages in the pregnant diabetic. The objective of the study was to construct an AFI nomogram for the diabetic and non-diabetic populations at our institution. From 1/1/88-12/31/90, 249 diabetics (classes A-R) had a total of 1,506 AFI measurements at varying gestational ages. These values were compared with a control group consisting of 1,518 patients who had a total of 6,494 AFI measurements at corresponding gestational ages.

Statistically significant increases in mean AFI were demonstrated at 32, 33, 36 and 37 weeks gestation between the diabetic and non-diabetic patients ($p < .05$), the maximum difference observed was 1.2 cm. These data provide the basis for future studies to validate the use of the AFI in the diabetic pregnancy.

503 HOW FREQUENTLY SHOULD AFI'S BE REPEATED D. Lagrew, R. Pircon, M. Nageotte, R.K. Freeman, W. Dorchester*, Dept Ob/Gyn, Long Beach Memorial Medical Center, Long Beach, CA, Univ. of California, Irvine, Orange, CA.

The amniotic fluid index (AFI) has become a widely utilized technique for assessing fetal well-being. Intervals for measurement and cutoffs for intervention have been established by clinical experience. We analyzed AFI's on patients undergoing serial surveillance in order to evaluate once versus twice weekly measurements with respect to the chance of developing oligohydramnios (AFI < 5 cm) at each interval according to the initial AFI measurement. There were 11,759 AFI's of which 7,393 had a subsequent measurement within 4 days and 8,094 in 7 days. Initial AFI's were compared with the subsequent lowest value at 4 and 7 day intervals. If the initial AFI was < 5.0 cm, 59.4% had persistence of this low level 4 days later. If the initial AFI was 5 to 8 cm. only 5.4% had subsequent measurements of < 5.0 cm 4 days later. AFI's < 5.0 cm 4 days after an initial AFI of 8 to 15 cm occurred only 0.6% of the time and only 0.4% if the initial measurement was 15 to 25 cm. A similar trend was noted at 7 day intervals. These results suggest. the following: 1) an increased chance of developing oligohydramnios is present if an initial AFI is 8 cm or less. 2) Values above 8 cm are associated with a very low risk of oligohydramnios occurring in < 7 days and need not be repeated at < 7 day intervals.

504 **ANTEPARTUM SURVEILLANCE SHOULD BEGIN PRIOR TO 42 WEEKS (294 DAYS FROM THE LAST MENSTRUAL PERIOD) IN PROLONGED PREGNANCY.** M. Druzin, W. Wagner[X], S. Inglis[X]. NY Hospital-Cornell Med Center, NY,NY

The post term pregnancy (PTP) is defined as ≥ 42 weeks from the last menstrual period (294 days). There are numerous reports of fetal compromise after 40 weeks (280 days) and prior to 294 days in prolonged pregnancy (PP). Antepartum fetal monitoring was begun at 41 weeks (287 days) on 1080 patients. Gestational age was confirmed by sonography. Nonstress test (NST) was used as the primary test, and contraction stress test and biophysical profile as back-up for abnormal testing. Pregnancy outcome was evaluated on deliveries within seven days of the last NST.

	PP 41-41.6 wk n = 868	PTP ≥ 42 wk n = 212
C/S Abnl. Fetal Heart Rate	255/868 (30%)	23/80 (29%)
Meconium	119/299 (40%)	58/212 (27%)
Small for Gestational Age Fetus	19/868 (2%)	4/212 (2%)
APGAR 5 ' < 7	1/868 (0.1%)	1/212 (0.5%)
Abnormal Fetus	0/868	0/212
Perinatal Mortality	3/868 (0.3 %)	0/212
	All P NS	

Results: There were 868 patients with PP, 212 patients with PTP. There were no differences in labor and delivery course or neonatal outcome between the two groups. **Summary**: 1) Intrapartum fetal compromise (abnormal fetal heart rate requiring emergency delivery and/or meconium passage) was no different in the two groups. 2) Antepartum fetal heart rate monitoring should begin prior to 42 weeks.

505 **OLIGOHYDRAMNIOS AS AN INDICATION FOR RECOMMENDING DELIVERY IN POSTDATES PREGNANCIES.** C. O'Reilly-Green[X], M. Divon, Albert Einstein College of Medicine, Bronx, NY.

Oligohydramnios is a marker of adverse fetal outcome in postdates patients. Purpose: To evaluate the consequences of recommending delivery of postdates patients with oligohydramnios (i.e., amniotic fluid index (AFI) less than 5cm). AFI was prospectively obtained in 635 patients over 41 weeks' gestation. Indications for recommending delivery included a favorable cervix, poor fetal testing and oligohydramnios. 56 patients (9%) had a sonographic diagnosis of oligohydramnios. The control group was composed of 102 patients matched for gestational age without oligohydramnios.

	Low AFI	Normal AFI	p value
Intervention	48/56	46/102	.000002
Oligohydramnios (on R.O.M.)	27/51	10/100	.000001
Thick meconium	8/51	8/100	NS
Cesarean section	23/56	31/102	NS
For dysfunctional labor	7/56	20/102	NS
For uncertain fetal status	16/56	11/102	.05
Low Apgar, low pH or NICU admission	13/51	15/100	NS

In conclusion, these preliminary results suggest that recommending delivery of postdates patients with oligohydramnios does not result in a significant increase in the incidence of cesarean section yet provides fetal outcome comparable with that measured in the controls.

506 AMNIOINFUSION DOES NOT ALTER THE LENGTH OF LABOR.
C. J. Macri, D. B. Schrimmer, J. S. Greenspoon, T.H. Strong, R.H. Paul, University of Southern California, Los Angeles, CA

Amnioinfusion is effective in improving the pregnancy outcome in pregnancies complicated by repetitive variable or prolonged decelerations of the FHR, preterm premature rupture of the membranes, meconium, and oligohydramnios. The effect of amnioinfusion on the length of labor has not been described. We prospectively, randomly compared the length of labor in 437 patients. Patients who received amnioinfusion were compared to those without amnioinfusion. Patients were included in the study for one of two indications: 1) prophylactic amnioinfusion for oligohydramnios (AFI< 5 cm) (178 treatment, 89 control); 2) thick meconium and oligohydramnios (85 treatment, 85 control). There was no significant difference between the lengths of labor in the subgroups determined by method of delivery. Patients receiving amnioinfusion were significantly more likely to deliver vaginally (p<0.001).

Variable	Treatment AI	Control No AI	P
No. Patients	263	174	
No. (%) with:			
vaginal delivery	189 (71.8%)	96 (55.2%)	.001
forcep delivery	17 (6.5%)	18 (10.3%)	NS
vacuum delivery	17 (6.5%)	11 (6.3%)	NS
Cesarean delivery	40 (15.2%)	49 (28%)	.05
Length of Labor(hrs)mean(SD)			
vaginal delivery	9.3 (6.3)	10.6 (6.9)	NS
forcep delivery	8.4 (3.2)	9.1 (3.4)	NS
vacuum delivery	11.2 (5.8)	9.3 (3.5)	NS
Cesarean delivery	11.1 (6.3)	13.0 (7.5)	NS

507 A COMPARISON OF COMPLIANCE AND ACCEPTABILITY OF TWO FETAL MOVEMENT COUNTING METHODS. MC Freda[X], MS Mikhail[X], E Pollizotto[X], E Mazloom[X], IR Merkatz. Dept. OB/GYN, Albert Einstein College of Medicine, Bronx, NY.

Fetal activity is a sign of fetal well-being.Fetal movement counting is a simple, non-invasive, cost effective method of fetal surveillance used to estimate fetal well-being which has recently been shown to enhance maternal-fetal attachment.Two methods of fetal movement counting are most often mentioned in the literature, with each claiming unique advantages over the other.Studies have not been done to determine which method works best or is most acceptable to women.To answer these important questions, a randomized study was done.All women had singleton, uncomplicated pregnancies between 28-32 weeks.Group A (n=63) used the Sadovsky method (counting 4 fetal movements 3 times a day).Group B (n=62) used the Cardiff method (counting the first 10 movements each morning).All women agreed to count for 1 month, then completed a 9 question acceptability survey.An expert panel reviewed each graph for quality and compliance, assigning a score of 1 (excellent) through 5 (poor). Acceptability of the method was assigned a score based on answers to the survey.Acceptability of the method was significantly associated with the quality of the graph (p<.025) regardless of the method used.Maternal age, education, race, marital status or employment did not mediate acceptability. There were no statistically significant differences in quality scores between the two methods. Results suggest that inner city patients can select either method of fetal movement counting and achieve the same level of compliance and quality of reporting.

508 **EFFECT OF ALTITUDE ON THE AMNIOTIC FLUID INDEX.** M.K. Yancey,[X] D.S. Richards, Department of Obstetrics and Gynecology, University of Florida, Gainesville, FL.

Altitude is known to effect fetal size and other aspects of maternal/fetal physiology. The effect of altitude on amniotic fluid volume has not previously been studied. The amniotic fluid index (AFI) is a reproducible means of assessing amniotic fluid volume. We studied the effect of altitude on the AFI by comparing similar populations of patients at low altitude (100 ft.) and high altitude (6000 ft.). A standard technique of measurement of the greatest vertical pockets of fluid in each quadrant with summation of values was utilized. Inclusion criteria included an uncomplicated singleton pregnancy between 20-42 weeks gestation with adequate dating criteria. Women were excluded from the study if any condition known to alter amniotic fluid volume was present. Patients were grouped by gestational age at two week intervals. Statistical analysis was performed with ANOVA. The population at high altitude (N = 364) had a significantly ($P < 0.0001$, $R^2 = 0.21$) increased AFI throughout gestation compared to the low altitude group (N= 514). The mean difference in the AFI between the two groups was 2.6 cm (range 1.1 - 3.6 cm for the various interval groups). We conclude that the amniotic fluid volume in normal pregnancies appears to be increased at high altitudes. The mechanism for this increase is unknown.

509 **PREGNANCY OUTCOME BY THE DEGREE OF MATERNAL SERUM ALPHA FETOPROTEIN ELEVATION.** W. Cusick[X], J. Rodis, A. Vintzileos, M. Albini[X], M. McMahon[X], W. Campbell, Univ. of CT Health Center, Farmington, CT

This retrospective study of pregnancies with unexplained second trimester elevated MSAFP sought to: 1) determine if a correlation exists between the degree of MSAFP elevation and adverse pregnancy outcome (intrauterine growth retardation, preterm births and pregnancy loss); 2) examine the timing of losses in pregnancies with bad outcome; and 3) develop a protocol for antepartum fetal surveillance in an effort to prevent these adverse outcomes. Well dated, singleton pregnancies with a single elevated MSAFP ($\geq$2.0 MOM) were eligible if targeted ultrasound elevation ($\leq$22 weeks) agreed with LMP dating and revealed no fetoplacental anomaly. A total of 371 patients were enrolled; delivery data was available on 337 infants. Stratified by MSAFP elevations of 2.0-2.49, 2.50-2.99, and $\geq$3.0 MOM, the rate of adverse outcomes were: 1) SGA (<10%ile) infants: 14/189 (7.4%), 10/91 (11.0%), 12/54 (22.2%); 2) preterm delivery (<37 weeks): 28/192 (14.6%), 15/91 (16.5%), 11/54 (20.4%); and 3) pregnancy losses (neonatal and intrauterine fetal deaths): 5/190 (2.0%), 3/89 (3.4%), 3/51 (5.9%), respectively. Seven early losses (3 fetal and 4 neonatal) occurred prior to 28 weeks. Of these seven, six fetuses exhibited IUGR by 23-26 weeks gestation and 5 of these 6 were associated with greater degrees of MSAFP elevation ($\geq$2.5 MOM). Four losses (2 fetal and 2 neonatal) occurred in the third trimester, including one neonatal death at 28 weeks with dextrocardia. Of these 4, the 3 structurally normal infants exhibited normal growth and were lost after 34 weeks gestation; all 3 of these pregnancies exhibited MSAFP elevations $\leq$2.5 MOM. This data suggest that any proposed program to improve pregnancy outcome in patients with unexplained MSAFP elevation must include: 1) repeat ultrasound evaluation at 24 weeks to rule out early IUGR in cases of MOM $\geq$2.5; 2) efforts aimed at preventing preterm delivery; and 3) fetal biophysical monitoring, even in normally growing fetuses, instituted at 32 weeks to detect fetuses at risk for intrauterine fetal death.

510 THE ROLE OF ANTENATAL TESTING IN THE CLINICAL MANAGEMENT AND OUTCOME OF FETAL ARRHYTHMIAS. A. Khoury,[X] M. Moretti, N. Meyer,[X] A. Nova,[X] T. DiSessa,[X] B. Sibai, P. Mace.[X] University of Tennessee, Memphis.

The purpose of this study is to report the clinical management and neonatal outcome in 18 fetuses with perinatally diagnosed cardiac arrhythmia. Two dimensional, guided M-mode echocardiography and pulsed doppler ultrasound studies were performed with commercially available scanners. The fetuses presented with various arrhythmias; PAC N=12, PVC N=1, A.Fib (2:1 block) N=2, A.Flutter (2:1 block) N=1, SVT N=2. All fetuses were devoid of structural heart disease. Antenatally the fetuses with PAC, and PVC were followed weekly with biophysical testing, the remainder were followed twice weekly. Results: mean gestational age at time of diagnosis was 30.1 week (range, 24-38), the mean number of antenatal tests used were 4.1 (range, 1-13), none of the fetuses had evidence of hydrops on examination. Four fetuses required treatment with digoxin; one fetus with SVT converted to normal rhythm and was delivered vaginally. Three were delivered by cesarean section for fetal arrhythmia. Two of these fetuses converted to normal rhythm spontaneously within 24 hours of birth. The third fetus (A. Fib) required transesophageal pacing in the first day of life. The mean gestational age at time of delivery 38.8 weeks (range, 37-40). Mean birth weights 3125 gm (range 2450-3685), all Apgars at 5 minutes were normal, mean 8.92 (range, 8-9), none of the neonates required prolonged hospitalization, mean 2.1 days (range 1-5). There were no neonatal deaths. Conclusion: Intensive and close antepartum testing is warranted in cases of SVT A.Fib & A.Flut., while routine follow-up for PAC, and PVC is adequate since the incidence of congenital heart lesions is low in this group of PA. Moreover all fetuses with PAC and PVC revert to normal rhythm in the neonatal period spontaneously and without medical treatment.

511 FETAL CATECHOLAMINE RESPONSES TO VIBRACOUSTIC STIMULATION K. Murphy,[1x] K. Hanretty,[1x] G. Inglis,[2x] A. Cameron,[1]
The Queen Mother's Hospital [1] *& MRC Blood Pressure Unit* [2], *University of Glasgow, SCOTLAND.*

The purpose of this study was to determine the role of the adrenal medulla in mediating fetal response to vibroacoustic stimulation. Forty-eight mothers undergoing elective Caesarean section at term under regional anaesthesia were randomly allocated either to a group who received fetal vibroacoustic stimulation 1-2 minutes prior to delivery of the infant, or to a group of controls. A 70 dB vibroacoustic stimulus lasting 3 seconds was applied to the maternal abdominal wall overlying the fetal head 110 (SD 49) seconds before delivery in 25 infants, and the levels of noradrenaline (NA), adrenaline (A) and renin (R) in both umbilical arterial and venous blood of these fetuses were compared with those from 23 controls. The two groups were comparable in all respects except for the stimulus. The median value for NA in the umbilical artery in the stimulated group (6.6 nmol/l) was not significantly different from that (8.4 nmol/l) in the control group (Mann-Whitney test; n=42, p> 0.05). Similarly, no differences were found for A, or R in either the umbilical artery or vein between the two groups, or for NA in the umbilical vein. Subjects who had hypotension (systolic BP <90 mmHg) induced by their regional block, particularly spinal anaesthesia, had significantly higher levels of NA in the umbilical artery at delivery compared with those who remained normotensive (median value 10.5 vs 5.5 nmol/l, $p < 0.05$). In addition there was a weak, but statistically significant correlation between umbilical artery NA levels, and the dose of ephedrine used to treat maternal hypotension (Spearman Rank correlation ; $r = 0.367$, n=42, $p < 0.05$). We conlcude that vibroacoustic stimulation does not induce fetal behavioural changes via a surge of catecholamines from the adrenal medulla, though fetal NA levels may be influenced by maternal blood pressure and ephedrine.

512 **SURVEY ON THE MANAGEMENT OF POST DATE PREGNANCY**

P. Roussis, S.M. Cox, B.A. Campbell, V.K. Harbison, F.C. Miller, University of Kentucky, Lexington, KY

Management strategies for prolonged pregnancies remain controversial. We conducted a survey of SPO members to determine the current strategies employed in the management of these patients. Material and methods: In November 1990 a questionnaire was mailed to 1,000 members of SPO. Six hundred and seventy seven (68%) completed questionnaires were returned. Results: The results in Table I reflect managements employed according to gestational age, with certain dates, and the condition of the cervix as judged by the Bishop Score (BS). Table II reflects the type of antepartum testing used. Table III reflects agents used for cervical ripening. Table IV reflects modes of induction. When dates were uncertain, 614 (91%) of the responders would intervene only if antepartum testing was abnormal. Finally, only 313 (46%) of responders had a written protocol for management of these patients.

Table I

	287 days *BS > 5	287 days BS ≤ 5	294 days BS > 5	294 days BS ≤ 5
Induction	65%	6%	97%	56%
Antepartum testing	27%	83%	1%	38%
No action	7%	10%	1%	4%
No response	1%	1%	1%	2%

Table II	Table III	Table IV
NST - 71%	PGE2 - 58%	Anmiotomy - 14%
CST - 4%	Oxytocin - 7%	Oxytocin - 34%
BPP - 21%	Laminaria - 7%	PGE2 gel - 1%
	Combination - 24%	Combination - 50%

Conclusion:
The majority of SPO members will induce labor at 287 days if the cervix is favorable and dates are certain. If the cervix is unfavorable, however, the responders initiate antepartum testing at 287 days and induce labor at 294 days. On the other hand when dates are uncertain, intervention is recommended only if antepartum testing is abnormal.

*BS = Bishop Score

513 ALPHA-FETOPROTEIN LEVELS FOLLOWING MATERNAL TRAUMA

W. L. Holcomb, Jr MD; E. Gunderson MD*; K. J. Staisch, MD. Washington University School of Medicine, St. Louis, Missouri

Maternal serum alpha-fetoprotein (AFP) has been proposed to assess fetal risk following maternal trauma. Serum specimens were obained at evaluation for trauma beyond 20 weeks gestation. Pregnancy outcome was evaluated. AFP levels were measured using an enzyme immunoassay. Complete data was available for 107 women. Mean and median AFP levels were 213.1 and 165.2 ng/ml, repectively. There was no linear trend for AFP level with gestational age (r=0.01; p=0.89). Fourteen women had AFP levels > or = 300 ng/ml. Outcome measures were similar for these women compared with the remainder:

AFP	<300	>300	Total
n	93	14	107
Delivered <37 weeks	17 (0.18)	3 (0.21)	20
Birth weight <2500 g	13 (0.14)	1 (0.07)	14
Apgar(5) < 7	2 (0.02)	1 (0.07)	3
Interval <7 days	14 (0.15)	2 (0.14)	16

(Interval = number of days from the trauma episode until delivery) The AFP level was 144.9 ng/ml in the one perinatal death due to abruption after trauma. Three women had levels > 800 ng/ml. Their complications were: labor at 36 weeks; marginal abruption and delivery at 35-36 weeks; and, induced delivery at term for positive fetal cell test. Very high AFP levels (> 800 ng/ml) may predict complications after trauma.

514 THE RELATIONSHIP BETWEEN THE RATE OF FETAL URINE PRODUCTION AND THE AMNIOTIC FLUID INDEX IN PREGNANCIES ≥ 38 WEEKS.

LJ Groome, FL Gaudier, JC Hauth, CL Neely[x], SP Cliver[x], J Owen. University of Alabama School of Medicine, Birmingham, Alabama.

It is often assumed that a normal amniotic fluid volume (AFV) is evidence of adequate fetal renal function, the implication being that AFV is a reliable measure of fetal urine production. Purpose: to determine the relationship between AFV and the hourly fetal urine production rate (HFUPR) in 134 normal pregnancies ≥ 38 weeks. The amniotic fluid index (AFI) was used as a clinical estimate of AFV; the HFUPR was determined by measuring the fetal bladder volume every 3-5 min for a period of 20-30 min. When controlled for gestational age, we found no correlation between the HFUPR and the AFI. However, a statistically significant ($p = 0.006$) relationship was found between an HFUPR below the tenth percentile (in this study, an HFUPR ≤ 30 ml/hr) and a clinical diagnosis of oligohydramnios. For the purpose of identifying fetuses with an HFUPR ≤ 30 ml/hr, an AFI ≤ 8 cm had a sensitivity of 71%, a specificity of 67%, a positive predictive value of 24%, and a negative predictive value of 94%. Conclusion: an AFI > 8 cm is a reasonable criteria by which to exclude the fetus with an abnormally low rate of urine production.

515 COMPUTERIZED VS. VISUAL ANALYSIS OF FETAL HEART RATE: A REDUCTION IN TESTING TIME.

Karin A. Blumofe[x], BA, Paula M. Broussard[x], RN, BS, Catherine A. Walla[x], MA, MN, Lawrence D. Platt, MD. Department of OB/GYN, Cedars-Sinai Medical Center, Los Angeles, CA.

A study was performed to determine if computerized analysis of fetal heart rate (FHR) tracings as opposed to visual interpretation can decrease the mean testing time in antepartum fetal surveillance. Eighty-one high-risk gravidas underwent 152 nonstress tests utilizing the Oxford Sonicaid System 8000. A FHR record was determined to be normal by this system according to the following criteria: FHR variation > 30 msec; the presence of ≥ 3 accelerations (>10 bpm above the baseline and a duration > 15 secs) or 1 maternally perceived fetal movement; and the absence of large decelerations. Criteria for reactivity by visual analysis included the identification of ≥ 2 accelerations ≥ 15 bpm above the baseline with a duration of ≥ 15 secs within a 10-minute period. Patient management was based on the visual interpretation of the FHR tracings. Results:

	Normal Test Results N (%)	Length of Test
Computer Analysis	145 (95.4)	16 ± 9 mins
Visual Analysis	138 (90.8)	35 ± 17 mins
p	0.50	< 0.0001

Computerized analysis of the FHR tracings provides interpretations comparable to those given by visual analysis while significantly decreasing the mean testing time.

516 A FOUR YEAR FOLLOW-UP OF HEARING AND NEURO-DEVELOPMENT IN CHILDREN EXPOSED IN UTERO TO VIBROACOUSTIC STIMULATION

By Westgren M, Nyman M, Barr M, Dept Obstet Gynecol Karolinska Institutet Huddinge University Hospital, Sweden

Several investigators have expressed concerns about exposing the fetus to VA stimulation we found it therefore essential to study the long-term effect.

A total number of 525 children were included in the present study. All children had been followed according to the routine Swedish health care program. At 4 years of age an extensive examination is performed including an auditory test (250-8,000 Hz).
Results: In this material two children had hearing defects (otosalpingitis, hereditary). Eight children were disabled, but no handicap could be related to the VA stimulation.
Discussion: This study does not provide any evidence that VA stimulation should be associated with an increased risk of neuro-developmental disorders nor impaired hearing.

517 **POSITION OF THE VIBROACOUSTIC STIMULATOR DOES NOT AFFECT FETAL RESPONSE.** **DP Eller, RB Newman, L Johnson[X]. Medical University of SC, Charleston, SC.**

The fetal vibroacoustic stimulation test (VAST) has become an established adjunct to the nonstress test (NST) for assessment of fetal well-being . However, positioning of the stimulator over the fetal vertex was empirically selected with little consideration for alternatives.The optimal placement of the vibroacoustic stimulator has not been established. Gerhardt measured extremely intense sound pressures (135 dbs) when an electronic artificial larynx (EAL) was applied directly over the fetal ear in pregnant ewes (AJOG1988; 159: 228-32). Sound pressures decreased as the distance from the EAL increased. The following study prospectively evaluated the fetal response to stimulation randomly applied over the fetal vertex or breech. The parameters evaluated include fetal heart rate (FHR) reactivity, fetal movement (FM) and fetal startle. Between December, 1990 and May, 1991, 205 patients with a nonreactive NST after ten minutes were prospectively randomized to receive VAST (Corometrics Model 145) over the fetal vertex (n=110) and over the fetal breech (n=95). Both groups were similar with respect to maternal age, gestational age, and indication for NST. A subset of 49 patients (24 breech and 25 vertex) was evaluated for a change in FM with VAST as recorded by a doppler fetal activity monitor (Actograph MT-320, Toitu Corp.). The fetal startle response (characterized by sudden gross body movements and flexion-extension of all extremities lasting 5-10 seconds after VAST) was observed ultrasonographically in 20 additional patients (10 breech and 10 vertex). Chi square analysis revealed virtually identical FHR responses in both groups. The increase in the number of FM after VAST compared to the pre-stimulation baseline was not different between groups. The fetal startle response was uniformly observed in both groups. VAST over the fetal breech elicits an identical short term fetal response compared to stimulation over the fetal vertex with a potentially less intense sound exposure. Until more is known about the long term effects of VAST on fetal hearing, stimulation over the breech may be preferable.

518 **FETAL HEART RATE ACCELERATIONS, FETAL MOVEMENT AND FETAL BEHAVIOR PATTERNS IN TWIN GESTATIONS.** **M.W. Gallagher,[X] T.R.B Johnson, Dept. Gyn/Ob, The Johns Hopkins Univ. Sch. of Med., Balto., MD. 21205**

Previous studies have shown that twins, when monitored simultaneously, show a remarkably high incidence of synchronous fetal heart rate accelerations (58%), prompting inquiry into the nature of the intrauterine interaction of twins. The present study is a retrospective examination of 20 fetal monitor strips from five sets of twins with simultaneous fetal heart rate and fetal activity recorded using a doppler fetal movement detector (Toitu MT-320-Fetal Actocardiograph). The strips were analyzed for coincidence of fetal heart rate accelerations and/or fetal movement episodes. Forty-eight percent of fetal heart rate accelerations were found to be simultaneous. Fifty-seven percent of movement epochs were considered simultaneous. The strips were then analyzed using concepts of fetal behavioral patterns based on descriptions of behavioral states by Prechtl and Nijhuis. We found that twins exhibited coincident behavioral patterns (basically sleep/awake state) 88% of the time. Twin-twin interactions are more consistently related than suspected when observation is limited to heart rate alone and the coincidence of and role of fetal behavioral states must be considered when twin interactions and behavior are studied.

519 AMNIOTIC FLUID VOLUME ESTIMATION IN THE POSTDATES PREGNANCY: A COMPARISON OF TECHNIQUES.

RL Fischer, M McDonnell[x], KW Bianculli[x], RL Perry, TO Scholl[x], ML Hediger[x]. Department of OB/GYN, UMDNJ-RWJ Medical School at Camden, Cooper Hospital/University Medical Center, Camden, NJ.

A number of techniques for amniotic fluid volume (AFV) estimation have been proposed, including the largest vertical pocket (LVP) and amniotic fluid index (AFI). Oligohydramnios has been variously defined as LVP < 1 or 2 cm, or AFI <5 cm or 2.5th percentile. Purpose: To determine the AFV technique that was most predictive of abnormal perinatal outcome in 137 postdates pregnancies. Gestational dating was based on an early ultrasound (≤26wks) which either confirmed or established the EDD, or a late ultrasound that was consistent with or greater than the menstrual age. With the ultrasound transducer in a longitudinal plane, the largest amniotic fluid pocket in each quadrant was measured in both vertical and transverse dimensions. The last AFV prior to delivery was correlated with perinatal outcome. Outcome was considered abnormal for: 1) operative delivery for non-reassuring FHR tracing, 2) meconium below the cords, 3) 5 minute Apgar <7, 4) umbilical artery pH <7.10 or venous pH <7.15, 5) admission to NICU, or 6) BW < 10%. A receiver operating characteristic (ROC) curve was employed to determine the optimal LVP and AFI. Results: The mean LVP was significantly lower in the abnormal outcome group compared to the normal group (3.4 ± 2.0 vs 4.2 ± 1.4 cm, p = .04), whereas no significant difference was noted using the AFI (8.7 ± 5.5 vs 9.7 ± 4.3 cm, p = .24).

AFV Test	Normal Outcome (N=103)	Abnormal Outcome (N=34)	p
LVP <1 cm	0 (0%)	3 (8.8%)	.01
LVP <2 cm	3 (2.9%)	8 (23.5%)	.0006
ROC LVP <2.5 cm	8 (7.8%)	12 (35.3%)	.0003
AFI <5 cm	12 (11.7%)	8 (23.5%)	.10
AFI <2.5%	21 (20.4%)	11 (32.4%)	.15

We conclude from our study of postdates pregnancies that: 1) an LVP <2.5 cm is the most useful AFV indicator of subsequent abnormal perinatal outcome, with a sensitivity of 35.3% and a specificity of 92.2%, and 2) the AFI has little diagnostic value in this population.

520 ANGIOTENSIN TESTING PREDICTS FETUSES BENEFITTING FROM LOW DOSE ASPIRIN. BJ Trudinger, C-M Cook[X], Dept. Ob/Gyn, Univ. Sydney, Westmead Hospital, Westmead, Australia.

Low dose aspirin improves fetal growth when used to treat placental insufficiency identified by an abnormal umbilical Doppler study, and a positive angiotensin infusion sensitivity test (AIST) identifies fetuses with an abnormal study at greatest risk of subsequent morbidity, even in the absence of maternal hypertension. We therefore investigated the effect of aspirin therapy in a group of mothers without hypertension identified by a high umbilical S/D and a positive AIST response (a group with a poor fetal prognosis). From 604 high fetal risk pregnancies 40 were found to have a high umbilical S/D of whom 23 exhibited a positive response to AIST. Gestational age at enrolment ranged from 26 to 35 weeks. This group was treated with aspirin 100mg/day. The AIST was repeated after at least 7 (range 7-23) days. In all 7 fetuses with absent diastolic flow the test remained positive. In the remaining 16 a negative repeat study (n=6) was associated with a decrease towards normal in umbilical S/D. The mean centile birthweight was less (6 to 26, $p<0.005$) and mean gestation at delivery earlier (35.1 to 38.6 wks, $p<0.001$) in the positive compared to negative second AIST result groups. The group with an intial negative AIST were not treated with aspirin and their outcome was comparable to the negative restudy group. We conclude that a positive AIST predicts the true positive high umbilical S/D fetuses with vascular disease in the fetal placenta and this response remains positive if aspirin fails to arrest the placental obliterative vascular pathology.

521 **VIBRATORY ACOUSTIC STIMULATION STIMULATES HUMAN FETAL VOIDING.** E. Z. Zimmer[X], C. R. Chao[X], G. P. Guy[X], F. Marks, W. P. Fifer[X], Dept. of Ob/Gyn, Columbia University, New York, NY

Although vibroacoustic stimulation (VAST) is a popular adjunct to fetal heart rate testing, its effects on many fetal organ systems are unknown. We hypothesized that VAST might stimulate fetal micturition. Fetal bladder volume was determined by ultrasound in 20 healthy fetuses at 38-41 weeks gestation. Measurements were taken 5 minutes prior to and immediately preceding a 3-second VAST and at 1 and 5 minutes following the VAST. All stimuli were performed during the filling phase of the bladder cycle; i.e., the volume immediately prior to VAST was greater than at 5 minutes prior to VAST.

Bladder Volume (ml)	Mean	SEM	Group*
5 minutes prior	17.7	2.1	a
Immediately prior	22.7	2.4	b
1 minute after	14.2	2.2	a
5 minutes after	13.3	1.9	a

*$p=0.001$, repeated measures ANOVA. Groups with same letter are not different by Neuman-Keuls post-hoc analysis at $p<0.05$; groups with different letters are significantly different at that level

Mean bladder volume was significantly decreased 1 minute and 5 minutes following the VAST compared to the volume immediately prior to the stimulus. The volume decrease was observed in 19 of the 20 cases at 1 minute following VAST. We speculate that fetal micturition following VAST may be part of a fearful reaction to the stimulus.

522 ELEVATED MSAFP AND RISK ASSESSMENT FOR PREGNANCY OUTCOME.
W Moroder*, RR Viscarello, S Yarkoni, D Brioschi*, and JC Hobbins, Dept. of OB/GYN, Yale University Sch. of Medicine, New Haven, CT.

Although elevated levels of MSAFP in pregnancy are associated with congenital anomalies, pre-eclampsia, low birth weight, and fetal death, it is difficult to assign accurate risks for these outcomes. The purpose of this study was to examine the relationship between elevated MSAFP levels and the risk of adverse pregnancy outcome. During a 2 year period, 439 patients with MSAFP levels >2.0 MOM were referred for targeted ultrasound examination. Sonographic findings and pregnancy outcome data were retrospectively reviewed in 355 patients (81%). Fetal or placental anomalies were noted in 141 pregnancies (39.7%), including 33 structural defects and 7 chromosomal aberrations. Mean MSAFP levels were significantly higher in patients with fetal anomalies (4.9 MOM vs. 2.6 MOM; $p< 0.01$). Placental abnormalities were detected in 14% of patients and were associated with a mean MSAFP value of 2.97 (range: 2.0 to 11.4). While 3.4% of pregnancies had oligohydramnios and 1.4% had polyhydramnios (mean MSAFP = 6.6 MOM), only the former was associated with a lower mean birthweight (2431g vs. 3181g; $p< 0.01$). Pregnancy complications included 6 cases of intrauterine fetal demise, 38 premature deliveries, and 34 patients with PIH (10%). Patients with pre-eclampsia had a mean MSAFP value of 2.6 MOM, which correlated with a significantly lower birthweight ($p< 0.005$). Of note, hemangiomas were reported in 23 neonates (7%) who were born to mothers with otherwise uncomplicated pregnancies, which suggests that these birthmarks have been a previously unrecognized cause of elevated MSAFP values. Our data confirm previous observations that an unexplained, elevated MSAFP level is a marker for high risk pregnancies. In addition, the increased risk for fetal and/or placental anomalies suggests that a targeted ultrasound examination is warranted in all patients with elevated levels of MSAFP.

523 **RELATION OF MILD IDIOPATHIC POLYHYDRAMNIOS TO PERINATAL OUTCOME.** **C.Smith, R.Plambeck[X], W. Rayburn, K. Albaugh[X], Dept of OB/GYN, Univ of Nebraska College of Medicine, Omaha, NE.**

The relation between clinically obvious polyhydramnios and poor perinatal outcome is well established. Much less is known about mild unexplained polyhydramnios, which usually is initially suggested by sonographic examination late in gestation. The purpose of the present investigation was to relate mild idiopathic polyhydramnios to perinatal outcome. Mild polyhydramnios was defined sonographically as an amniotic fluid index of 25-39 during fetal biophysical testing. All cases involved single gestations not complicated by conditions known to predispose to polyhydramnios. Mild polyhydramnios was diagnosed in 97 (8.2%) of 1177 patients undergoing fetal testing between 26 and 42 gestational weeks. Findings of premature delivery, intrapartum complications, and neonatal depression were no more frequent in pregnancies complicated by mild, unexplained polyhydramnios than in a comparable control group of patients but with a normal fluid volume. The incidence of birth weights greater than 4,000 grams was significantly higher in the mild polyhydramnios group than in the control group (18.6% vs 8.6%; $p<0.05$). We conclude that mild idiopathic polyhydramnios based on sonographic examination in late gestation is not associated with an increased risk of adverse perinatal outcomes, except for a higher incidence of large-for-gestational-age fetuses.

524 ABSENT UMBILICAL ARTERY END DIASTOLIC VELOCITY(AEDV) AND REVERSE FLOW - CLINICAL OUTCOME OF 60 CASES. JG Bell[X], A Ludomirsky[X], J Bottalico[X], S Weiner, Pennsylvania Hospital, Philadelphia, PA

We studied our experience of 60 cases with a diagnosis of AEDV(n=50) or reverse flow(n=10). Mean time from onset of AEDV to delivery was 19.1 days(range 0-107). Gestation at diagnosis ranged from 18 to 34 weeks. The mean time from diagnosis of AEDV to reverse flow was 16.3 days. Management of AEDV included hospitalization with bed rest, oxygen therapy, and intensive fetal monitoring. 8 of 9 fetuses with reverse flow at viable gestational ages were delivered on the day of diagnosis. Indications for delivery with AEDV included abnormal NST/CST in 56%, maternal indications in 22%, and others in 12%. Karyotypes were available on 22 fetuses with 9% abnormal. Major structural anomalies were present in 4 others. Pathology revealed infarctions in 46%of placentas. Of 16 arterial cord pH values available, mean pH was 7.27.

	AEDV	Reverse Flow
IUGR by US(<10%)	26/50(52%)	8/10(80%)
Oligohydramnios	22/50(44%)	2/10(20%)
Avg.Birthwt.(gms)	1076(range 450-2400)	930(280-1879)
Neonatal Death	10/50(50%)	3/10(30%)
Survivors	33/50(66%)	6/10(60%)
# Days in Nursery	55(range 5-186)	65(44-126)
IVH	3/50(6%)	1/10(10%)

Conclusion:Similar perinatal and necnatal outcomes were found in both AEDV and reverse flow, and were not as poor as those previously reported in the literature.

525 **ROLE OF THE ABBOTT TDxFLM ASSAY IN ASSESSING FETAL LUNG MATURITY (FLM)** MM Schnoor[X], WNP Herbert, JF Chapman[X], Dept. Ob/Gyn and Path, UNC School of Medicine, Chapel Hill, NC.

The TDxFLM test (Abbott Laboratories, Abbott Park, IL 60064) is an automated test for FLM based on quantitative fluorescence polarization. In 102 patients, 22 of whom had infants with RDS, we assessed the TDxFLM test with respect to other tests (L/S, FSI, and Amniostat-PG [Irvine Scientific, Santa Ana, CA 92705]) and respiratory outcome. We also evaluated various strategies for FLM testing using sequential and parallel approaches. In comparing tests, the TDxFLM (referent value 30 mg/g) had the highest sensitivity (SE), specificity (SP), predictive values (FVm mature, PVi immature) and efficiency (EF). For sequential and combination testing, the FLM (if negative) followed by the FSI was comparable to other combinations in SE, SP, PV, EF, and cost.

Test(s)	SE(%)	SP(%)	PVm(%)	PVi(%)	EF(%)	Cost
Individual Tests & Referent Values for Maturity						
TDx (≥30mg/g)	100	82.5	100	61.1	86.3	$30
L/S (≥2.0)	86.4	72.5	95.1	46.3	75.5	$32
FSI (≥48)	86.4	77.5	95.4	51.4	79.4	$ 8
AMN-PG (≥wk+)	100	36.3	100	30.1	50.0	$28
Multiple Testing Approaches (sequential vs. combination)						
FLMi then FSI	86.4	95.0	96.2	82.6	93.1	$32
FSIi then L/S	77.3	87.5	93.3	63.0	85.5	$20
AMNi then FSI	86.4	86.3	95.8	63.3	86.3	$34
FSIm & L/Sm	95.5	62.5	98.0	41.2	69.6	$40

Conclusion: The Abbott TDxFLM Assay compares favorably with other FLM tests. Its simplicity, rapid analysis time, precision and clinical reliability warrant its strong consideration as a "first-line" test for FLM.

526 **FETAL HEART RATE PATTERNS AND SUBSEQUENT CEREBRAL PALSY: CONVERSION OF REACTIVE NST TO PATTERN OF CHRONIC DISTRESS.** Barry S. Schifrin, M.D., James R. Shields, M.D.[X] Department of Obstetrics and Gynecology. Tarzana Regional Medical Center, Tarzana, California

Some fetuses who develop cerebral palsy (CP) demonstrate during labor persistently absent variability, small variable decelerations with overshoot and absent asphyxia. We have interpreted this pattern as neurological injury antedating labor. To better understand its appearance, we analyzed the antepartum NST results from 44 CP patients with this pattern during labor. Decreased fetal movement, decreased amniotic fluid volume, meconium staining, and dysmaturity were common findings.

NST RESULT	NO.	%	DECELS	%
Reactive NST	34	77.3	8	23.5
Intermediate NST	6	13.7	1	16.7
Non-reactive NST	4	9.0	0	0.0
Total	44		9	

The conversion of the reactive NST with its normal fetal behavior pattern to a pattern of absent variability in the clinical setting of decreased fetal movement and/or oligohydramnios suggests that the neurologic injury in these cases is of relatively recent origin and that NST testing may be of value in timing the injury. The NST may also prompt timely intervention when decelerations, oligohydramnios, or intermediate results are present. The NST alone, however, does not anticipate the majority of the injuries in this unique group of patients. Evaluation of fetal movement and amniotic fluid volume may improve the prediction.

527 **DOES THE AMNIOTIC FLUID INDEX (A.F.I.) CHANGE OVER A SHORT TERM TIME INTERVAL?** D. Schwartz[1], Y. Daoud[1X], K. Schukter[2X], J. Freeman[2X], K. McGirr[2X], S. Campbell[2X].
[1] Sinai Hospital, Wayne State Univ, Detroit, MI., [2] Kings College Hospital, London, England.

The amniotic fluid index (A.F.I.) is commonly used to assess amniotic fluid volume, as the technique is relatively rapid and simple. This assessment is usually used in conjunction with other tests of fetal wellbeing that may extend over a variable time interval. The data on inter-observer and intra-observer variability has not stated the interval between measurements, although it is likely that they would have been repeated immediately. In this study an A.F.I. was repeated after a short time interval to assess for a significant difference, as this may be clinically relevant. In 91 patients, the same individual performed the test at the beginning and at the end of an ultrasound scan for either growth and development (43), or for doppler velocimetry (48). The gestational ages ranged from 20 to 41-3/7 weeks. The interval between the two measurements was 30 to 45 minutes. The two values were correlated and assessed for a significant difference using a paired t-test. For the two measurments, the respective results were as follows: mean 18.4 vs 18.7; standard deviation 4.2 vs 3.9; minimum value 10.1 vs 11.0 and maximum value 35.0 vs 30.0. There were no significant differences between the two measurements ($P>0.133$; df=90) and the correlation coefficient was 0.874 ($P<0.0001$). In 57 cases (63%), the difference was less than 10% and in 82 cases (90%), it was less than 20%. The current results validate the reproducibility of the AFI measurement over a 30-45 minute time interval, during which time most adjunctive tests associated with the A.F.I. are usually completed. Therefore, the timing of the A.F.I. in relation to the other tests is not critical and repeating the A.F.I. within 30-45 minutes of a preceding assessment is not necessary.

528 **PREDICTION OF LONG TERM NEUROLOGIC HANDICAP IN VERY LOW BIRTHWEIGHT NEWBORNS**

FL Gaudier,* RL Goldenberg, M Peralta,* KG Nelson,* M DuBard,* SE Johnson,* RA Steele,* TY Roth*
University of Alabama Hospitals, Birmingham, Alabama

This study was performed to determine if factors other than low BWT predict neurologic handicap. 310 infants with a BWT of 500-1000 gms who delivered between 1979-89, with a last evaluation at ≥1 year of age were studied. The factors studied included BWT, GA, Apgar score, and umbilical arterial cord gases including pH, HCO_3, pCO_2 and pO_2. Outcomes evaluated included mental retardation (MR) defined as an IQ <70 on the last IQ test performed, cerebral palsy (CP), and any major handicap (MH) including MR, CP, blindness, deafness and hydrocephalus. BWT was not associated with any of the outcomes studied, while the GA was inversely associated with CP (p=.05) and MH (p=.02). Both 1 and 5 minute Apgar scores were associated with MR (p=.02) and MH (p=.02). Both high and low pH values were associated with CP and (p=.003) and MH (p=.001). As an example, 5 of the 6 infants with a pH <7 had a MH (p<.001) compared to 20% with a pH >7 and <7.35. Of infants with a pH of >7.35, 50% had a MH (p<.0001). Levels of HCO_3 were inversely associated with all 3 outcomes (p≤.01). As an example, a HCO_3 of ≥26 was associated with 9% MH while a HCO_3 <14 was associated with 54% MH. Both high and low levels of O_2 and CO_2 were associated with the 3 poor outcomes. Regression analyses, controlling for GA, BWT, 1 minute Apgar score and type of anesthesia were performed to confirm the relationships between cord gases and outcome described above. As an example, the Odds Ratios (OR) for MH associated with a pH <7 was 4.1 and the OR for MH for a pH >7.35 was 3.9 compared to a pH of 7 to 7.35 . The OR for MH for a HCO_3 <13 compared to a HCO_3 of >23 was 6.4. The U-shaped relationship between both high and low CO_2 and O_2 and MH was confirmed. In summary, cord gas measurements are highly predictive of long term neurologic handicap in very low birthweight infants, but the relationships are more complex than originally anticipated.

529 OBSTETRIC PREDICTION OF THE SYMPTOMATIC GROWTH RETARDED NEONATE. H.M. Wolfe, M.P. Dombrowski, R.J. Sokol, Y.W. Brans[x], Dept. of Ob/Gyn, Hutzel Hosp./Wayne State Univ., Detroit, MI

Studies suggest that weight for length (w/l), rather than birthweight percentile (bwt%) may be more sensitive for the identification of symptomatic IUGR. We studied 12,238 non-LGA near term births (≥ 36 wks) to compare the utility of measures of growth (w/l, bwt%, w/l for gestational age and birthweight (bwt)) in the prediction of six adverse growth-related neonatal outcomes. By multivariate analysis, overall morbidity was best predicted by w/l. W/l (not adjusted for gestational age) showed the strongest association with hypoglycemia, low 5 minute apgar score and polycythemia. Only meconium aspiration was better predicted when w/l was adjusted for gestational age (w/l/ga). No significant relation was found between cesarean section for fetal distress or need for resuscitation and any measure of growth. The most significant predictor of 4/6 outcomes was w/l, with only a small amount of additional variance explained by bwt%. These findings are consistent with the supposition that symptomatic IUGR is related to in utero caloric deprivation as reflected in decreased w/l. Since adjustment for gestational age adds little to the prediction of adverse outcomes in the near term infant, initial identification of the high risk neonate can be expediently made in the delivery room by the simple process of assessing neonatal weight and length. Further evaluation of the low w/l near term infant by the pediatrician should include assessment of bwt%.

530 **PREMATURITY AND FETAL GROWTH: 'NORMAL' WEIGHTS BASED ON ABNORMAL PREGNANCIES.** SF Bottoms, IE Zador, and KL Chan. Wayne State Univ., Hutzel Hospital, Detroit, MI.

Currently the same proportion (10%) of preterm and term are classified as SGA. Consequently "normal" birth weight standards for preterm infants are based exclusively on data from abnormal births (prematures). Recent studies suggest that preterm delivery is associated with diminished fetal growth. The purpose of this study is to develop birth weight norms based on the entire population, including the normal undelivered fetus. We studied 4653 consecutive singleton live births having complete ultrasound examinations and delivering at our hospital from 1983-1988, excluding major congenital malformations. Gestational age at time of ultrasound was calculated based on pediatric examination. There was no significant difference between mean EFW and mean birth weight for the 479 premature infants who delivered within 3 days of ultrasound. EFW percentiles based on the entire population were developed for each week from 26-36 weeks. Classification based on these tables according to gestational age at delivery is summarized below.

	Preterm	Term
SGA	100(20.9%)	332(8.0%)
AGA	351(73.3%)	3406(81.6%)
LGA	28(6%)	436(10.4%)

Growth classification of preterm infants based on EFW differed from that of term infants ($p < 0.0001$), and from current birth weight classification ($p < 0.0001$). We conclude that current growth classification systematically underestimates the relative frequency of diminished growth among preterm infants as compared to those delivered at term.

531 FETAL AND NEONATAL HEMATOLOGIC PARAMETERS IN RED CELL ALLOIMMUNIZATION: PREDICTING THE NEED FOR NEONATAL TOP-UP TRANSFUSION. George R. Saade, M.D.[X], Kenneth J. Moise, Jr., M.D., Michael A. Belfort, M.D.[X], Diane Hesketh, R.N.[X], Robert J. Carpenter, Jr., M.D.; Dept. of Ob/Gyn; Baylor College of Medicine; Houston, Tx.

Recently, there has been an increased awareness for the need for top-up transfusion (TUT) in neonates treated with intrauterine transfusion (IUT) for red cell alloimmunization. **Purpose:** To determine whether any fetal or neonatal hematologic parameter can be used to predict the need for TUT. **Material and Methods:** The records of 36 patients who underwent IUT's and had adequate neonatal follow-up were reviewed. The patients that needed TUT were compared to those that did not using X^2 and unpaired Student t test. **Results:** No statistically significant difference was found between the two groups in the number of IUTs or neonatal exchange transfusions, the gestational age at first IUT, the presence or absence of hydrops, the fetal hct or hgb at the last IUT, and the umbilical cord retic count or bilirubin. Fetuses who required TUT had a lower retic count at their last IUT (1.5 ± 2.3 vs 4.9 ± 4.8 %; p = .01) and longer duration between their lowest retic count and delivery (42.1 ± 23.5 vs 24.3 ± 17.6 days; p = .03). In addition, these newborns had a higher umbilical cord hgb (13.5 ± 1.7 vs 11.0 ± 2.3 gm %; p < .01) and % adult red cells (96.0 ± 7.7 vs 82.5 ± 19.6; p = .02). None of the newborns with a cord hgb < 11.8 gm% required TUT. **Conclusions:** The data suggests that the need for TUT is related to the extent and duration of fetal bone marrow suppression caused by transfusion of adult cells in utero.

532 THE RELATIONSHIP OF "COMPLETE" CORD ARTERIAL BLOOD GASES TO GESTATIONAL AGE AND NEONATAL OUTCOME. A. Hiett, L.Devoe A.Youssef, Dept.OBGYN,Med.Col.Georgia, Augusta,GA

We reviewed umbilical artery blood gases(UABGs) in 3000 consecutive deliveries, 32 - 42 weeks' gestation,to determine rates of neonatal metabolic (MET),mixed(MIX),and respiratory (RESP) acidoses, (by criteria of Gilstrap, Obstet Gynecol 1987;70:191), and gestational-age related rates of infant morbidity not due to sequelae of respiratory distress or major anomalies. Acidosis types and rates were similar for term(T) and preterm(PT) groups (v. table, numbers in ( ) = morbidity).

GA(wks)	Total	MET	RESP	MIX
32-36	261	3(1)	17(6)	20(9)
37-42	2315	16(7)	151(26)	233(38)

Morbidity was significantly lower for all T (3%) than PT (6%) acidosis groups. While morbidity rates rose as pH fell (7.20 -> 6.75), 50% of morbid cases in both groups occurred at pH >7.15 and < 7.20. Morbidity in the PT group was similarly distributed in all acidosis types (X^2=.42,NS); in the T group, it was significantly higher with MET (p=.02). These data suggest that UA pH alone may be adequate for preterm infants as any acidosis appears equally harmful. Term gestations require complete UABGs to discriminate risk of morbidity.

533 **INTRAUTERINE GROWTH RETARDATION: 1988 U.S. DATA COMPARED TO PREVIOUS STANDARDS**

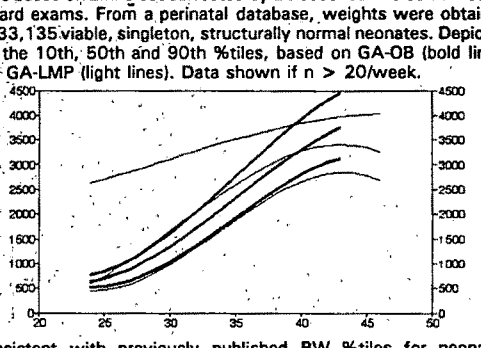
M. Kiely,* J.L. Kiely,* Maternal and Child Health Bureau, Health Resources and Services Administration, Rockville, MD, and NCHS.

17 years ago Hoffman et al. published birth weight for gestation percentiles based on a 50% sample of all US live births born in 1968 (Obstet Gynecol Surv 1974;29:651-81). The purpose of our analysis was to explore whether distributions of birth weight for gestation in the US shifted upward between 1968 and 1988. We used US live birth files from the National Center for Health Statistics. For each year from 1968 to 1988, we calculated the median birth weight and the 10th percentile for gestations between 28 and 45 weeks. This was done separately for 8 groups by race (blacks, whites), parity (primiparae, multiparae) and sex. In all 8 race/parity/sex subgroups there were substantial upward shifts in birth weight at gestational ages of 36 weeks and more. The 10th percentile increased 80-190 grams. The table below shows these upward shifts for selected gestational ages among males. These data provide further evidence for the recommendation of Goldenberg et al. (Am J Obstet Gynecol 1989; 161: 271-7) that new national standards for IUGR should be developed.

Tenth percentile birth weight values at various gestational ages				
	36	38	40	42
Whites: 1968	2259	2621	2890	3010
1988	2426	2807	3050	3090
Difference	+167	+186	+160	+80
Blacks: 1968	2227	2544	2676	2660
1988	2325	2665	2835	2835
Difference	+98	+121	+159	+175

534 **INFANT MORTALITY IN HIGHER ORDER MULTIPLE BIRTHS, UNITED STATES 1960 AND 1983-1985.**

J.L. Kiely,* M. Kiely,* J.C. Kleinman,* National Center for Health Statistics, Hyattsville, MD and Maternal and Child Health Bureau, HRSA.



Recent reports on higher order multiple births (triplets & higher) cared for in tertiary centers suggest that their survival has improved dramatically (e.g., Gonen et al. Am J Obstet Gynecol 1990; 162: 454-9). But hospital-based studies may not be generalizable to the entire birth population. We therefore analyzed birthweight-specific infant mortality rates (IMRs) among singletons, twins, and higher order multiple births in the U.S. in 1983-5 and compared the latter rates to those in 1960. In whites in 1983-5, the relative risk (RR) of infant mortality among higher order multiple births compared to singletons was 15.9 (130.3 vs. 8.2 per 1000 live births). In blacks, the RR was 13.2 (224.5 vs. 17.0). This was due almost entirely to the lower weight distribution of higher order multiple births. In whites, 89% weighed <2500g, as compared to 4.8% of singletons. In blacks, 92% weighed <2500g, as compared to 11.4% of singletons. Higher order multiple births who weighed 500-999g had about the same IMR as singletons. In weight categories 1000-2499g, the IMR in higher order multiple births was much lower: weight-specific RRs ranged from 0.30 to 0.73. Between 1960 and 1983-5, in high order multiple births the IMR declined 49% in VLBW white infants (from 683 to 351), 55% in VLBW black infants (from 941 to 423), 80% in whites weighing 1500-2499g (from 75 to 15), and 73% in blacks weighing 1500-2499g (from 129 to 35). Similar patterns were found in analyses of perinatal mortality. Thus, modern intensive care techniques have had a similar beneficial impact on the survival of singletons, twins,* and higher order multiple births.

---

* See Kleinman et al. (Am J Epidemiol 1991; 133: 133-43) for a detailed analysis of U.S. time trends in infant mortality in twins and singletons.

535 MENSTRUAL DATING-NOW AN INADEQUATE ESTIMATOR OF GESTATIONAL AGE MP Dombrowski, HM Wolfe, YW Brans,* AA Saleh, RJ Sokol, Depts of Ob/Gyn and Pediatrics, Wayne State Univ./Hutzel Hosp., Detroit, MI

Although current practice is to use fetal ultrasound and Ballard for gestational age (GA) dating, birth weight percentiles (BW %tiles) are still based solely on GA by last menstrual periods (GA-LMP). The purpose of this study was to develop a standard consistent with current technology and practice. Obstetric estimates of GA (GA-OB) were based on LMPs but corrected by ultrasounds and confirmed by Ballard exams. From a perinatal database, weights were obtained for 33,135 viable, singleton, structurally normal neonates. Depicted are the 10th, 50th and 90th %tiles, based on GA-OB (bold lines) and GA-LMP (light lines). Data shown if n > 20/week.

Consistent with previously published BW %tiles for neonates preterm by GA-LMP, data are widely divergent with a decrease in median BW %tiles beyond 42 weeks when compared to BW %tiles by GA-OB. We conclude: 1) use of ultrasound increases the precision of GA dating, 2) BW %tiles based solely on LMP are likely to be inaccurate for preterm and post-term gestations, 3) since fetal growth typically continues to 44 weeks, macrosomia rather than growth retardation is the greater risk of post-datism.

536 MATERNAL SERUM ALPHA-FETOPROTEIN LEVELS DO NOT INCREASE WITH LABOR

C. M. Meyers, R. N. Andersen[x], S. Elias, M. Brownlee[x], E. A. Tolley[x], J. L. Simpson, Dept. Ob/Gyn, Univ. of Tennessee, Memphis.

The usefulness of second and third trimester maternal serum alpha-fetoprotein (MSAFP) as a predictor of outcome in complicated pregnancies is under investigation. We sought to clarify the effect of labor, a potentially confounding variable in these studies, on MSAFP. In 13 singleton, term pregnancies without antepartum complications, MSAFP was measured at the following times: (1) prior to labor, (2) on admission for delivery, (3) active labor, (4) during the second stage of labor, (5) after delivery, and (6) the first day post partum. MSAFP levels decreased between samples obtained prior to labor (1) and in labor (2 or 3) (p=0.001), and continued to decrease in subsequent samples. One might have predicted the opposite result, if fetal-maternal transfusion occurs regularly during labor. Conclusions: (1) MSAFP decreases after the onset of labor in comparison to prior samples in uncomplicated, term pregnancies. (2) MSAFP does not increase during labor, suggesting fetal-maternal transfusion during labor is not common in these individuals.

537 LOW FOLATE AND B_{12} LEVELS AND THE INCIDENCE OF SPONTANEOUS ABORTIONS. Ran Neiger, MD, Charlotte Wise, MD[x], Stephen A. Contag, MD, Marea Tumber[x], Jacob A Canick, PhD[x]. Brown University/Women and Infants Hospital, Providence, Rhode Island.

We examined the hypothesis that low folic acid levels around the time of conception were associated with an increased rate of miscarriages. Over a six-months period we obtained folate and B_{12} levels on 225 women who presented to Women and Infants Hospital emergency room due to first trimester vaginal bleeding, and studied their pregnancy outcomes. Inclusion criteria were intrauterine pregnancy of less than 14 weeks gestation and HCG>25 mIU/ml. Seventy-four women were excluded due to low HCG levels, ectopic pregnancies, molar pregnancies, elective terminations, or lack of information about pregnancy outcome. Of the 151 women who were included, 99 had normal folate levels (≥4.0 ng/ml) and 52 had low folate levels. The average age, gravidity, parity, gestational age and HCG levels at the time of presentation were similar between the two groups. The rate of spontaneous abortions was similar among women with low folate compared with those whose folate was normal (39 of 52 (75%) and 66 of 99 (67%), p=0.3). Of the 46 women who delivered a viable newborn, the average gestational age at delivery, birth weights, and 1 and 5 minutes Apgar scores of the two groups were similar. There was no difference in pregnancy outcome among women whose B_{12} levels were low compared with those with normal B_{12} levels. We conclude that among pregnancies complicated by first trimester vaginal bleeding, folate and B_{12} levels appear to have little association with pregnancy outcome. The benefit of pre-pregnancy folic acid supplementation for improving pregnancy outcome awaits further evaluation.

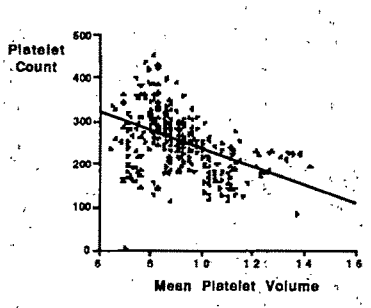
539 MATERNAL CAFFEINE CONSUMPTION AND UMBILICAL ARTERY VELOCIMETRY IN NORMAL THIRD TRIMESTER PREGNANCY. L. Devoe, MD, C. Murray, RN,[x] A.Youssef, MD,[x]. Dept OBGYN, Med.Coll. of Georgia,Augusta, GA.

Most fetuses receive caffeine exposure via maternal ingestion. Since caffeine has vasoactive effects, we sought to determine if its chronic maternal consumption could influence umbilical artery(UA)resistance. We studied UA Doppler velocimetry of 20 normal third trimester fetuses, from 30 to 40 weeks. Serial systolic:diastolic (S:D) ratios of UAs were obtained every 2 weeks. Values from Doppler insonation at 3 different intervals(10 cycles each) were averaged for each session.Using a previously validated questionnaire,10 patients were identified as high caffeine consumers (> 500 mg/day) and 10 as low consumers (< 200 mg/day). Comparison of S:D ratio trends within each group showed no significant time effect(p=.89)or differences between groups (p=.37). Regression plots of maternal plasma caffeine levels at each study vs S:D ratio showed no significant correlation (r=.03, p=.83). The level of maternal caffeine intake does not appear to affect the course of UA Doppler velocimetry observed in normal pregnancy or, by inference, alter fetal umbilical vascular resistance.

540 UMBILICAL CORD γ-GLUTAMYL TRANSFERASE (GGT): IS IT A MARKER FOR FETAL ABNORMALITY? Mordechai Hallak, Stanley M. Berry, Jennifer A. Bichalski,[x] Honor M. Wolf, Mark P. Johnson,[x] Mark I. Evans, David B. Cotton; Dept Ob/Gyn; Wayne State University / Hutzel Hospital; Detroit, MI

Normal values for fetal hematologic parameters, blood chemistries, and liver function tests (LFT's) have been previously established. Elevated GGT is a sensitive marker for hepatic dysfunction even though it is produced by other organs including the pancreas, kidney, and heart. Infection and placental insufficiency have both been associated with elevated fetal GGT levels; hepatic inflammation has been implicated in the former condition and hypoxic hepatocellular damage in the latter. **Material and Methods:** We evaluated LFT's and complete blood counts in 30 consecutive fetal blood specimens obtained by cordocentesis. GGT's were obtained on 25 specimens. The indications for cordocentesis included: fetal malformation (12), red blood cell isoimmunization (6), possible fetal infection (5), oligohydramnios (4), advanced maternal age (1), combined problems (2). Mean gestational age was 26.8 ± 5.0 weeks (range of 19 - 37). **Results:** All fetal hematologic parameters were within normal limits. LFT results were as follows (mean ± SD):

LFT's	Results	Normal Levels
Total protein (g/dl)	3.58 ± 0.78	3.04 ± 0.06
Albumin (g/dl)	2.17 ± 0.42	2.14 ± 0.04
Total bilirubin (mg/dl)	1.63 ± 0.33	1.57 ± 0.06
ALT (GPT) (IU/l)	8.51 ± 4.24	not reported
AST (GOT) (IU/l)	25.23 ± 8.04	21.1 ± 2.0
GGT (IU/l)	138.08 ± 102.6*	24.4 ± 9.6



Conclusions: 1. Fetal GGT levels are significantly ($p < 0.001$) elevated in several abnormal fetal conditions. 2. These data suggest that several seemingly unrelated fetal conditions are associated with mild degrees of liver dysfunction; alternatively, GGT elevations in these circumstances may be related to other organ systems.

543 **RELATION OF TOTAL MATERNAL WATER (TMW), ARTERIAL PRESSURE (AP) AND PROGESTERONE (PROG) TO NEWBORN WEIGHT (BW).** F Mardones-Santander[x], G Salazar[x], F Mardones-Restat[x], J Alvear[x], GJ Valenzuela. INTA, U. Chile, Santiago and Ob Gyn, Loma Linda U., Santiago and California.

Maternal factors that influence have been studied separately, and usually in small samples. We decided to assess the relation of TMW, maternal weight, ponderal index, plasma volume, AP, Hcto, PROG, aldosterone and estradiol to BW. We determined those parameters in a total of 114 normal pregnant women, with a wide range of maternal weights, during the last part of pregnancy. Mean ± SD were TMW= 33.08± 5.5, PROG 182 ± 68.7 ng/ ml, sytolic AP 113± 6.4 and diastolic AP 69.07 ± 8.6 mm Hg. The data was analyzed by logistic regression. BW was positively correlated to TMW ($r=0.31$), PROG ($r=.19$) and AP ($r=.26$). Other classical factors (maternal weight, etc.) became important only when the effect of TMW was removed from the analysis. We concluded that the normal mechanism that produce maternal water retention is important in determining BW. The exact mechanism of how these factors influence BW remains unclear at this time.

544 A COMPARISON OF THE CHANGES IN PLATELET SIZE AND PLATELET COUNT IN PREECLAMPSIA. J J Walker, A D Cameron, C Singer[+], C Fraser[+]. Perinatal Research Unit, Glasgow Royal Maternity Hospital, Glasgow, Scotland, UK.

Platelet count is known to fall in preeclampsia. We have previously shown that rising platelet size may precede the drop in platelet count. The purpose of this study was to investigate the relationship between platelet count and platelet size in patients who were preeclamptic. Three hundred and twenty six primigravid patients with moderate or severe preeclampsia were studied. Blood was drawn and the platelet count and mean platelet volume were calculated using a Coulter Counter S.

There was a significant negative correlation between the platelet count and the mean platelet volume ($r=-0.5$, $p<0.001$). **Conclusions.** These results imply that changes in platelet size is associated with a fall in platelet count. However, the count will often remain in the normal range.

545 **MATERNAL FETAL GLUCOSE GRADIENT.** R.Shiffman, G.Kuo[x], J.Josimovich[x], Dept. Ob/Gyn, Methodist and Brookdale Hospa., B'klyn, NY

Maternal glucose (MG) is thought to cross the placenta by facilitated diffusion. Evaluation of maternal-fetal glucose gradients (Delta) was done at term. **METHODS:** 74 patients with singleton pregnancies and no known diabetes had MG and cord venous and arterial glucose (VG,AG) drawn at delivery. Delta (MG-VG) was calculated as well as FDelta (VG-AG). Correlation coefficient and t-tests were performed using the SPSS program. **RESULTS:** Pearson r and P values are listed below. When comparing MG≤120 to MG>120, there was a highly significant difference. No correlation was found with neonatal weight.

	MG/VG	MG/AG	MG/Delta	MG/FDelta
r:	.8626*	.7468*	.5261*	.4034* *P<.001
	VG	AG	Delta	FDelta
MG≤120:	72.9±1.4	63.2±1.9	17.1±1.1	1.7±1.2
MG>120:	107.5±2.8*	89.0±4*	27.5±3.7*	18.5±1.7*

CONCLUSIONS: At higher MG levels there is a significantly greater Delta, suggesting a placental regulatory mechanism for varying glucose delivery to the fetus. Similarly, the amount of glucose utilized by the fetus (proportional to Fdelta) may also depend on maternal levels.

546 EFFICACY OF PREINDUCTION "DILAPAN" ON LOWERING THE CESAREAN SECTION RATE. GJ Gilson, JF Smith, LB Curet, LA Izquierdo, MS Chatterjee, GM Joffe[x], GO Del Valle[x]. University of New Mexico Hospital, Albuquerque, New Mexico.

The objective of the current study was to investigate whether or not "DILAPAN" (polyacrylate hydrogel) intracervical hydroscopic dilators (DIL) would have an effect on the outcome of oxytocin induction of labor at term. Methodology entailed study of 59 term gravidas randomized to receive preinduction DIL or no pretreatment. All subjects had Bishop scores of 4 or less. Nulliparas and multiparas were equally represented in the two groups. Results revealed that, compared to controls, the DIL group exhibited a significant change in Bishop scores (2.8±1.0 to 5.0±2.0, $p\leq .0001$), but no significant difference in induction to delivery interval (DIL:19.2±9.7 hours, control: 14.9±5.6 hours). Of more importance, there was no significant difference in cesarean section rate (DIL:13 of 29[44.8%], control: 8 of 30[26.7%]), although there was a tendency for DIL subjects to have a more advanced dilatation when they underwent abdominal delivery. Infant weights (DIL: 3118±721, control: 2981±713) and Apgars (DIL:8.6±0.9, control: 8.5±0.8) were not significantly different and no adverse maternal or fetal effects could be attributed to use of the device. Conclusion: Preinduction cervical ripening with DIL does not appear to appreciably lower the cesarean section rate.

547 **RISK FACTORS FOR THE RECURRENCE OF GESTATIONAL DIABETES** F.L. Gaudier[x], M.G. Poist[x], J.C. Hauth, D. Corbett[x]
The University of Alabama Hospitals, Birmingham

We evaluated the recurrence of gestational diabetes mellitus (GDM) by identifying ninety women with a pregnancy complicated by glucose intolerance and whose subsequent pregnancy was managed at our institution. Forty-seven (52%) of the patients had a recurrence of GDM in their subsequent gestation.

	Recurrent (n=47)	Non-Recurrent (n=43)	P
Race (Black)	79%	84%	0.55
Family History	57.4%	46.5%	0.30
Index Pregnancy			
Macrosomia (≥4000g)	23%	7.5%	0.05
Glucose values (mg/dl)			
Screening Test (1 hr value plasma)	189±50	168±39	0.04
GTT - Fasting	110±25	99±22	0.42
1 hour	228±43	205±35	0.01
2 hour	225±60	184±38	0.0004
3 hour	163±54	158±42	0.63
Required Insulin	69%	31%	0.04
Subsequent pregnancy			
BMI ≥35	34.1%	10.0%	0.01
Pre-pg wt. (kg)	83.4±23.2	75.0±22.9	0.09
Wt. gain in pg (kg)	10.9±5.7	13.1±7.0	0.11
Newborn wt. (gm)	3479±732	3359±680	0.42

BMI = Body Mass Index

We conclude that women with a prior history of GDM are at increased risk for recurrence. These patients may benefit from earlier screening for glucose intolerance in their subsequent pregnancies and especially those who are obese, had fetal macrosomia, or required insulin during their previous pregnancies.

548 HbIAc PREDICTS PREGNANCY MORBIDITY IN DIABETICS. R. Figueroa, U. Verma, F. Wiltshire[x], N. Tejani.
Dept. of Ob/Gyn, NY Med. Coll., Valhalla, NY.

Objective To evaluate the correlation on initial HbAlc and adverse outcome in diabetic pregnancies. **Study design** Medical records of 174 pregnancies in diabetic women were reviewed. Information obtained was initial HbAlc value and gestational age (≤12 wks., ≤20 wks., ≤24 wks., >24 wks) when obtained, adverse pregnancy outcome (major congenital malformations, spontaneous abortion, fetal death after viability) and normal outcome. Pregnancies were subdivided into HbAlc ≤9%, HbAlc >9% -≤12% and HbAlc >12%. Data was analyzed using ANOVA and t-tests. **Results** Compared to pregnancies with normal outcome, HbAlc was higher in pregnancies with major congenital malformations (10.2% vs 7.3%; p<0.01), spontaneous abortions (13.3% vs 7.3%; p<.005), and when all adverse outcomes were considered (10.9% vs 7.3%, p<.005). A HbAlc of >12% at ≤12 wks. gestation predicted a 100% morbidity.

TABLE
ADVERSE PREGNANCY OUTCOME (CUMULATIVE NUM.)

HbAlc	GA (Weeks) ≤12	≤20	≤24	ALL
>12%	6/6	10/11	11/13	11/16
>9% ≤12%	2/8	3/17	5/20	7/27
≤9%	0/6	2/18	3/27	11/131

Conclusions HbAlc is a reliable predictor of adverse pregnancy outcome.

549 **FIXED MINIDOSE WARFARIN FOR PROPHYLAXIS OF THROMBOEMBOLIC DISEASE IN PREGNANCY: A SAFE ALTERNATIVE FOR THE FETUS?** Robert S. McDuffie, Jr., M.D., Sanford Peck, M.D.[x], Richard P. Porreco, M.D., Presbyterian/St. Luke's Perinatal Program, University of Colorado Health Sciences Center, Denver, Colorado

Fixed minidose warfarin may be effective prophylaxis for venous thrombosis in high risk patients. Complete anticoagulation with warfarin in the second and third trimester of pregnancy may lead to fetal and maternal bleeding complications. Parenteral heparin by subcutaneous injection or infusion pump is inconvenient, painful and associated with complications of bleeding, thrombocytopenia, and osteoporosis. The following patient offered the opportunity to study the usefulness and safety of minidose warfarin in late pregnancy.

Case Report: A 28 year old para 1 with antithrombin III deficiency suffered a right subclavian vein thrombosis at 18 weeks gestation and was treated with intravenous heparin with resolution. Subcutaneous heparin was substituted for prophylactic therapy but was unsuccessful in prolonging the partial thromboplastic time (PTT) to any degree. A continuous infusion pump was required to assure adequate prophylaxis, but the patient was unreceptive to prolonged therapy of this type. Minidose warfarin (1 mg a day) was offered as an alternative at 32 weeks gestation. Maternal and fetal blood samples were analysed at 33 and 36 weeks gestation.

	33 Week Maternal	33 Week Fetal	36 Week Maternal	36 Week Fetal
PT	12.3 sec.	14.3 sec.	12.3 sec.	13.4 sec.
II	87%	23%	91%	24%
VII	159%	48%	195%	52%
IX	115%	15%	194%	15%
X	121%	22%	152%	37%
Sonoclot	"hyper"	"normal"	"normal"	"normal"
Warfarin	1.0 mcg/ml	0.09mcg/ml	<0.1mcg/ml	<0.1mcg/ml

Conclusion: Fixed minidose warfarin did not result in any clinically significant abnormalities of maternal-fetal coagulation. Some vitamin K-dependent factors in the fetus were mildly depressed. Efficacy of minidose warfarin in pregnancy requires further investigation, though this case study suggests that the fetus is not at increased risk of hemorrhage.

551 LONG-TERM HEALTH OF CHILDREN OF INSULIN DEPENDENT WOMEN

J.E. Converse[x], Dept. of OB/GYN, University of Wisconsin, Madison, WI, M.S. Cranley[x], School of Nursing, University of Buffalo, Buffalo, NY, and L.B. Curet, Dept. of OB/GYN, University of New Mexico, Albuquerque, NM

A retrospective, descriptive study was designed to investigate the health status of children born to insulin dependent diabetic mothers (IDDM). The relationship of the child's health to the maternal obstetrical course was also examined. The convenience sample consisted of 80 children born to 56 predominately married, middle-class, medically insured IDDM mothers who received obstetrical services from a midwestern university perinatal center from the years of 1971 to 1987. The children ranged in age from 7 months to 16 years. Three children had died, 2 in infancy and 1 in childhood.

Conclusion: The results showed that in comparison to general population national health statistics, the children in this study had two to four times greater incidences of child health conditions related to medical, neurological, and developmental problems at birth, in the neonatal period, and throughout childhood. The greater the number of maternal health risk factors, the earlier the infant was born, and the more health problems the child had at birth and in childhood. The differences in child health were not related to the trimester in which prenatal care began with the perinatal program nor correlated with maternal hyperglycemia and elevated glycosylated hemoglobin.

552 MANAGEMENT OF PREMATURE RUPTURE OF MEMBRANES (PROM) : STATE OF THE ART, 1991, Uchenna Nwosu, M.D. Dept. of OB/GYN, East Tennessee State University College of Medicine, Johnson City, TN.

We surveyed all 1,041 members of the Society of Perinatal Obstetricians by signed questionnaire concerning their current practice in the management of PROM at various gestational periods, with regard to induction of labor, use of antibiotics, tocolytic agents and corticosteroids.We received 529 replies, 235 from regular and 294 from associate members.Analysis showed no difference in the practice of the two groups.With respect to labor induction the most controversial periods were 33-35 weeks with mature fetal lungs where 50% will induce from 0-48 hours and 50% will await spontaneous onset of labor, and 19-22 weeks where 48% remained silent.Most responders do not use antibiotics at any time, and most of the antibiotic users do so for a limited period of time only, with ampicillin the overwhelming choice.Most responders do not use tocolytic agents at any time and most users do so therapeutically rather than preemptively, with $MgSO_4$ favored 2:1.Most responders do not use cortiosteroids to enhance fetal lung maturity at any period. This survey indicates need for a study of outcome of newborns induced with mature lungs 0-48 hours following PROM at 33-35 weeks, as compared with similar newborns delivered following spontaneous labor.

553 PERINATAL OUTCOME IN DIABETIC PATIENTS WITH NEPHROPATHY AND RETINOPATHY VS. DIABETICS WITH ISOLATED PROLIFERATIVE RETINOPATHY. Joffe GM, Del Valle GO, Izquierdo LA, Vill M[x], Jones D[x], Gilson GJ, Chatterjee S, and Curet LB, Univ. New Mexico Med. Ctr., Albuquerque, NM

An eight year review of pregnant diabetic patients with nephropathy and retinopathy vs those with isolated retinopathy was completed. Out of 10,500 admissions, 14 patients with both nephropathy and retinopathy and 9 patients with isolated proliferative retinopathy were identified (incidence 0.13% and 0.08% respectively). Patients with nephropathy and retinopathy were older (26.4+/-4.43 vs 21.8+/-2.28 years p=.005), had higher incidence of chronic hypertension (86% vs 0% p=.001), had higher incidence of cesarean section (86% vs 25% p=.01), had earlier gestational age at delivery (34.4+/-2.6 vs 36.8+/-2.41 wks p=.01), and had lower neonatal birth weight (2388+/-785 vs 3214+/-863 gm p=.01). Maternal age of onset of diabetes, gravidity, parity, Hgb A1C, APGAR scores, and incidence of congenital anomaly (12.5% in isolated retinopathy group) were not significantly different. This study demonstrates that isolated proliferative retinopathy may precede development of nephropathy and chronic hypertension and is associated with significantly better perinatal outcome.

554 EFFECT OF GENDER ON PERINATAL OUTCOME IN PREGNANCIES COMPLICATED BY DIABETES.
L.A. Bracero, and, S. Cassidy*, Dept. of OB/GYN New York Medical College, Valhalla, New York

Low birthweight female infants have been shown to have a higher survival rate than low birthweight males. This sex difference in mortality has been attributed to a higher incidence and severity of Respiratory Distress Syndrome in male infants. The purpose of this study was to determine whether there is a sex difference in the morbidity and mortality of infants born to diabetic mothers. A review of 107 newborns from diabetic mothers was performed. There were 63 males and 44 female infants. We looked at demographics, parity, White's classification, glycemic control, blood pressure, Hgb/Hct, mode of delivery, incidence of low birthweight & preterm deliveries and found no statistically significant difference between the groups. There was one female stillbirth as a result of an episode of ketoacidosis in the mother. There was more morbidity in the male group mainly as the result of hypoglycemia (23.8% of males vs 6.8% of females; Relative Risk=3.50; P value=.0208) and need to stay in the NICU $\geq$ 2 days (52.4% of males vs 29.5% of females; Relative Risk =1.78; P value=.0189). It appears that there is a disadvantage to being the male infant of a diabetic mother.

555 OBSTRUCTIVE UROPATHY: A CAUSE OF REVERSIBLE HYPERTENSION IN PREGNANCY. A.J. Satin[x], G.L. Seiken[x], F.G. Cunningham. Dept. OB/GYN, Univ. Texas Southwestern Med. Ctr., Dallas, TX and Dept. Nephrology, Brooke Army Med. Ctr., San Antonio, TX.

Hypertension with deterioration of renal function after mid-pregnancy often signifies preeclampsia and the need for delivery. Over the past 12 years, we have encountered four pregnant women with reversible hypertension related to obstructive uropathy. These women presented between 24 and 35 weeks gestation with mean arterial pressure increased >20 mmHg above pregnancy baseline accompanied by significantly increased serum creatinine (mean increase = 2.5mg/dl). Although pregnancy-induced hypertension was considered initially in all, there was no other evidence for preeclampsia. Ureteral obstruction was confirmed by ultrasound and was associated with congenital urinary anomalies in two, massive leiomyoma in one, and hydramnios in the other. Relief of obstruction by ureteral stent placement or decompression of amnionic fluid volume resulted in resolution of hypertension and a fall in serum creatinine (mean decrease = 2.2mg/dl). Despite this, all four developed recurrent hypertension and/or renal insufficiency within 1 to 7 weeks, necessitating delivery between 31 and 36 weeks gestation. Importantly, delivery was delayed more than 6 weeks in the 3 women in whom stents were placed. We can implicate urinary obstruction as the cause of hypertension because blood pressure control improved after relief of obstruction. In one early report (NEJM, 278:1133,1968) unilateral hydronephrosis was associated with renin mediated hypertension. Studies in men have implicated bilateral ureteral obstruction as a cause of hypertension secondary to salt and water retention. Thus, urinary obstruction has been reported as a cause of reversible hypertension in nonpregnant patients, but to our knowledge, this is the first report of ureteral obstruction with reversible hypertension secondary to the gravid uterus.

557 **A NOVEL THERAPEUTIC APPROACH FOR REFRACTORY HYPEREMESIS GRAVIDARUM**

W Burrows, S Zwick[x], MA Krew, L Dierker, PM Catalano, MetroHealth Medical Center, Case Western Reserve University, Cleveland, Ohio

A two year retrospective analysis was done to evaluate the use of nasoalimentary feeding (Dobhoff tubes) in the therapy of severe hyperemesis gravidarum. At our institution, after an initial attempt to treat hyperemesis on an outpatient basis, failures are admitted for prolonged intravenous hydration and antiemetic therapy. Severe cases were unresponsive to this treatment or required multiple admissions. The charts of 55 patients with an admission diagnosis of hyperemesis gravidarum were reviewed. Seven (13%) received nasoalimentary tube feedings. These 7 included patients with prior pregnancies involving intractable hyperemesis (5), prior elective abortion for hyperemesis (3), multiple admissions for hyperemesis in the index pregnancy (5) and prolonged admission over 7 days (7). These 7 patients had a mean of two admissions prior to initiation of tube feedings. Five cases were considered to be successfully treated for intractable hyperemesis. Two cases were considered treatment failures. In one, the patient was unable to tolerate continued tube feedings, (but had no further hyperemesis). In the other case, symptom relief was transient with multiple subsequent admissions for hyperemesis. In all but this case, no further admissions were required after nasoalimentary feeding began. Two patients continued nasoalimentary therapy after discharge.One patient receiving nasoalimentry therapy electively aborted for a fetal anomaly (holoprosencephaly). Of the 48 who were treated in the standard fashion, 4 (8%) aborted because of hyperemesis. A prospective randomized study is being implemented to evaluate further this low cost alternative to central hyperalimentation.

558 DEPRESSIVE MOOD AT THE BEGINNING OF PREGNANCY

L.Duperron,[x] J.F.Saucier,[x] H.David,[x] Dept. Ob/Gyn, Psychiatry Sainte-Justine Hospital, Montreal, Canada.

The goal of the study was to determine whether there are specific factors which identify patients at increased risk for depression in early pregnancy. Four hundred and twelve primiparous (56.6%) and secundiparous (43.4%) were interviewed in early pregnancy, between the 10th and the 22nd week. They were from all social classes; 55.4% (N: 229) were married, 31.2% (N: 128) were in a stable relationship, 6.1% (N: 25) were single, 1.5% (N: 6) were separated or divorced, 1.5% (N: 6) were separated or divorced and remarried, and 4.4% (N: 18) were separated or divorced and living in a stable relationship. No relationship was found between the social class or the civil status and depressive mood, as measured by the short form of the Beck scale. On the other hand, the following situations in these pregnant women were significantly related to the presence of depressive mood: 1- Having a male child (among secundiparous subjects). 2- Being 35 to 39 of age (as compared with being 20 to 34). 3- Having a weak support system, especially if one finds it unsatisfactory. 4- Having two disturbing persons in their social environment who cannot be avoided. In addition, women whose parents were divorced when they were a child or a teenager, were more often inclined (p.07) to feel depressed when pregnant. Ongoing studies will determine whether these factors identify patients at increased risk of post-partum depression.

559 **SARCOIDOSIS IN PREGNANCY**

J.C. King, Dept. Ob/Gyn, Georgetown University School of Medicine, Washington.DC

Pulmonary sarcoid is a rare complication affecting at most 0.05% of pregnancies. Previously it has been suggested that no special management during pregnancy was necessary for patients with sarcoid since clinical status is rarely changed. We report 6 cases of advanced sarcoidosis occurring between 1985 and 1991 complicating pregnancy. Two patients having undergone pulmonary resections for progressive cavitary disease with one of these patients subsequently developing HIV infection potentially from blood transfusion at the time of surgery. Serial pulmonary function testing revealed reduced vital capacity for all patients. Additionally, there frequently was a significant impairment of diffusing capacity. While the use of steroids should not be withheld, 50% of steroid users developed carbohydrate intolerance requiring either diet or insulin therapy. There were no maternal deaths but there was 100% maternal morbidity from a high frequency of infection with staphylococcus aureus or other pathologic organisms. There was a 16% incidence of perinatal mortality(stillbirth) with a higher than expected frequency of smaller infants. The finding of secondary pulmonary hypertension in two patients underscores the importance of serial cardiovascular assessment. In both patients the development of pulmonary hypertension was not discovered until the middle of the third trimester. While physical examination is often suggestive of pulmonary hypertension, the utility of echocardiography and right heart catheterization will be discussed. A clinical management scheme will be presented.

561 **MILD GLUCOSE INTOLERANCE AND PERINATAL OUTCOME**

S. Coleman[x], B. Campbell, P. Roussis, G. Harbison[x], S. Cox
University of Kentucky, Lexington, KY

This retrospective review was to determine pregnancy complications associated with mild glucose intolerance defined by an abnormal 50 gram glucose screen but a normal 3 hour oral glucose tolerance test (OGTT). During a 34 month period, 822 glucose screens were positive (one hour glucose $\geq$140 mg/dl). Of these, 594 (72%) had a normal OGTT, 108 (13%) had one abnormal value, and 120 (15%) were found to have two or more abnormal values (ie. gestational DM). The study consists of 200 normal controls and 100 patients from each group from which delivery data was available. There was no difference in gestational age at delivery, five minute Apgar scores, or shoulder dystocia (Table). Although the incidence of macrosomia in the normal group (10%) was higher than expected, patients with one abnormal value of the OGTT had a significantly higher risk (19%, $P<0.01$) as did those with two abnormal values (16%, $P<0.05$). The incidence of cesarean section was also significantly higher in these two groups of patients. The results suggest that women with mild glucose intolerance (as evidenced by one abnormal OGTT value) are susceptible to the same pregnancy complications as those with gestational diabetes. These pregnancies have a two-fold increase risk of fetal macrosomia and cesarean section when compared to normal controls. Therefore, it would seem reasonable to incorporate a more aggressive approach to mild glucose intolerance in an attempt to further decrease perinatal morbidity. Patients with an abnormal screen followed by a normal 3 hour OGTT were also noted to have an increase in incidence of macrosomia. This could represent false negative oral glucose tolerance tests and warrants further study to evaluate perinatal morbidity and its prevention in this group.

Table I

	Control N = 200	Nl 3° OGTT N = 100	1 Abnl. N = 100	Gest. D.M. N=100
Macrosomia	19 (9.5%)	13	19**	16*
Cesarean section	24 (12%)	11	20+	31***
Forceps/Vacuum	8 (4%)	11	10	5
Preeclampsia	12 (6%)	7	6	3

* $P<0.05$ ** $P<0.01$ *** $P<0.001$ +p = 0.09

562 NEUROFIBROMATOSIS IN PREGNANCY

A. Weissman,[X] P. Jakobi,[X] I. Zaidise,[X] A. Drugan[X]
Dept. Ob/Gyn, Rambam Medical Center and Faculty of Medicine, Technion, Haifa, Israel.

Neurofibromatosis (NF) is one of the most frequent human genetic disorders. Pregnancy in NF patients is rare and commonly associated with a dismal outcome. We report our experience with 34 pregnancies in 9 NF patients treated at our Center (see Table). Despite previous reports, fertility is not impaired in these patients, although they experience higher rates of first trimester abortion (20.7%), stillbirth (8.7%), and IUGR (13%). Cesarean delivery was effected in 26% of these pregnancies. However, with proper prenatal care, it appears that more than 90% of pregnancies which continue beyond the first trimester end in viable newborns.

Table - Obstetric Data in NF Patients

Pregnancies	Abortions		Deliveries**	
	TOP*	Spontaneous	Vaginal	CS
34	5	6 (20.7%)	17	6

* TOP - Voluntary Termination of Pregnancy

** 2/23 fetuses were delivered as stillbirths

563 **DDAVP IN THE MANAGEMENT OF VON WILLEBRAND'S DISEASE IN PREGNANCY.** Swanbeck J*,Baxi L, Hurlet AM*.Dept. Ob/Gyn, Ped. Hem.,College of P & S, Columbia Univ.,Columbia Presbyterian Med. Center.New York,NY

Two patients (3 pregnancies) with Type I Von Willebrands disease (VWD) with previous significant bleeding episodes, were administered DDAVP (1-disamino-8-D arginine vasopressin) .3ugm/kgm at delivery; one of them for delayed post-partum bleeding as well. Factor VIII levels and VW Factor antigen (VWF:ag) level increased throughout pregnancy, and increased acutely following the administration of DDAVP. Intrapartum blood loss was normal for both patients and no untoward effects of DDAVP were noted. Presented below are data from one patient.

Date	Factor VIII 50-150%	VWF:ag 50-150%	Comments
9/8/89	23%	10%	3rd trimester
11/30/89	60%	27%	at delivery pre DDAVP
11/30/89	190%	55%	at delivery post DDAVP

By accurate prenatal diagnosis of VWD Type and by assay of levels of Factor VIII and VWF:ag an assessment of probability of significant bleeding episodes at parturition can be made, particularly in patients with previous episodes of bleeding diatheses. We conclude that timely prophylactic therapy with DDAVP in patients with Type I VWD can acutely raise levels of Factor VIII and VWF ag and avert acute episodes of bleeding at parturition. This treatment avoids the potential complications associated with human blood products. Potential problems (water intoxication, convulsions), from DDAVP administration during pregnancy noted in previous reports were not observed in our patients. Another patient with VWD is now being prospectively managed under the same protocol.

564 **IMPACT OF A DIABETES NURSE SPECIALIST IN A HEALTH MAINTENANCE ORGANIZATION.** J.L. Davis, B.R. Morgan,[X] J.S. Greenspoon, K. Bloumofe,[X] F. Wall,[X] Dept OB-GYN, Cedars-Sinai Medical Center, Los Angeles, Ca.

We demonstrate the benefits of employing a diabetes nurse specialist (DNS) to provide out-patient management and education in a health maintenance organization. Pregnant diabetic patients requiring insulin who were managed by a DNS during Jan-July 1991 were compared to a similar group delivered in 1989-1990 managed without a DNS. Protocols for care were identical between the two groups, except that the DNS did not admit patients for control or education unless out-patient efforts failed. Maternal and neonatal outcomes and costs were compared (Table). Maternal complications consisted of preterm labor, preeclampsia, and infection. Neonatal complications consisted of RDS & metabolic disorders. There was no difference in outcome, but a considerable savings in hospital days.

Table	Before DNS (N=40)	After DNS (N=22)	P*
Mean mat age (yrs)	31.8±6.23	31.6±6.54	NS
#Gest. diabetics (A2)	65.0%	54.5%	NS
#Pregest. diabetics	35.0%	45.5%	NS
Maternal Complications	30%	27.3%	NS
Neonatal Complications	41.5%	47.8%	NS
Primary C section	21%	23%	NS
Gest. age at delivery (wks)	37.4±2.03	37.0±4.04	NS
Birthwt. (gms)	3342±646	3324±955	NS
#Hospital days	9.1±10.7	4.9±7.4	.0004

*NS = not significant
Values are means ± standard deviations or percentages.

565 DOES A HISTORY OF A SEVERELY AFFECTED ANTI-D ALLOIMMUNIZED PREGNANCY PREDICT FUTURE OUTCOME? D.E. Carlson, L.D.Platt, A.L.Medearis, USC+LAC Women's Hospital and Cedars-Sinai Medical Center, Depts. Ob/Gyn, Los Angeles, CA

It is commonly stated that a pregnancy complicated by anti-D alloimmunization will subsequently have increasingly severely affected fetuses. To test this hypothesis we reviewed eight anti-D alloimmunizaed patients who had: 1.history of a hydropic fetus or newborn who either died (IUFD/NND), required intrauterine transfusions (IUT) or multiple (greater than five) newborn exchange transfusions (XEch); 2. with the same partner had two subsequent pregnancies (A/B) under our outpatient management from 1986 to 1990 at USC/LAC; 3. delivered Rh+ newborns with postive direct Coombs on cord blood.

Pt	Hx	APtx	DHct	HBili	NBTx	Outcome
		A/B	A/B	A/B	A/B	A/B
#1	NND	N/1IUT	31/26	19/21	2Ech/6Ech	DW/DW
#2	XEch	N/5IUT	41/34	18/13	Bil/Bil	DW/DW
#3	XEch	N/N	34/41	11/16	Bil/Bil	DW/DW
#4	IUFD	N/N	46/58	9/7	Bil/Bil	DW/DW
#5	IUFD	N/N	48/60	9/20	N/Bil	DW/DW
#6	NND	2IUT/N	-/48	-/12	-/Bil	IUFD/DW
#7	XEch	N/N	48/45	21/13	Bil/Bil	DW/DW
#8	XEch	N/N	26/45	24/14	5Ech/Bil	DW/DW

Key: NND: Neonatal death IUFD: intrauterine fetal demise N:None APtx:antepartum therapy NBTx: Newborn therapy DHct:delivery hematocrit HBili: Highest bilirubin Bil:Bililites DW:Doingwell None of the patients had a predictive pattern of worsening outcomes. We conclude that one cannot counsel patients concerning future pregnancy outcomes based on previous poor history.

566 ANTEPARTUM FETAL HEART VARIABLE DECELERATIONS: WHEN ARE THEY SIGNIFICANT?

L. McLean, S. Cox, P. Roussis, B. Campbell, F. Miller, University of Kentucky, Lexington, Kentucky

The significance of antepartum fetal heart variable decelerations in pregnancies not at risk for oligohydramnios is uncertain. METHODS: A retrospective review of 2360 nonstress tests was performed. Patients with identifiable risk factors for oligohydramnios (i.e. chronic hypertension, IUGR, post dates) were excluded. Variable decelerations (> 15 bpm, > 15 sec but < 60 sec) were identified in 50 patients and a 4 quadrant amniotic fluid index was obtained. RESULTS: Selected pregnancy outcomes from these 90 patients are presented in Table I.

Table I

	Amniotic Fluid Index		
	< 10 cm	10-20 cm	> 20 cm
n=	23	60	7
intrapartum variables	4 (18%)	9 (15%)	1 (14%)
operative delivery (fetal distress)	2 (9%)	8 (13%)	1 (14%)
meconium	4 (18%)	12 (20%)	1 (14%)
Apgar <7 @ 5 minutes	2 (9%)	0	1 (14%)

*Includes four patients with an AFI < 5 cm.

These results suggest there are no increased incidence of intrapartum complications based on the presence of antepartum variable decelerations. In 12 patients variable decelerations were noted on serial NSTs and they too had no increase in complications. We next evaluated selected pregnancy outcomes based on the indication for obtaining the NST (Table II).

Table II

	Indication		
	Med Comp	Post term (41 wk)	Other
n=	43	15	38
intrapartum variables	7(16%)	4(27%)	3(8%)
operative delivery (fetal distress)	5(12%)	2(13%)	4(10%)
meconium	8(19%)	4(27%)	5(13%)
Apgar <7 @ 5 minutes	2	0	1

Examination of these data reveals an anticipated increased incidence of meconium stained fluid and intrapartum variable decelerations in post term pregnancies. SUMMARY: We conclude from this study that in pregnancies without risk factors for oligohydramnios antepartum variable decelerations are not a poor prognostic sign and do not signal the need for further antenatal testing beyond an AFI.

568 EVALUATION OF INDIVIDUAL DIFFERENCES IN THE RATE OF FETAL HABITUATION.

LJ Groome, CL Neely[x], MA Deason[x], PM Murphy[x], R Walls[x]. Departments of OB/GYN at the University of Alabama at Birmingham, Alabama, and the University of Arkansas for Medical Sciences, Little Rock, Arkansas.

The demonstration of habituation in the human fetus suggests that some degree of learning can be assessed early in life. A measure of habituation is the trials-to-criterion (TTC), which is usually arbitrarily defined as the number of trials until "no fetal response occurs for 2-5 consecutive trials." Purpose: To establish an objective basis for specifying the fetal TTC. Seventy human fetuses at 34-40 weeks received 8 trials of a 1-sec vibro-acoustic stimulus (VAS) with a 10-sec inter-stimulus interval. A behavioral response score (BRS) was determined for each trial based on the intensity of the response (10=most intense). By calculating the ratio of the observed response to what would occur by chance, a significant behavioral change was found to occurr between a BRS of 6-4 and a BRS of 3-0; there was no difference in this ratio for a BRS of 3-0, implying that a score of "3" was behaviorally equivalent to "no response." Once a BRS ≤ 3 was achieved, the BRS in 15% of subsequent trials was > 3; this frequency decreased to <5% if the BRS remained ≤ 3 for either 2, 3, or 4 consecutive trials. Furthermore, following a BRS ≤ 3, 35% of the BRS > 3 occurred in runs of ≥ 2; conversely, following a sequence in which the BRS remained ≤ 3 for ≥ 2 consecutive trials, 85% of the responses with a BRS > 3 occurred as a single, isolated event. Using as a TTC a "BRS ≤ 3 for ≥ 2 trials", 70% of the fetuses habituated by trial 8; conversely, > 85% required >8 trials to habituate using the criteria "no response for ≥ 2 trials." Conclusion: a BRS ≤ 3 for ≥ 2 consecutive trials is a more objective criteria for assessing individual differences in the rate of fetal habituation.

569 HEART RATE AND EYE MOVEMENT ORGANIZATION IN THE HUMAN FETUS AT 38-40 WEEKS.

LJ Groome, KP Singh[x], SL Burgard[x], CL Neely[x], AA Bartolucci[x]. Departments of OB/GYN at the University of Alabama at Birmingham, Alabama and the University of Arkansas for Medical Sciences, Little Rock, Arkansas.

Abnormal state organization has been demonstrated in hydrocephalic and growth-retarded fetuses, and in fetuses of diabetic mothers. However, no measure exists to evaluate state organization independent of behavioral state identification. Purpose: to compare two methods for assessing fetal heart rate (FHR) - fetal eye movement (FEM) synchronization: 1) periods of high (HV) and low (LV) variability in FHR and the presence (EM) and absence (NEM) of FEM were determined visually, and the association between FHR and FEM was expressed as the percent study time for which no periods of LV-NEM and HV-EM were identified; and 2) the maximum cross-correlation coefficient (r_{max}) and the lag at r_{max} (L_{max}) were determined by computer analysis of FHR and FEM data. Twenty fetuses at 38-40 weeks were examined for a total 2051 min (mean 103 min; range 72-150 min). State HV-EM was observed twice as often as was LV-NEM; neither state was identified during 12.4% of the study time. A three-minute moving window was used to calculate r_{max} (mean 0.52; range 0.18-0.77). The relationship between the period of no coincidence and r_{max} and L_{max} was significant (r^2=0.32; p=0.04); however, the low r^2 implies that 68% of the variability is due to other factors. Although this may be the result of inappropriate selection of objective measures, the low r^2 probably reflects the subjective nature of visually assessing FHR-FEM synchronization. Conclusion: Direct computer analysis may provide a more precise measure of fetal state organization.

571 L/S RATIO AS A MARKER OF SEVERE PULMONARY HYPOPLASIA.

H. Harris[x], M. Truesdale[x], and J. Sumners. Sect. Ob/Gyn & Peds. Meth. Hosp., Indpls. IN

Pulmonary hypoplasia has been associated with a number of pathologic conditions in the fetus. Previous reports have suggested that the amniotic fluid L/S ratio may reflect the degree of pulmonary hypoplasia. 4 cases of fetal pulmonary hypoplasia diagnosed clinically or at autopsy had an L/S ratio obtained prior to delivery. 2 cases involved a diaphragmatic hernia, 1 had a bladder outlet obstruction with severe oligohydramnios, and the remaining was a neuromuscular disorder known to be associated with pulmonary hypoplasia (Pena-Shokeir phenotype). In each case, the L/S ratio was significantly below the gestational mean for a normal pregnancy. In 1 patient with diaphragmatic hernia, L/S was 0.6 and 0.9 at 36 and 37 weeks, betamethasone was given at 36 weeks following the initial amniocentesis and spontaneous delivery ensued at 38 weeks with neonatal death from pulmonary hypoplasia. Thus, an abnormally low L/S ratio may be a marker for a lethal form of pulmonary hypoplasia when associated with fetal conditions in which pulmonary hypoplasia is known to occur.

572 **THE EFFECTS OF VIBROACOUSTIC STIMULATION (VAS) ON BIOPHYSICAL PROFILE TESTING (BPP).** Thomas N. Balaskas, M.D., Joseph A. Spinnato, M.D., University of Louisville School of Medicine, Department of Obstetrics and Gynecology, Louisville, Kentucky.

Vibroacoustic stimulation (VAS) of the fetus has been shown to reduce the number of falsely non-reactive nonstress tests while shortening testing time. The objective of this study was to investigate whether VAS results in improvement of abnormal BPP scores and reduces the latency period for appearance of scoring parameters. ***Methods:*** One hundred four (104) high-risk obstetrical patients between 28-42 weeks gestation with BPP scores ≤ 6 were randomized to VAS (n=51) versus no VAS (n=53). Ultrasound evaluation was continued for an additional 15 minute time period to assess for improvement of score and the time of appearance of scoring parameters. ***Results:*** Of 51 patients who received VAS, 26 (50.1%) showed improvement of BPP score while 21 (39.6%) of the 53 patients randomized to no VAS showed improvement in score (p=NS). Time to appearance of BPP parameters (minutes ± SD) in both VAS and no VAS groups revealed:

	VAS	NO VAS	P
Total Score	(n=30)	(n=25)	
	5.66±5.08	10.8±4.0	<.05
Breathing	(n=9)	(n=12)	
	8.11±6.6	11.6±4.4	NS
Tone	(n=11)	(n=9)	
	6.18±5.1	10±3.5	NS
Gross body	(n=10)	(n=4)	
Movement	4.4±3.5	10±4.1	<.05

Conclusions: Although not statistically significant, VAS applied after BPP testing in patients with scores of ≤6 appears to result in improvement of scores when compared to no VAS. VAS significantly reduced the latency period for appearance of scoring parameters compared to no VAS. These data suggest that VAS may potentially be utilized to shorten testing times and to reduce equivocal or falsely abnormal results.

574 UMBILICAL ARTERY DOPPLER VELOCIMETRY DOES NOT IDENTIFY PERINATAL RISK IN CASES OF OLIGOHYDRAMNIOS. J.R. Wax,* L. Paine,* N.A. Callan, C. Gegor,* T.R.B. Johnson, Dept. Gyn/Ob, The Johns Hopkins Hospital, Baltimore, MD.

Background: Since oligohydramnios and abnormal umbilical artery doppler systolic/diastolic (S/D) ratios are felt to reflect uteroplacental insufficiency, we sought a correlation between these two parameters. Since the minority of patients with oligohydramnios suffer perinatal morbidity, we compared the S/D ratio to the non-stress test (NST) as a means of stratifying perinatal risk in cases of third trimester oligohydramnios. **Methods:** One hundred eighty three structurally normal high risk fetuses underwent simultaneous NST, S/D ratio, and amniotic fluid index (AFI) within seven days of delivery. Data collected on each newborn were: birth weight, ponderal index, hematocrit, 1- and 5- Apgar scores, arterial cord pH and base excess, need for resuscitation or intensive care admission, delivery for distress, and meconium staining. **Results:** No significant correlation was found between the S/D ratio and AFI. In 64 patients with oligohydramnios, the sensitivity of the NST was significantly greater than that of the S/D ratio for detecting risk for low birth weight ($p<.05$), abnormal hematocrit ($p<.05$), arterial cord pH <7.20 ($p<.05$), delivery for fetal distress ($p<.0001$), and ponderal index ≤10% for gestational age ($p<.02$). In 119 patients with normal AFI, the NST was significantly more sensitive than the S/D ratio in detecting risk for abnormal hematocrit ($p<.05$), arterial cord pH <7.20 ($p<.05$), ponderal index ≤10% for gestational age ($p<.05$), and meconium staining ($p<.02$). **Conclusions:** The S/D ratio does not correlate with the AFI in a group of high risk pregnancies. The NST is superior to the S/D ratio in identifying risk for perinatal morbidity by a variety of outcomes in our high risk population.

576 USE OF OXYTOCIN IN PATIENTS WITH PREVIOUS CESAREAN SECTION. B.Gross, A.Fleischer, Dept. Ob/Gyn Albert Einstein College of Medicine, Bronx, N.Y.

This is a retrospective study concerning the efficacy of oxytocin in patients with a previous cesarean section. During the period evaluated, 362 patients with prior cesarean sections were identified 248 of which had a trial of labor. The remaining 114 patients had an elective repeat cesarean section. Oxytocin was used for the usual obstetric indications in 70 patients (28%) irrespective of the reasons for the primary cesarean section. In the absence of oxytocin 124 patients (50%) had a vaginal delivery. An additional 46 women delivered vaginally following oxytocin augmentation, bringing the total rate to 67% ($P<.05$). With this approach, the vaginal delivery rate among patients with CPD as the reason for their primary cesarean section was similar to those with other indications for their primary procedure. Among patients with a primary cesarean section for CPD, 57% delivered a larger baby vaginally. There was no increase in maternal or fetal morbidity in the trial of labor groups compared to elective repeat cesarean sections, nor was there increased morbidity associated with the use of oxytocin among patients delivered by the same route.

577 COMPARISON OF MORBIDITY IN CESAREAN-TUBAL VS. CESAREAN HYSTERECTOMY. Mohammed A Bey, Joseph M Miller, Jr., Joseph G Pastorek,II and Harvey A Gabert, LSU Medical Center, New Orleans, LA.

Cesarean hysterectomy (C-Hyst), often an emergency procedure, is an alternative to cesarean with tubal ligation (C-BTL). Patients undergoing scheduled repeat C-BTL (n=45) were compared to scheduled C-Hyst (n=48). Outcome parameters were compared by t-test, chi square or Fisher exact tests as appropriate.

	C-BTL	C-Hyst	p
Blood Transfusion	8/45	12/48	.397
Post Op Comp	0/45	1/48	1.000
Febrile Morbidity	13/45	9/48	.250
Est Blood Loss (cc)	690±259	1101±450	.0001
Pre-Op Hct (%)	34.7±4.5	35.7±3.4	.2373
Post-Op Hct (%)	31.2±3.6	30.9±5.2	.7495
Δ Hct (%)	3.8±2.8	3.6±2.4	.5983
Op Time (min)	75±21	111±28	.0001
Hosp Stay (d)	4.9±1.4	5.2±2.4	.4566
Patient Age (yr)	26.9±5.1	30.9±5.7	.0007
Gest Age (wk)	38.8±1.7	38.4±1.6	.2471
Parity	3.3±1.5	2.7±1.5	.0577

Operating time and estimated blood loss are increased, but the incidence of blood transfusion and post operative febrile morbidity and other complications were not more common. Elective C-Hyst is a reasonable alternative to C-BTL.

578 SURVEY OF OPERATIVE VAGINAL DELIVERY IN NORTH AMERICA IN 1990. S. Ramin, B. Little*, L. Gilstrap, Dept. Ob/Gyn, Univ. Texas Southwestern Med. Ctr., Dallas, TX

Nearly a decade ago, a survey of obstetric forceps training in North America was published. Since then, the American College of Obstetricians and Gynecologists has published new definitions for forcep deliveries. Our purpose was to survey residency training and current use of obstetric forceps in 1990. Of 294 programs surveyed, 201 (68%) responded, encompassing a minimum of 458,000 deliveries. All but 2 (99%) were familiar with the new definitions which were utilized by 161 (80%) of the programs. The frequency of operative vaginal delivery is summarized below:

	0%	<5%	5-9%	10-15%	16-20%	No Response
Outlet	--	48%	33%	10%	5%	4%
Low	--	60%	30%	4%	1%	4%
	0%	<1%	1-4%	5-8%	>9%	No Response
Mid	14%	59%	25%	0.5%	0%	2%
Vacuum	10%	21%	46%	16%	4%	3%

Attending faculty were the primary instructors in 66% of U.S. and 100% of Canadian programs. Simpson forceps were the most common instrument for outlet (46%) and low (43%) deliveries. Kielland's (27%) and Simpson (24%) were most commonly used for midforcep deliveries. As with the earlier survey, hospitals with high cesarean section rates did not perform significantly fewer midforcep operations. In conclusion, operative vaginal delivery is still commonly taught in residency training programs in North America in 1990. However, the rate of midforcep use apparently has decreased over the past decade (86% vs. 99%). This may reflect the newer, stricter definitions for midforceps utilized by 80% of the respondents.

580 **ACUTE APPENDECTOMY DURING PREGNANCY: A RISK FOR PRETERM LABOR ?** C.Hamel*, L.Leduc. Dept Ob/Gyn, Sainte-Justine Hospital, Montréal, Québec, Canada.

Acute appendicitis is the most common non-obstetrical surgical complication of pregnancy. Generally, the emphasis has been on the diagnostic challenge rather than on the effects of appendectomy on the pregnancy outcome. Therefore, we determined if there is an increased risk of preterm labor after appendectomy. We reviewed the charts of 27 pregnant women admitted to Ste-Justine hospital over a 10-year period. The patient's and gestational ages at admission ranged from 17-37 years (mean: 27 ± 1) and 14-37 weeks (mean: 25 ± 2) respectively. The incidence of preterm labor was higher when appendectomy was performed after 30 weeks of gestation (5/11 vs 0/16, p < 0.01). All delivered within 1 week of surgery and none received prophylactic tocolysis. The mean interval between the admission and the surgery was 15.7 ± 2.0 hrs before 30 weeks and 27.6 ± 7.8 hrs after. The overall rate of misdiagnosed appendicitis was 14.8% (4/27) with a lower rate in the group less than 30 weeks (12% vs 18%). CONCLUSION: 1)Appendectomy appears to increase the risk of preterm labor after 30 weeks of gestation. 2) Prophylactic tocolysis should be considered in these cases.

581 **THE RELATIONSHIP BETWEEN THE BISHOP SCORE AT 41 WEEKS AND THE DURATION OF POSTDATES PREGNANCIES.** KB Porter, WF O'Brien, T Nguyen,* L Johnson,* E Brooks,* J Holbrook.* University of South Florida College of Medicine, Tampa, Florida.

A retrospective chart review of 1,268 women delivering at 41 weeks or later over a 3 year period were evaluated. Of this population, 389 women entered a postdates screening program at 41 weeks. One hundred and eight had assured dates having had either a first or second trimester sonogram. When comparing those women with confirmed versus unconfirmed dating, no differences were found in the mean Bishop score, incidence of nulliparity, or in the rate of induction (30%). In both groups those women with unfavorable Bishop scores delivered at a later gestational age.

	% Delivered		
Bishop Score	41-42 wk.	42-43 wk.	≥43 wk.
0-5	47.40	35.84	16.76
6-8	60.38	33.96	5.66
>8	93.75	6.25	0

In conclusion, cervical condition at 41 weeks regardless of dating accuracy strongly predicts the likelihood of pregnancy lasting beyond 42 weeks.

583 Prenatal Care of the Adolescent. C.J. Sims, H.R. Giles, Dept. of Ob/Gyn, Medical College of Pennsylvania/Allegheny Campus, Pittsburgh, PA.

In an effort to provide optimum care of the pregnant adolescent a review of the needs of the adolescent in our community was undertaken. Educators, county officials, health care providers, adolescents and community leaders were interviewed. The consortium agreed upon the importance of early, consistent, quality prenatal care that enhanced the long term quality of life of the adolescent family. The importance of continuation of her education ranked high on the list of needs. Therefore, an agreement was made between the city school board and a local health care provider for school based prenatal care. A consistent team of providers was established. Members included: 1) Educational director of the school-based clinic, 2) Maternal-Fetal medicine specialist with an interest in adolescent pregnancy, 3) perinatal nurse specialist/case manager, 4) school nurse, 5) nurse's assistant, 6) Adolescent medicine specialist (providing long term care for the adolescent and her infant), and 7) psychiatric social worker. The implementation of this model program was an example of a community's combined efforts enacted to address the alarming concerns of inner city adolescents. After two years of operation, the consortium agrees that this program has a salutary impact. This program is depicted as a successful model of a synergistic health care/educational environment.

584 SHOULDER DYSTOCIA: RELATIONSHIP BETWEEN NEONATAL INJURIES AND ACID BASE STATUS. IA Hoskins, P Ehrlich,[1] SA Ordorica, BK Young, RF Porges,[1] Dept. Ob/Gyn, NYU Med. Ctr., New York, NY.

Morbidity with shoulder dystocia (SD) may be due to delayed delivery and asphyxia. We reviewed 13,440 deliveries from 1/1/81 to 5/1/91 to identify SD and correlate severity of injuries with acid base status. There were 81 cases with complete followup in 67 (83%). Neonates were grouped according to severity of injuries. Group I (n=30, 45%) no injuries; group II (n=26, 39%) moderate injuries eg. bruising, hypotonia; group III (n=11, 16%) severe injuries eg. fractures, palsy. Overall incidence of acidosis (pH < 7.20) was 43%. It was 81% in group II vs. 7% and 55% in groups I and III ($p < 0.05$). Of the 6 acidotic neonates in group III, 4 (67%) had palsy whereas 2 (33%) had isolated fractures, $p < 0.05$. Incidences of low (≤ 3) Apgar scores were 7%, 19% and 18% in the 3 groups (NS). There was no correlation between severity of injury and meconium, seizures, hypotonia or apnea. Excessive, prolonged traction on the infant (causing hypotonia, palsy) was associated with neonatal acidosis whereas fractures appeared to expedite delivery and prevent acidosis.

585 FETAL DETERMINANTS OF ASSISTED VAGINAL DELIVERY. M.C. Williams, W.F. O'Brien. Department of Obstetrics and Gynecology, University of South Florida, Tampa, FL

Prior investigations of successful vaginal delivery have identified significant correlations with such factors as fetal weight and maternal pelvic dimensions, while the association with fetal asymmetry, as assessed by the ponderal index (birthweight/length^3), is unknown. Data were compared between 126 control vaginal deliveries, and successful assisted vaginal deliveries for cephalopelvic disproportion (72) and fetal distress (99). Chi-square goodness of fit comparisons between the control group and population norms found them similar for birthweight, crown-heel length, and ponderal index percent for gestational age, while head circumference percent among controls was slightly smaller than expected (mean 47%, $P<0.05$). The three groups were found similar for maternal height, weight, previous cesarean section, labor induction, meconium, gestational age, and birthweight. Ponderal index percent was significantly associated with assisted delivery ($P<0.004$). Logistic regression for need for assisted vaginal delivery found previous successful vaginal delivery ($R=0.23$, $P<0.0001$), ponderal index % ($R=0.16$, $P<0.001$), and head circumference % ($R=0.13$, $P<0.004$) formed a model which correctly assigned 68% of cases with a non-significant model chi-square goodness of fit ($P<0.42$). Maternal height, weight, and history of previous cesarean were not significantly associated. Ponderal index % is correlated with assisted delivery.

	NSVD	CPD	DISTRESS	SIG.
BIRTH WEIGHT %	48	51	42	NS
HEAD CIRCUMF %	47	58	51	<0.04
PONDERAL IDX %	49	40	37	<0.004
UMB ARTERY pH	7.28	7.29	7.22	<0.0001
BASE DEFICIT	3.6	4.2	5.4	<0.0001

587 INDIRECT SONOGRAPHIC GUIDANCE FOR EPIDURAL ANESTHESIA IN OBESE PREGNANT WOMEN DELIVERED BY CESAREAN SECTION

D. Wallace, M.D.[1], L. Gilstrap, M.D., J. Currie, M.D.[1], and R. Santos, M.D.[1]
Departments of Anesthesiology & Obstetrics/Gynecology, UT Southwestern, Dallas, TX

Obesity and edema which obscured lumbar landmarks resulted in technical difficulties and prolonged our attempts to achieve epidural anesthesia. However, indirect sonographic guidance with use of either the Toshiba SAL-32B or RT 3000 GE machine with 5mHz transducer (visual field width 5.6 or 8cm) has allowed us to identify the midline by saggital scan of the easily imaged laminae of lumbar vertebrae 2,3,4; to predict needle depth (ND) from ultrasound depth (UD, skin-to-lamina distance); and knowing UD, the midline, and transducer center site marked where positioned over the 2nd or 3rd interspace before its removal, percutaneously advance a 9.5 or 11.4cm Tuohy needle perpendicularly from the site until epidural puncture (EP). We prospectively studied 36 obese women scheduled for elective repeat C/S. ND was measured by marker and measure, and epidural anesthesia was successfully administered to all patients. Simple linear regression analysis was performed, with strong positive results (See figure).

Plot of Observed Values, Regression Line & 95% Confidence Interval on Predicted Values

Indirect and continuous sonographic guidance studies, designed to determine if sonography reduces complications, are currently being planned.

588 ADENOSINE INDUCES TACHYCARDIA AND LOWERS BLOOD PRESSURE IN THE PREGNANT EWE. Brian A. Mason, MD[1], Brian J. Koos, MD, DPhil. Dept. of Obstetrics and Gynecology, Nicholas S. Assali Perinatal Research Laboratory, UCLA School of Medicine, Los Angeles, CA 90024

Adenosine has recently been approved by the FDA for termination of paroxysmal supraventricular tachycardia (PSVT). Due to its very short half life, this purine nucleoside may be particularly useful in pregnant women with PSVT. Because adenosine can cause tachycardia and hypotension, the relative safety of this agent must be established before it can be recommended for general use in pregnancy. We therefore investigated the effects of graded intravenous infusions of adenosine in three chronically catheterized gravid ewes (>0.8 term). Infusions were increased in a stepwise manner from 25 to 400 μg/kg/min by doubling the infusion rate at five minute intervals. The same procedure was performed in reverse, beginning at 400 and decreasing to 25 μg/kg/min with results being similar in both cases. No significant changes occurred in mean pH, PCO_2, or PO_2. Mean heart rate increased from 110 ± 3.7 to 173 ± 4.3 BPM ($P<0.001$) with statistically significant response ($P<0.05$) noted at infusion rates as low as 50 μg/kg/min. MAP decreased from 85.5 ± 3.4 to 79.4 ± 4.5 mmHg ($P<0.01$). Conclusion: While the effects on MAP and HR are statistically significant, they probably pose no clinical risk to gravidas because the effects are within a range which is tolerated physiologically and are transient. Possible fetal effects of maternal adenosine infusions require further investigation. Supported by HD-18478.

589 FETAL ASCITES FLUID - A NEW SOURCE OF CELLS FOR CHROMOSOMAL ANALYSIS. J.R. Wax,* K.J. Blakemore, G. Stetten,* Dept. of Gyn/Ob, The Johns Hopkins Univ. Sch. of Med. Baltimore, MD.

Background: The optimal source of cells for chromosomal analysis of the sonographically anomalous fetus is influenced by the accessibility of the cells, procedure-related risks, and the speed with which results may be obtained. We have rapidly and reliably performed cytogenetic analysis using cells cultured from fetal ascites. **Methods:** Fetal ascites was obtained during therapeutic paracentesis from two patients at 33 weeks and 19 weeks gestation. Following a differential cell count, ascitic fluid was set up at 10^6 cells/ml of media, stimulated with phytohemagglutinin (PHA), synchronized, and harvested at 96 hours according to a standard lymphocyte protocol. **Results:** In the first patient, the cultured ascites cell karyotype confirmed the diagnosis from fetal blood lymphocytes and amniocytes as 45,X. In the second patient, the ascites cell karyotype confirmed the amniocyte diagnosis of 47,XY,+13. **Conclusion:** Fetal ascites is an easily accessible source of cells for culture and rapid karyotype. The fluid is readily visible sonographically and easily removed without undue fetal risk by ultrasound-guided needle aspiration. More rapid cytogenetic results should be possible as with peripheral blood lymphocytes using shorter culture times.

590 PRENATAL DIAGNOSIS OF BIRTH DEFECTS. A REVIEW OF 67,349 DELIVERIES. D. Ogunyemi[X], P. Brown[X], R. Willis-Hassan[X], M. Hernandez, T. Fukushima. King-Drew Medical Center, Los Angeles, CA.

This study was undertaken to examine the efficacy of current practices of prenatal care in detecting birth defects. Methods: All deliveries from 1982 through 1989 were evaluated; chi-square test was used for statistical analysis. Results: A total of 385 cases of birth defects were identified (5.7/1000). Birth defects were considered amenable to prenatal diagnosis in 250 (66%) cases and not detectable by current technology in 135 (34%). However, the actual number of cases detected by routine prenatal care was only 67 (27%). In 183 potentially detectable cases diagnoses were not made for the following reasons: No PNC (26%); had PNC but was not tested (50%); tested but defect was missed (4%); too young for amniocentesis (30%).

BIRTH DEFECTS	CNS	M-S§	CARDIAC	CHROMOS.	PN Deaths
Detected (67)	45(41%)	5(31%)	2(10%)	11(16%)	39(59%)
Not detec.(183)	64(59%)	11(69%)	19(90%)	63(84%)	45(25%)

(All differences p<.0001) § M-S = Musculo-Skeletal

Conclusions: In this population, the majority of birth defects was not detected prenatally, although only 4% were missed when appropriate diagnostic techniques had been used. To diagnose all potentially detectable cases, the following tests would have been required: Ultrasound (60%); amniocentesis (30%); and fetal echocardiography (10%). A more liberal use of these procedures, including amniocentesis for younger women (<35 y/o), may enhance the rate of detection of birth defects.

591 THE PREVALENCE AND CLINICAL SIGNIFICANCE OF THE ISOLATION OF UREAPLASMA UREALYTICUM IN MIDTRIMESTER AMNIOCENTESIS. M. Mazor, S. Horowitz,[X] R. Romero, C. Walter,[X] M. Glezerman,[X] Depts. of Ob/Gyn, Soroka Med. Center, Ben Gurion Univ., Israel and Yale Univ. School of Medicine, New Haven, CT

The causes of pregnancy loss following midtrimester amniocentesis are unknown. Pre-existing subclinical microbial invasion of the amniotic cavity may be a predisposing factor for membrane rupture and chorioamnionitis following the procedure. The purpose of this study was to determine the frequency and clinical consequences of microbial invasion of the amniotic cavity in women undergoing midtrimester amniocentesis for genetic indications. This study focused on Mycoplasmas (Ureaplasma urealyticum and Mycoplasma hominis) because these are the microorganisms most frequently isolated in cases of microbial invasion of the amniotic cavity. Materials and Methods: Amniocentesis for genetic indications was performed in 193 consecutive patients. Amniotic fluid was cultured for Mycoplasma hominis and Ureaplasma urealyticum using methodology previously described. Cervical cultures were obtained following amniocentesis. Follow-up was available in all patients. Results: The prevalence of positive amniotic fluid cultures was 2.5% (5/193). Ureaplasma urealyticum was the only isolate from amniotic fluid. The rate of spontaneous preterm delivery was higher in patients with a positive amniotic fluid culture than in patients with a negative culture (42.8% [3/7] vs. 5.3% [10/186]; p <0.05). One patient with a positive culture ruptured her membranes one hour after the amniocentesis. (All patients with a positive amniotic fluid culture had Ureaplasma urealyticum isolated from the lower genital tract.) Conclusions: 1) Microbial invasion of the amniotic cavity with Ureaplasma urealyticum was detected in 2.5% of women undergoing midtrimester amniocentesis. 2) Pre-existing microbial invasion of the amniotic cavity can be responsible for a fraction of post-amniocentesis pregnancy loss. 3) Colonization of the amniotic cavity with Ureaplasma urealyticum is a risk factor for preterm delivery. 4) Routine culturing of amniotic fluid for Mycoplasmas must be considered at the time of midtrimester amniocentesis.

592 **FOUR YEAR REVIEW OF PRENATAL DIAGNOSIS BY PUBS.** R.D. Wilson, D.F. Farquharson[x], D. Shaw[x], B.K. Wittmann[x]. Dept. Ob/Gyn, Univ. British Columbia, Grace Hospital, Vancouver, B.C. Canada.

Fetal evaluation by percutaneous umbilical blood sampling has allowed a more rapid diagnosis of fetal conditions. We present our four year experience with 214 PUBS procedures. Indications included fetal anomalies requiring chromosome diagnosis in 135 (63%), evaluation of fetal platelets 49 (23%), maternal Rh disease 24 (11%), and miscellaneous indications in 6 (3%). For the chromosome indication 122 were for fetal karyotypes and 13 for fragile X evaluation. The number of failed procedures was 15 (7%). The number of post-procedural deaths was 4 (1.9%), and neonatal deaths 2 (0.9%) with an overall loss rate of 2.8%. The most common malformations necessitating chromosome diagnosis were intrauterine growth retardation (21), fetal hydrops (17), central nervous system abnormalities (15), and multiple congenital anomalies (14). Fetal blood sampling to evaluate fetal mosaicism was used in 7 cases where CVS or amniocentesis had indicated possible mosacism. Gestational ages at the time of the procedure was equally distributed between 5 gestational age groups - less than 20 weeks, 20-25 weeks, 25-30 weeks, 30-35 weeks, and greater than 35 weeks.

593 TRANSABDOMINAL-GUIDED TRANSVAGINAL CHORIONIC VILLUS SAMPLING. LP Shulman, JL Simpson, OP Phillips[X], RE Felker[X], DS Emerson[X], S Elias. University of Tennessee, Memphis.

Transvaginal chorionic villus sampling (CVS) using *endovaginal* ultrasound guidance has been previously described to obtain chorionic villi from patients who desire CVS but have placentas inaccessible to either transabdominal (TA) or transcervical (TC) approaches. We describe here use of *transabdominal*-guided transvaginal CVS in 9 women undergoing CVS. An ultrasound examination is first performed to evaluate placental location and presence of intervening structures (e.g., bowel, blood vessels). TA ultrasonography is then performed to visualize the needle used for anesthetic infiltration. If the needle is clearly visualized, we proceed with TA ultrasound-guided transvaginal CVS. A 35 cm, 18-gauge aspiration needle (Cook Urological Inc) is inserted through the posterior wall of the vagina and uterus into the placenta. A 20 cc syringe containing 4 cc transport medium is attached to the needle hub. Chorionic villi are obtained by 10-15 aspirations of the syringe plunger to 20 cc negative pressure; upon completion, the needle is removed under continuous negative pressure. Patients are monitored for 15 minutes for any untoward effects (e.g., hemorrhage) prior to discharge. **RESULTS:** We have performed this CVS technique to obtain chorionic villi from 9 patients (mean gestational age: 11.2 weeks). Adequate samples were obtained with only a single needle passage in all 9 women. Direct and culture cytogenetic results were obtained from all 9 specimens and all analyses revealed normal complements. There were no immediate or long-term complications (i.e., maternal infection, hemorrhage, pregnancy loss). Six patients have been delivered at term of healthy infants, whereas 3 pregnancies are continuing uneventfully. **CONCLUSION:** Transabdominal-guided transvaginal CVS is a useful method for obtaining chorionic villi in a select group of patients, specifically those women with placentas located posteriorly within a retroverted, retroflexed uterus. However, CVS by either transcervical or transabdominal aspiration is preferable until the safety and accuracy of the transvaginal approach is known.

594 **EFFECTS OF PRENATAL EXPOSURE TO METHANOL AND T-BUTANOL IN LONG EVANS RATS.** E.L. Abel[X] and P.J. Bilitzke.[X] Department of Obstetrics/Gynecology and Fetal Alcohol Research Center, Wayne State University School of Medicine, Detroit, MI.

Pregnant rats consumed liquid diets containing methanol (1.6%, 0.9%, 0.6% v/v) or t-butanol (10.9%, 1.3%, 0.65% v/v) beginning on gestation day 8 until parturition. Each group had its own pair-fed controls. After parturition mothers were put on lab chow ad lib. Methanol did not affect fecundity but reduced maternal weight gain, decreased litter sizes (from 12 to 5 pups per litter), increased perinatal mortality (from 4% to 25%) and postnatal mortality (from 0% for controls to 100% for offspring in the highest dose group), and decreased weights at weaning for survivors in the other methanol groups. Since methanol treated animals did not differ from pair fed controls in weight gain, these effects could not be due to decreased maternal weight gain. T-butanol reduced maternal weight gain, litter sizes (from 11 to 3 pups per litter), birth weights, and weights at weaning and increased perinatal mortality (from 2% to 14%) and postnatal mortality (from 6% to 100%). These results indicate that prenatal exposure to methanol and t-butanol can result in very high postnatal mortality rates. These rates are much higher than we have previously seen in connection with prenatal alcohol exposure. Supported in part by grant P50 AA07606 from NIAAA.

595 AMNIOTIC FLUID VOLUME AND PRENATAL GROWTH DISTURBANCES IN FETUSES WITH MONOSOMY X OR XO MOSAICISM. J Cullen[X], J Abramowicz, L Metlay[X], Depts. Ob/Gyn & Pathology, Univ. Rochester Sch. of Med., Rochester, NY

Sonographic and/or autopsy information on 13 fetuses with Monosomy X and 6 fetuses with Turner mosaicism (XO/XX or XO/XY) was retrospectively reviewed. Fetal growth was assessed by sonographic parameters and/or autopsy measurements. Amniotic fluid volume (AFV) was recorded from ultrasound (U/S) reports. Pathologic data regarding structural anomalies was recorded as well. Altered fetal growth was demonstrated in 8/10 fetuses with Monosomy X and 2/5 fetuses with Turner mosaicism. In both groups, normal AFV was seen prior to 16 weeks gestation (GA). U/S data after 16 weeks was available for 11 fetuses with Monosomy X, and severe oligohydramnios was demonstrated in 10 of these. U/S data was available for 5 fetuses with XO mosaicism. 4/5 pregnancies underwent termination prior to 20 weeks GA. Serial U/S data was available for the fifth pregnancy; normal AFV was seen until 25 weeks GA, at which time oligohydramnios was identified. No structural anomalies were found in the mosaic population. Frequently noted structural anomalies in fetuses with Monosomy X included cystic hygroma, hydrops fetalis, hypoplastic aortic arch, and single umbilical artery. No renal anomalies were identified. Placental findings, though suggestive, were nondiagnostic. Conclusion: Fetal growth alterations and severe oligohydramnios frequently occur in association with Monosomy X. The etiology of these findings remains unclear.

597 RACIAL DIFFERENCES IN BIRTH DEFECTS IN A LOW INCOME MINORITY POPULATION. A REVIEW OF 67,349 DELIVERIES. D.Ogunyemi,* P.Brown,* R.Willis-Hassan, T.Fukushima, King/Drew Medical Center, Los Angeles, CA.

Previous studies have suggested that the high perinatal mortality rate in low income Black women may be due in part to congenital defects. The purpose of this study was to determine if there were differences in the prevalence and types of birth defects in low income Black and Hispanic women and assess the associated prematurity and mortality rates. All deliveries from 1982 to 1990 were included; the data were evaluated with Chi-square test. Results:

	Blacks	Hispanics	
No. Cong. Anomalies	81	295	
Rate/1000	10.7	7.6	p<0.0001
CNS defects	28%	31%	p<0.05
Facial-oral defects	9%	16%	p<0.05
Cardiac defects	14%	6%	p<0.05
Genital defects	7%	2%	p<0.05
Chromosomal defects	14%	21%	p<0.05
LBW	53%	30%	p<0.0001
Preterm births	42%	20%	p<0.001
Postdate pregnancy	10%	21%	p<0.001
Perinatal mortality rate	221	237	NS

Conclusion: There was a significantly increased incidence of birth defects in Blacks vs Hispanics, with a different pattern distribution (cardiac vs chromosomal). Birth defects in Blacks were more likely to be accompanied by low birth weight and prematurity. The similar mortality rate in both groups suggests that defects in Blacks are more compatible with survival.

600. **PURE PLACENTAL TRISOMY 16 ASSOCIATED WITH A 46,XY INFANT AND SEVERE PREECLAMPSIA: A CASE REPORT.** K. K. Vernof [x], J. A. Ney, G. W. Dewald [x]. Departments of Ob/Gyn and Cytogenetics, Mayo Clinic. Rochester, Minnesota.

We report the clinical presentation, placental pathology, and cytogenetic studies of a rare case of trisomy 16 placenta associated with a 46,XY infant. The patient, a 32-year-old gravida 2, para 1, was referred at 32 weeks gestation for evaluation of hypertension, proteinuria, and hyperreflexia. Shortly after admission, an emergent cesarean section was performed for prolonged fetal bradycardia. A 1120 gram male was delivered, and although he weighed less than the 10th percentile for age, the infant appeared normal. The placenta was grossly abnormal with multiple, diffusely located hydropic villi. Cytogenetic studies revealed 29 of 29 metaphases from the placental biopsy with trisomy 16 and 50 of 50 cells from cord blood with 46,XY. We hypothesize nondisjunction very early in development as an explanation for a trisomic placenta and karyotypically normal neonatal lymphocytes. Aneuploid placentation is a possible etiology for the placental insufficiency, severe preeclampsia, and intrauterine growth retardation observed in this case.

601 **NEW EXPERIENCES WITH THE PRENATAL DIAGNOSIS AND THERAPY OF FETAL PARVOVIRUS B19 INFECTION.** W. Holzgreve, T. Schwarz, M. Evans, B. Holzgreve, Dept. Ob/Gyn, Univ. of Münster, Dept. of Virology, Univ. of München, FRG; Wayne State Univ./Hutzel Hospital, Detroit, MI

Maternal parvovirus B19 infection in pregnancy causes hydrops fetalis leading to fetal death in up to 10% of the cases. After anemia due to aplastic crisis is confirmed by cordocentesis, intrauterine transfusions are now routinely performed by our group. In our series in one case, however, we encountered intrauterine fetal demise despite successful treatment of hydrops. This may be due to a direct cardiac effect of B19 in utero. We also found that the sensitivity of dot blot hybridization for the detection of prenatal B19 infection is only sufficient in fetal blood with a high level of viremia. We further encountered a case of severe hydrops, eight weeks after onset of maternal exanthema, in which at the time of aplastic crisis in the fetus both maternal and fetal blood were negative for anti-B19 IgM. In this case fetal infection could ultimately be confirmed by PCR in amniotic fluid, ascites and fetal blood. The dramatic life-threatening state of the fetus required intrauterine transfusions already before laboratory confirmation of fetal B19 infection was available.

602 **THE IMPACT OF PREVIOUS LOW BIRTHWEIGHT ON FETAL GROWTH IN THE CURRENT PREGNANCY.**

RL Goldenberg, HJ Hoffman,* SP Cliver,* GR Cutter,* RL Copper.*
University of Alabama Hospitals, Birmingham, Alabama.

A history of low birthweight (HLBW) in a previous pregnancy is associated with low birthweight in the next pregnancy. However, the effect of HLBW on the gestational age at delivery and various newborn anthropometric measurements is less clear. In 1545 pregnancies, 38% with a HLBW (defined as a birth <2750 g) and using multiple regression techniques adjusting for maternal race, age, height, weight, weight gain, hypertension, smoking, alcohol and drug use, the effect of HLBW was evaluated. Women with HLBW had a 23.4% rate of preterm delivery compared to 9.5% in women without this history. ($p < .001$) The mean gestational age for HLBW was 37.7 ± 3.2 weeks vs 38.7 ± 2.9 wks in women without HLBW. ($p < .001$) The mean birthweight for HLBW women was 2913 ± 669 g vs. 3219 ± 651 g for non-HLBW women ($p < .001$), a difference of 306 g. Of this a difference of 128 g was associated with preterm birth, with 178 g associated with differences in size in term births. Smoking was associated with a decreased weight of 149 g and black race a decrease of 148 g, with maternal hypertension, drug use, height, weight, and weight gain all having a significant impact on weight. However, even adjusting for these factors, HLBW was associated with a 107 g reduction in birthweight. While all anthropometric measurements were less in infants with maternal HLBW, the differences in length measurements and all skinfolds were not significant. However, the head, chest, abdomen, arm and thigh circumferences as well as the ponderal index were all significantly smaller. These results suggest that the pattern of growth restriction associated with HLBW resembles the condition described as asymmetric growth retardation. However, because the skinfold measurements were not significantly reduced in relationship to HLBW, the pattern of growth restriction associated with HLBW is not typical of asymmetric growth retardation.

604 **ONE AND 5-MINUTE NEONATAL OXYGEN SATURATION: CLINICAL CORRELATIONS:** D.Faustin, B. Podbielski,[x] D.Gotlin,[x] Y. Fuchs,[x] S. Mccalla,[x] K. Violaris,[x] H. Minkoff, Dept OB/GYN, SUNY/Health Science Center, Brooklyn, NY. **Introduction:** Successful adaptation of newborns to extrauterine life depends on their ability to carry oxygen in sufficient amount to vital organs. Little is known however, about how useful noninasive O_2 saturation monitoring can be in the delivery room during early adaption. **Materials and Methods:** We studied the umbilical cord oxygen saturation (O_2 sat) at birth and compared it with the 1 and 5-minute transcutaneous neonatal O_2 Sat in two groups of term infants: Group A comprised 14 neonates with no abnormal fetal heart rate patterns during labor and no difficulties at delivery; Group B, 10 newborns with such complications. The prenatal course was normal in both groups and delivery occurred between 38 and 42 weeks. Mean cord pH and O_2 Sat at birth, O_2 Sat at 1 and 5 minutes (pulse oximeter SENTINEL 2,000) and change in O_2 Sat from 1 to 5 minutes were compared between groups A and B. Student t-test and X^2 were used for statistical analysis with $p<.05$ considered significant. **Results:**

	Mean Birth Cord pH	O_2 Saturation birth	1 min	5 min	Decreased in O_2 Sat from 1-5 min (by at least 5%)
Group A n=14	7.31±.05	38.8±22	66.8±17	89.4±10	0
Group B n=10	7.25±.05	29.5± 31	85±11.5	81.0±12.7	7
Signifance	p<.02	NS	p<.01	NS	p<.005

There was no statistical difference in Apgar scores at 1 and 5 minutes between the two groups. **Conclusions:** There was a significantly lower mean cord pH at birth between groups A and B. In this preliminary study a decrease in O_2 saturation from 1 to 5 minutes by at least 5% was significantly associated with fetal monitoring signs of fetal distress. This may represent a compensatory mechanism to maintain adequate neonatal tissue oxygenation in the midly acidotic neonate.

606 FDCREP- A DATABASE DESIGNED FOR ANTENATAL DIAGNOSTIC SERVICES. D. Lagrew, H. Doan[X], R. Steiger, Dept Ob/Gyn, Saddleback Memorial Medical Center, Laguna Hills, CA., and Univ. of California, Irvine, Orange, CA.

Antenatal diagnostic centers follow patients with a range of prenatal diagnostic services which including ultrasound, genetic sampling and fetal well being studies. A comprehensive database was developed to collect data, generate reports and analyze results of diagnostic services. The application was developed in RBASE, a PC-based database language. FDCREP is operating efficiently on a network system with 9 work stations. Data entry has been expedited by numeric coding. Redundant entries are minimized so that the system is time efficient. After entering data on 2932 patients, 4155 ultrasounds, 972 amniocenteses and 3479 antepartum tests, the database occupies 6.4 Meg of disk space. Data entry forms for patient demographics, past medical history, ultrasound, amniocentesis, and fetal testing have been developed. Ultrasound calculations are made at the time of entry. Reports are generated for ultrasounds (gynecologic, 1st trimester, obstetrical), fetal well being (CST,NST,BPP,AFV), and amniocentesis (letter, tabular). In addition chronologic summary reports of fetal well being results can be produced. Summary reports on numbers of tests, types of tests and referral usage are generated. The system allows for quality assurance analysis and research statistics. In summary a comprehensive database for antenatal services has been developed which requires a minimal amount of memory for archiving.

607 LDLOG - A DATABASE DESIGNED FOR SUMMARIZING AND MAINTAINING LABOR AND DELIVERY STATISTICS. D. Lagrew, H. Doan[X], R. Steiger, Dept Ob/Gyn, Saddleback Memorial Medical Center, Laguna Hills, CA, and Univ. of California, Irvine, Orange, CA.

Rapid and accurate statistics of labor and delivery information are required for hospital, local and state agencies. Such analysis allows for utilization analysis and quality improvement. In order to expecite entry and analysis a computerized labor and delivery database was developed. Written in RBASE, a PC-Based database program, the forms were developed with maternal and neonatal information. Numeric coding has allowed efficient storage with nearly 6000 deliveries being stored in 3.7 Meg of hard disk space. The efficient use of memory utilized by this program allows for the archiving of many years of data on one hard disk. A monthly summary including labor and delivery statistics, log of deliveries, and physician statistics are generated by the application. A breakdown of cesarean rates, indications and VBAC attempts are generated. Individual cesarean section reports analyze each physician's rate and risk factors. Summary logs by physician can be generated. The results are utilized for quality improvement and utilization review. The timely feedback has allowed physicians to evaluate their own practice patterns.

608 A MULTI_USER PC AND MACINTOSH PERINATAL ULTRASOUND DATABASE FOR CLINICAL AND RESEARCH USE.

Beattie RB, McLaughlin P[X], Dept. Obstetrics/ Gynaecology, Queens University Belfast, Northern Ireland.

A customised ultrasound database based on commercially available software (Omnis 5- Blythe Software) has been developed to meet the service and research needs of a regional referral unit with file sharing on a mixed PC and Apple Macintosh network. The user-interface is predominantly icon driven and affords easy and rapid entry of data with minimal typing and "point and click" selection of most options. The hierarchical relational database design permits unlimited entry of multiple pregnancies and ultrasound examinations with easy searching using standard and user-defined searches to identify mothers, fetuses or ultrasound examinations which meet the search criteria. Biometric and menstrual data are used to calculate gestational age and estimated fetal weight based on published formulae and to generate customised pregnancy specific growth curves based on an individual mother's demographic data and past obstetric history. Data export to statistical and graphical programmes is easily accomplished whilst textual reports including management reccomendations are generated for clinical use and output to file, screen or printer as required. Doppler studies and ultrasound guided procedures such as CVS, Amniocentesis and Cordocentesis are catered for and a simple Perinatal Outcome module is included to allow the system to be used as a stand alone Perinatal database.

609 PRETERM BIRTH PREVENTION IN A LARGE MEDICAID POPULATION. R.C. Floyd,[X] R.W. Martin, K.S. Gookin,[X] W.E. Roberts, B.N. McLaughlin,[X] J.C. Morrison, Dept. Ob/Gyn, Univ. Mississippi Med. Ctr., Jackson, MS

Objective: Determine the results of a comprehensive program of premature birth prevention in Medicaid women. Population: Over a 70-month period, 4008 pregnant Medicaid patients (Group I) from 47 states received patient education, frequent cervical examinations, daily nurse contact and home uterine monitoring (Tokos Medical Corp., Santa Ana, CA). These were compared to a matched group (II) of women from one state (MS) who received high-risk standard care (N=91). Those delivered for medical indications or because of patient/physician non-compliance were not included (N=996, 20 respectively). Main Outcomes Measured: In this retrospective study, the gestational age at diagnosis of preterm labor (PTL) and delivery, interval between tocolysis and birth in those with PTL, incidence of PTL, and number delivering delivering preterm were recorded. Results: In the 4008 patients there were 8702 risk factors, 2280 (26%) were for PTL during the current pregnancy. Preterm delivery or PTL in a prior pregnancy and multifetal gestations accounted for 43%. Multiple risk factors comprise the other 31% of monitored subjects. The risk factor percentage was similar in Group II.

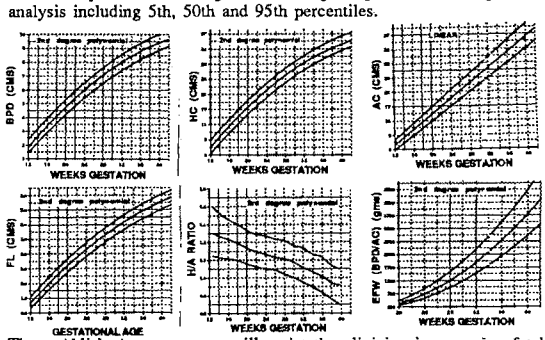
Group	Number	PTL	GA at Diagnosis	PTD	GA at Delivery
I	3012	65%	30.0	21%	265 ± 14 d
II	71	61%	29.3	46%	238 ± 12 d

The percentage of women with PTL in each group was similar as was the gestational age at diagnosis of PTL. The gestational age at delivery ($P < .001$) was lower and the number delivering < 37 weeks ($P < .001$) was higher in the group receiving standard care. Conclusions: In a large Medicaid population, a comprehensive program of intensive perinatal nurse assessment, ambulatory uterine monitoring, and aggressive provider care rendered better results concerning preterm delivery percentage than did a program of high-risk care alone.

611 FETAL RENAL BIOPSY: TECHNIQUE DEVELOPMENT. W.A. Campbell, H.T.Yamase,* C.M.Salafia,* A.M.Vintzileos, J.F.Rodis. University of Connecticut Health Center, Farmington, Ct.

Intrauterine vesico-amniotic shunting for fetal obstructive uropathy, can prevent irreversible renal damage which causes renal dysplasia. Technical success has been achieved. However, current case selection criteria using fetal urine electrolyte profile and ultrasound appearance, have shortcomings. We hypothesize that a fetal renal biopsy might detect dysplasia and improve case selection. This study reports initial work towards defining an adequate needle gauge for fetal renal biopsy. **Methods:** Fresh autopsy kidney specimens from 16 to 40 weeks were used. Needle biopsy aspiration was obtained using 20, 18, 16, &14 gauge needles. Biopsies underwent fixation and preparation for histologic examination. Biopsy specimens were evaluated for the recognizable presence of cortex and medullary structures. Biopsy grading: completely adequate (CA)-both cortex & medulla present, partially adequate (PA)-only cortex or medulla present, not adequate (NA)-only part of cortex or medulla present, & no sample (NS)-tissue did not survive processing. **Results:** 75 biopsies were taken from 18 kidneys: 20g (17), 18g (20), 16g (19), 14g (19). Of these, 39/75 (52%) were CA, 24/75 (32%) were PA, 2/75 (3%) NA, and 10/75 (13%) NS. Needle gauge evaluation Table 1.

	20 gauge	18 gauge	16 gauge	14 gauge
CA	35.0 %	25.0 %	69.0 %	79.0 %
PA	47.0 %	35.0 %	26.0 %	21.0 %
NA	6.0 %	5.0 %	0.0 %	0.0 %
NS	12.0 %	35.0 %	5.0 %	0.0 %



Summary: Adequate biopsies (CA,PA) were obtained in 84% of the specimens; 62% were CA. The 16 & 14 gauge needles give the best results. However, the aspiration technique fragments the specimen; small fragments are lost during processing and account for NA and NS results. A cutting biopsy may avoid this and provide a better idea of a needle gauge adequate for evaluation.

612 **CHEEK TO CHEEK DIAMETER IN SONOGRAPHIC ASSESSMENT OF ABNORMAL FETAL GROWTH**
Jacques S. Abramowicz, M.D., David M. Sherer, M.D., James R. Woods, Jr., M.D., University of Rochester, Rochester, NY

The fetal cheek to cheek diameter (CCD) and its growth have previously been described in 200 normal control pregnancies (SPO 1991, Abstract #33). The CCD was found to be linearly correlated to gestational age (GA) from 20 to 41 weeks. The CCD/BPD ratio was almost GA independent (ranging from 0.6 ± 0.08 to 0.7 ± 0.08). In the current study, we evaluated the CCD and CCD/BPD ratios in 110 fetuses with the following growth disturbances: IUGR, EFW <10th percentile (n=16) and macrosomia, EFW >90th percentile with (n=30) or without (n=64) maternal diabetes mellitus. Both CCD and CCD/BPD ratios were significantly smaller in IUGR as compared to our normal control group (p=0.0001). Macrosomic fetuses of nondiabetic (p=0.017) and diabetic women (p=0.0009) demonstrated larger CCD's than the control group. The CCD/BPD ratios of macrosomic fetuses were also different from the control group with higher significance in the diabetics (p<0.00001) than the nondiabetics (p=0.05). Subsequent to this study, diabetic mellitus was suspected in the third trimester in three women with no prior prenatal care, solely on the basis of high CCD and CCD/BPD ratios and later confirmed by chemical testing.
CONCLUSION:The CCD is an effective measurement in the evaluation of subcutaneous tissues and reflects nutritional status in fetuses with normal and abnormal growth.

613 **LONGITUDINALLY ESTABLISHED FETAL GROWTH CURVES BASED ON 6,048 ULTRASOUND EXAMS.** W. Cusick[X], A. Vintzileos, D. McLean, D.Nardi, Univ. of CT Health Center, Farmington, CT

Existing fetal growth curves, including common biometric parameters and weight estimation, have traditionally been constructed using cross-sectional data obtained from a limited number of patients. This retrospective study sought to develop longitudinal growth curves throughout gestation in a large number of patients followed by serial ultrasound evaluations at the University of Connecticut Health Center. Patients were referred for a wide range of indications. Singleton, well dated pregnancies without anomalies detected by ultrasound, were followed with serial ultrasounds throughout gestation. A total of 6,048 ultrasound evaluations were performed on 2,419 patients (mean exams/patient: 2.5, range 2-7). The following curves of commonly used ultrasound parameters were generated using computer assisted regression analysis including 5th, 50th and 95th percentiles.

The established normograms will assist the clinician in assessing fetal growth throughout gestation in a variety of high risk situations.

616 HUMERUS LENGTH MEASUREMENT AS A SCREENING METHOD FOR DOWN SYNDROME. D. Oberkrom[X], A. Fleming, D. Bonds[X], Dept. Ob/Gyn, Creighton Univ., Omaha, NE

In an attempt to diagnose Down syndrome (DS) by non-invasive means, we undertook the present study. FitzSimmons reported humerus length shortening in autopsy studies done on fetuses affected with DS. This was confirmed by antenatal sonographic studies performed by Benacerraf and Fleming. The purpose of this study was to see if sonographically determined humerus length could be used to identify fetuses with DS in patients at increased risk. Humerus length was measured in 60 patients with known risk factors for DS, including those with low maternal serum AFP, advanced maternal age, and a prior fetus affected with trisomy 21. Two humerus length (HL) measurements greater than 2 standard deviations below the mean established by Romero and Jeanty were observed. Of these, one had DS and the other, although genetically normal, had multiple congenital anomalies. Normal genetic outcome was noted in the 58 normal scans. These results support our previous findings and suggest that a HL measurement should be utilized as a screening method for DS.

618 **MATHEMATICAL MODELING OF FETAL WEIGHT PREDICTION**

C.Exacoustos[x], P.Rosati[x], A.Caruso[x], S.Mancuso[x].
Dept. Ob/Gyn, Catholic University, Rome, Italy

Previous studies suggested that birth weight (BW) prediction was enhanced by using formulas specifically derived from different gestational periods.In 440 pregnant patients between 24-40 weeks of gestation an ultrasound examination was performed within 72 hours of delivery. The following ultrasound parameters were considered: biparietal diameter(BPD), head circumference (HC),mean abdominal diameter (AD), abdominal circumference(AC), femur(FL) and humerus length(HL). Ultrasound measurements were correlated to fetal weight with multiple stepwise regression analysis in three different gestational periods: before 32 wks, 33-37 wks and 38-40 wks.The best mathematical models in predicting fetal weight in the different gestational periods were selected on the basis of the largest value of R^2 and the lowest mean unsigned and signed percent error : BW= 705.05-11.428 AC + 0.083 BPD^2 + 0.036 AC^2 + 0.244 FL^2 before 32 weeks; BW= -1374.397 + 0.128 BPD^2 + 0.198 AD^2 + 0.298 HL^2 between 33-37 weeks; BW= -5431.362 +19.17 BPD + 43.745 AD + 30.838 FL between 38-40 weeks. The accuracy observed during model development was confirmed during testing upon 809 non-model cases for the different gestational periods with an ultrasound examination obtained between 7 days of delivery(R^2=0.95; 0.90; 0.85 respectively). Comparison with other weight estimation procedures showed that our models gives weight estimates that are more accurate as those obtained with other methods proposed in the literature for different gestational ages.

Partially supported by grant 91.00110.PF41 from Progetto Finalizzato FATMA, CNR.

620 **Intrauterine Growth Retardation Overestimation by Ultrasound Predicted Estimated Fetal Weight.**

C. J. Sims, J. Y. Fang,[x] D. R. Burholt,[x] H. R. Giles, Dept. Ob/Gyn, Medical College of Pennsylvania/Allegheny Campus, Pittsburgh, PA

Intrauterine growth retardation (IUGR) is a significant antepartum diagnosis that is associated with a marked increase in fetal and neonatal morbidity and mortality rates. Assuming an ultrasound estimated fetal weight less than the 10th percentile per gestational age, a diagnosis of IUGR was made. Clinical observation at delivery hinted towards an overestimation of the diagnosis in our population, based on birth weight criteria only. Between September 1987 and May 1991, 102 singleton pregnancies were identified as less than the 10th percentile estimated fetal weight (Acuson 128, OB calculation package). A retrospective review of maternal and neonatal records was undertaken. Parameters analyzed included maternal body mass index, amniotic fluid volume, fetal position, the number of ultrasound measurements obtained, placental grade, placental position, gestational age at the time of measurement and the interval between ultrasound measurements and delivery. A miscalculation of ultrasound predicted IUGR was identified as a birth weight greater than the tenth percentile. 28/102 (27.5%) were miscalculated (expected 12-20%). None of the individual factors analyzed were statistically significant in predicting a miscalculation. We conclude from these data that there are other factors influencing the ultrasound overestimation of IUGR in our population. Institutional derived birth weight curves correlated with the OB calculation package may allow for a more accurate prediction in our population.

621 **THE EFFECT OF GESTATIONAL AGE AND AMNIOTIC FLUID INDEX ON THE ABILITY TO VISUALIZE THE FETAL ABDOMINAL WALL CORD INSERTION BY ULTRASOUND**

S.J. Carlan, A.Pena[x], M.Gore[x], W.F. O'Brien
Depts. OB/GYN,U of S Fl, Tampa, FL,and ORMC, Orlando, FL.

Fetal abdominal wall defects, especially omphaloceles, can be difficult to detect by ultrasound because of fetal trunk flexion, and/or small part crowding. This study was designed to investigate whether successful imaging of the umbilical cord at the fetal abdominal wall was related to gestational age and/or amniotic fluid index. Fourteen normal women were scanned every 2 wks from 20 wks to delivery. The amniotic fluid index was obtained and if the cord insertion into the abdomen could be visualized, the diameter was obtained. There were no maternal disorders, amniotic fluid, or fetal abnormalities. The mean birth was weight 3569 ± 169 grams.

WEEKS	CORD DIAMETER (cm)	# (%) VISUALIZED	AFI
20	9.2 ± 1.2	13/14 (92.9)	129.3 ± 30.7
22	10.1 ± 1.1	12/14 (85.7)	135.8 ± 33.7
24	11.2 ± 1.0	12/14 (85.7)	139.6 ± 24.5
26	12.3 ± 1.3	10/14 (71.4)	153.3 ± 26.7
28	14.0 ± 2.1	7/14 (50)	154.5 ± 34.6
30	14.3 ± 2.5	7/14 (50)	147.1 ± 30.9
32	15.3 ± 2.3	4/14 (28.5)	147.1 ± 24.8
34	14.0	1/14 (7.1)	156.0 ± 36.3
36	19.0	1/14 (7.1)	166.4 ± 35.6
38	18.0	1/14 (7.1)	156.7 ± 45.5
40		0/12	165.0 ± 36.2

We conclude that in spite of a trend toward a progressively increasing amniotic fluid index, the umbilical cord at the abdominal wall insertion becomes progressively more difficult to image. In fact, from 28 wks until term, the incidence of visualization well enough to obtain a measurement was less than or equal to 50%.

622 **SINGLE UMBILICAL ARTERY: IMPLICATIONS OF SONOGRAPHIC DIAGNOSIS**

V Catanzarite, C Maida[x], A Mendoza[x], L Cousins, J Schneider

Maternal-Fetal Medicine and Pathology, Sharp Memorial Hospital Women's Center, San Diego

Eighteen cases of single umbilical artery (SUA) were diagnosed in utero over a 3 year period. There was one false positive diagnosis (at 18 weeks) and one patient is yet undelivered. Of the remaining 16 cases, 11 were referred for various obstetric indications, one for 2V cord, and 4 for fetal anomalies.

Eight patients had isolated 2V cord, including one with unexplained polyhydramnios. Each was correctly identified by sonography. Eight patients had identified associated anomalies; including one case each of Trisomy 13, Trisomy 18, Trisomy 21 and Turner Syndrome. The remaining cases were: VACTERL (2), holoprosencephaly (1), and omphalocele with bladder extrophy (1). In each case, sonography differentiated normal from abnormal babies, but in two of the anomalous infants, one or more major anomalies were missed by sonography. Based upon this experience, our current approach to the patient with SUA detected in utero is as follows: If careful sonographic evaluation shows no associated defects, we offer but do not recommend chromosomal studies. If other defects are seen, patients are counselled accordingly and amniocentesis is advised.

623 **GRAY SCALE AND COLOR DOPPLER ULTRASONOGRAPHY IN THE DETERMINATION OF AMNIOTIC FLUID INDEX**
G Colmorgen, C Foster,[X] A Janneman,[X] A Sciscione,[X] P Shlossman, R Gorman[X]
Medical Center of Delaware, Newark, DE

Concern that space occupied by the umbilical cord could be included inappropriately in measurements for amniotic fluid index (AFI) in pregnancies complicated by oligohydramnios led to an investigation comparing measurement of AFI by gray scale as opposed to color Doppler. Two hundred thirty-one patients (of whom 24 had oligohydramnios) were entered into the study. The general group of patients, as well as the sub-group with oligohydramnios, was found to have statistically lower AFI when measured by color Doppler than with gray scale alone ($P<0.05$). This finding was most important for the evaluation of patients with oligohydramnios. Conclusion: Use of color Doppler supplementing gray scale ultrasonography to determine AFI is more sensitive than gray scale alone for the prediction of oligohydramnios.

624 PRENATAL ULTRASOUND FINDINGS IN ASPHYXIATING THORACIC DYSTROPHY (ATD). O. Khawli, R. Morcos, M. Makii[X] Dept. Ob/Gyn, St. Elizabeth Hospital Medical Center, Youngstown, OH

Two cases of ATD (Jeune Syndrome) were diagnosed prenatally. Case #1: 30 year old G2 P1 has a child with Jeune Syndrome, referred because of a short femur at 36 weeks. The femur & humerus were < 5th percentile for gestational age. The thorax was bell shaped & on real time exams two weeks apart the fetus was in the same position, flat on the back with both thighs & knees flexed. The diagnosis of Jeune Syndrome was confirmed at delivery. Case #2: 34 year old G1 with negative family history, referred at 23 weeks because of short femur by ultrasound. At 16 wks, femur was at the 90th percentile. At 23 wks, femur was < 5th percentile & thorax was at 97th percentile. At 27 & 34 weeks, the femur & humerus were < 5th percentile (Rhizomelic Dwarfism). The thoracic circumference, which was > 50th percentile at 27 wks, fell below 5th percentile at 34 weeks. Diagnosis of Jeune Syndrome was suspected & confirmed after birth.
CONCLUSION: Prenatal diagnosis of Jeune Syndrome can be made by ultrasound based on the short femur length & a small thorax.

625 **ANTENATAL SONOGRAPHIC DIAGNOSIS OF DANDY-WALKER MALFORMATION IN THE LATE FIRST TRIMESTER.**
J. N. Bottalico, D.O., D. Huff, M.D.[X], B. Penny, R.D.M.S.[X], L. Miller, R.D.M.S.[X], University of Medicine and Dentistry of New Jersey-School of Osteopathic Medicine, Departments of Ob/Gyn and Pathology, Stratford, NJ

The Dandy-Walker Malformation (DWM), characterized by complete or partial absence of the cerebellar vermis, cystic dilatation of the fourth ventricle and frequently hydrocephalus has been detected in-utero, but often after fetal viability. DWM is thought to originate in the 6th or 7th week of embryonic development but most case reports to date describe antenatal diagnosis at gestations averaging about 24 wks. Early prenatal diagnosis allows more time for thorough fetal anatomic evaluation and chromosome studies, thus increasing management options. We recently detected a cystic dilatation in the posterior fossa of a fetus at 12.5 wks. gestation (by LMP and crown rump length) along with probable cerebellar maldevelopment, using transvaginal sonography (TVS). Repeat TVS at 13.5 wks revealed dilatation of the fourth ventricle which appeared to communicate through the absent vermis with a posterior fossa cyst. Transabdominal CVS revealed a normal karyotype and no other anomalies were noted. The patient elected termination of pregnancy at 18 wks. via prostaglandin induction of labor. Evaluation by a fetal pathologist confirmed the DWM with a cystically enlarged fourth ventricle, absent cerebellar vermis and elevation of the tentorium and torcula. A 4mm round midline occipital defect was also found along with mandibular hypoplasia, cleft palate and limb contractures. Thus it becomes apparent that TVS may allow the antenatal diagnosis of DWM as early as 13 wks though problems remain regarding the prediction of its natural history in-utero as well as prognostication for postnatal life.

627 EFFECT OF LOW DOSE ASPIRIN ON MATERNAL AND FETAL FLOW VELOCITY WAVEFORMS. Peter Mc Parland,[X] J.M. Pearce,[X] Fetal Welfare Laboratory, St. George's Hospital, London, U.K.

Preeclampsia is associated with reduced uteroplacental and umbilical blood flow. The increased platelet activity and reduced placental flow that occur in this disorder may be due to thromboxane A2. Low dose aspirin (LDA) has been shown to reduce the incidence and severity of preeclampsia by inhibiting platelet thromboxane (TxA2), a potent inhibitor of vascular smooth muscle contraction and platelet aggregation whilst relatively sparing prostacyclin production. Thus it may be expected that LDA would improve blood flow resistance indices from the uteroplacental and umbilical circulations. As part of a randomised placebo controlled study evaluating the role of LDA (75mgs/day) from 24 weeks in high risk patients Doppler studies were performed in patients at 24-25, 27-28, 32-34 and 36-37 weeks.

Results

	Uteroplacental (RI)		Umbilical (S/D)	
Weeks	Placebo (SD) (n=26)	Aspirin (SD) (n=26)	Placebo (n=26)	Aspirin (n=26)
24-25	0.68 (0.08)	0.67 (0.05)	4.08 (1.2)	4.09(0.9)
27-28	0.62 (0.09)	0.57 (0.09)	3.72 (1.5)	3.32(0.8)
32-34	0.61 (0.08)	0.55 (0.1)	3.07 (0.8)	3.06(0.8)
36-37	0.53 (0.07)	0.52 (0.1)	2.57 (0.4)	2.64(0.5)

Although clinical benefit was seen in the aspirin group, no differences in resistance indices were seen between the 2 groups suggesting no significant vasodilatory effect of low dose aspirin

628 ABDOMINAL AORTIC TIME TO PEAK: AN INDEX OF FETAL MYOCARDIAL CONTRACTILITY. IM Bernstein, MC Meyer, Dept of Ob/Gyn, Univ. Vermont, Burlington, VT

We examined the fetal abdominal aortic time interval between initiation of systole and peak velocity systolic flow (time to peak) to establish measurement reproducibility and the normal values across gestational age. Sixteen subjects with AGA newborns were studied. We obtained an average of 5.2 sets of observations per subject between 21 and 39 weeks gestation. An ADR Ultramark IV (ATL, Bothell, WA) pulsed doppler was used. The abdominal aorta was insonated between the diaphragm and the aortic bifurcation during fetal apnea. A minimum of two waveforms, obtained from distinct angles of sonoincidence, with normal S/D were measured per observation. Intraobserver coefficient of variation with two observations was 12.6%. Interobserver coefficient of variation was 15.5%. Mean abdominal aortic aortic time to peak values demonstrated a significant positive linear relationship with gestational age (range; 0.045 sec to 0.072 sec). We believe that the examination of fetal abdominal aortic time to peak will assist in evaluating the contribution of myocardial dysfunction to the generation of abnormal fetal arterial waveforms.

629 **REOCCURRENCE OF UMBILICAL END DIASTOLIC FLOW THROUGH MATERNAL VOLUME EXPANSION**

Veronique H.M. Karsdorp MD*, John M.G. van Vugt MD PhD*, Gustaaf A. Dekker MD PhD*, and Herman P. van Geijn MD PhD*, Dept. of Obstetrics, Free University Hospital Amsterdam, The Netherlands.

Absent or reversed end diastolic (ARED) flow velocity waveforms in the umbilical artery are associated with poor fetal outcome. In the current study the effect of volume expansion on placental blood flow and neonatal outcome was investigated in 7 prenancies with ARED flow (group I). Seven pregnancies with ARED flow but conventional treatment served as controls (group II). In group I end diastolic flow completely reappeared temporarily after volume expansion, in the control group all cases continued to demonstrate ARED flow. In group I the overall survival rate was significantly higher (71%) than in group II (14%). There was no significant difference between the two groups with regard to birth weight or mean gestational age at delivery. No complications were seen with volume expansion. These preliminary data suggest that it is possible to temporarily improve uteroplacental circulation with volume expansion, resulting in a better neonatal outcome. It is suggested that this improvement may be based on an elevation of maternal-fetal oxygen and fluid exchange which may lead to a decrease of the oxygen free radicals mediated vasoconstrictive effect and/or improves local haemorrheologic conditions and/or a decrease in local uteroplacental angiotensin II production.

630 AGE-STANDARDIZED DOPPLER SD VALUES IN HIGH-RISK PREGNANCIES. T.Kaneoka, Y.Makino*, H.Izumi*, K.Shirakawa*, Fukuoka Univ. Sch. Med., Japan

All perinatal parameters depend on both gestational age and methods. In order to assess the clinical value of umbilical and uterine arterial Doppler PI values and other perinatal parameters to predict fetal outcome, all perinatal values obtained in 207 high-risk pregnancies were converted to age-standardized SD values based on our own standard values. As a result, it was found that the correlation coefficients of the umbilical PI values were 0.71 to NST, 0.64 to CST, 0.61 to fetal distress, -0.43 to plasma hPL, -0.39 to AC, and -0.37 to fetal body weight. The negative predictive values of the umbilical PI value (cut off value: 2SD) were 95% in NST, 89% in CST, 87% in fetal distress, 96% in low Apgar score and 85% in IUGR. The positive predictive values for fetal distress were 100% in intrapartum CTG, 45% in NST, 65% in umbilical PI and 52% in uterine PI, and those for IUGR were 96% in estimated fetal body weight, 57% in umbilical PI and 44% in uterine PI. However, the positive and negative predictive values of umbilical AEDV were 93% and 91%, respectively. It was concluded that age-standardized Doppler values were useful in the antenatal screening.

633 EXPECTANT MANAGEMENT OF HYPERTENSION IN PREGNANCY
L.S. Voto, A.M. Lapidus*, R. Waissman*, P. Catuzzi*, F. Uranga Imaz*, M. Margulies. Division of Obstetrics, Hospital Juan A. Fernández, Univ. of Buenos Aires, Argentina.

Aim: To assess the value of expectant management through the analysis of perinatal results. Method: Home bedrest if diastolic blood pressure (dBP) ≤ 99mmHg; hospitalization if dBP ≥ 100mmHg with single drug treatment if necessary. Interruption of pregnancy in cases of hypertensive emergencies and/or unresponsive eclampsia, severe intrauterine growth retardation and/or fetal distress. Material: 230 hypertensive pregnant women were studied: 126 with essential hypertension (EH) (G.1), and 104 with pregnancy-induced hypertension (PIH). Of these 104 PIH women, 34 only had hypertension (G.2), and 70 had preeclampsia (PE) (G.3). 115 normotensive pregnant women were used as controls. Results: Mean dBP in the 3rd trimester was 104.4 ±10; 98± 8 and 108±9mmHg in Groups 1, 2 and 3, resp. Mean gestational age (GA) at delivery was ≥ 38 wks in the 3 hypertensive groups. The rate of spontaneous delivery was 79 % in controls, 66% in G.1 and 56% in Gs. 2 and 3. Group 3 had the lowest mean birthweight (BW) as compared with non proteinuric PIH (G.2) (2691±749g vs 3119±718g). Low BW for GA was 50% and 29% for G.3 and G.2, resp. In EH, mean BW (3382±637g) was similar to that in normotensives (3344± 498); however, there was a lower rate of low BW for GA babies than in controls (9.5% vs 12.2%,resp.). Conclusion: Expectant management allowed for a decrease in preterm deliveries and an increase in spontaneous labor. EH per se was not related to poor perinatal prognosis.

634 **NIFEDIPINE IN THE SECOND-LINE TREATMENT OF SEVERE PRE-ECLAMPSIA REDUCES THE AMOUNT OF PROTEINURIA** Romanini C.[Y], Tranquilli AL.[X], Valensise H.[Y], Garzetti GG.[Y] Institute of Obstetrics & Gynecology, University of Ancona, Ancona, Italy

Nifedipine was assessed as a second-line treatment in 59 severe preeclamptic patients resistant to previous labetalol or methyl-dopa treatment. Nifedipine was added at a dose of 40-60 mg/day. Blood pressure was controlled and became stable at ≤ 90 mmHg diastolic within 48 hours, in 55 patients, allowing to prolong pregnancy (mean 12 days, range 3-45). The combination of nifedipine and labetalol reduced the amount of proteinuria by ≥ 25% in 15 patients. Nifedipine should be included in the treatment of severe pre-eclampsia and seems to protect against the evolution of proteinuria.

636 NISOLDIPINE : PRELIMINARY RESULTS USING A NEW ORALLY ADMINISTERED CALCIUM ANTAGONIST IN THE TREATMENT OF SEVERE POSTPARTUM PREGNANCY INDUCED HYPERTENSION (PIH). Michael Belfort.[X] Dept. OB/GYN, Groote Schuur Hospital, University of Cape Town, South Africa.

Calcium antagonists are frequently used to manage severe PIH. This study was designed to assess the clinical use of nisoldipine, a new, oral, long acting dihydropyridine, in severe postpartum PIH. MATERIALS AND METHODS: Nisoldipine (Bayer) was given orally (20mg, eight hourly) to 12 patients with severe postpartum PIH (MAP>126 mmHg: >3+ proteinuria). Blood pressure was continuously monitored using an arterial line. Continuous and intermittent 12 lead ECG monitoring was undertaken. Data analysis was with 1-way ANOVA($p<0.05$ was significant) RESULTS: Systolic ($p<0.01$) and diastolic ($p<0.01$) blood pressure fell within 30 minutes of initiation of therapy. Significantly reduced blood pressure was maintained with successive doses (q 8 hrs) for the 24 hr study period. There were no significant changes in the heart rate or ECG. There were no adverse reactions despite the high dosage. CONCLUSIONS: Nisoldipine rapidly, effectively and safely reduces blood pressure in severe postpartum PIH. The potential advantages of this oral calcium antagonist should stimulate further controlled investigation.

637 **MANAGEMENT AND OUTCOME OF SEVERE PRE-ECLAMPSIA IN 209 PRETERM PREGNANCIES.** John F. Rodis, Edward J. Wolf, Luanna Lattieri, Dennis Scribner[X], Winston A. Campbell, Anthony M. Vintzileos, University of Connecticut Health Center, Farmington, CT

In 1978, Zuspan stated "severe forms of preeclampsia are preventable and should never occur, but once present they should yield a zero maternal mortality rate and a fetal salvage of greater than 90 percent." We undertook this retrospective study of severe preterm preeclampsia over 10 years (1980 - 1989) to assess whether Zuspan's goals are achievable in a preterm population. All charts with a diagnosis of preeclampsia were reviewed. Severe preeclampsia was diagnosed in 209 preterm patients (21-36 weeks) based on the following criteria: BP≥160/110 (75%), cerebral symptoms (34%), epigastric pain (22%), severe proteinuria (63%), oliguria (1%), elevated liver enzymes (29%), elevated creatinine (28%), thrombocytopenia (29%), or intrauterine growth retardation (27%). Mean (±SD) maternal age 26.3 (±5.9)yrs; 71% were nulliparous, 81% were white , 88% had singleton gestations, mean gestational age was 31.9 wks(±3.0); and 89% were maternal transports. Management consisted of maternal stabilization and prompt delivery, either via oxytocin induction or cesarean section. IV $MgSO_4$ was used in 97% of cases. The cesarean section rate was 83%. The mean number of antepartum and postpartum days in the hospital were 1.9 and 5.7 respectively; 87% of patients were discharged ≤7 days of delivery. Only 5 patients (2.5%) were discharged with significant morbidity (1 cortical blindness, 2 Bell's palsies, 1 aphasia and 1 blurred vision); all resolved spontaneously. Of 238 infants, 23 % were SGA with mean birthweight of ± 1661 grams; and 93% were discharged alive. Our data suggest that with aggressive management (i.e. delivery), routine use of magnesium sulfate and the liberal use of cesarean section, Zuspan's goals of zero maternal mortality and greater than 90% fetal salvage rates are obtainable, even in preterm severe preeclamptics.

638 **ENDOTHELIN-1 SERUM LEVELS IN NORMAL AND PREECLAMPTIC PREGNANCIES.** C. Croom, MD[X], T. Nolan, MD[X], L.Devoe,MD, B.Lightfcot,MS[X], R.Caruana,MD.[X].Dept OBGYN and Nephrology, Med Coll Of Georgia,Augusta,Georgia

Endothelin-1(ET1) is a potent vasoconstrictor; its serum levels rise in response to endothelial cell damage. We studied 5 normal women before pregnancy and during all trimesters and labor to determine the course of ET1 levels. We studied 18 additional normal third trimester women before and during labor,8 term preeclamptic(PE) patients before and during labor,and 21 third trimester PE patients in active labor. Serum ET1 was determined by RIA. In normal pregnancy, mean ET1 levels rose significantly from 0.5 pg/ml(1st trimester) to 1.1 pg/ml and 1.7 pg/ml (third trimester and labor, respectively). Mean ET1 levels of PE patients were significantly higher than those of normal patients before labor (1.9 pg/ml vs. 1.2 pg/ml, p=.04) and during labor(3.5 pg/ml vs 1.6 pg/ml, p = .006).Mean ET1 levels in PE did not change significantly with labor(p=.07). The gradual increase in ET1 with gestational age and the differences in PE and normal patients are consistent with earlier reports. As the presence of labor and PE both lead to significant increases in ET1, the potential value of ET1 for discriminating PE from normal patients would be greatest before labor begins.

639 **PLACENTAL ABRUPTION AND RENAL DYSFUNCTION** SL Baker*, FL Gaudier, JC Hauth, SP Cliver. University of Alabama at Birmingham

Placental abruption severe enough to cause fetal death can result in acute renal failure or transient dysfunction. Over a seven year period (January 1983-June 1990), 37 patients with placental abruption and fetal demise were managed at our institution. Six of the women had renal dysfunction (one required dialysis on 7 occasions over 10 days), defined as a maximum serum creatinine ≥3.0 mg/dl. These women were compared to those whose creatinine remained <3.0 mg/dl (n=31). Both groups hac a similar maternal age and parity, gestational age, and birth weight. Their admission hematologic and coagulation studies and mean units of blood, other blood products, or crystalloid given in the first 6 or 12 hours were similar. The diagnosis-to-transfusion or delivery intervals were similar in each group. Serum creatinine and urine output (UOP) values were:

Serum Creatinines/Urine Output	Maximum Creatine <3.0 mg/dl	Maximum Creatine >3.0 mg/dl	P Value
Admission creatinine (mg/dl)	0.9	1.5	.06
Discharge creatinine (mg/dl)	0.9	2.2	.04
Maximum creatinine (mg/dl)	1.1	6.6	.03
Urine output-first 6 hrs (cc/hr)	53	21	<.01
Urine output-first 12 hrs (cc/hr)	65	33	.01

All six women with a maximum serum creatinine of ≥3 mg/dl had preeclampsia and thrombocytopenia (<100,000 platelets/mm3) versus 19 (60%) of those whose maximum creatinine remained <3.0. Hypofibrinogenemia (< 150 mg/dl) was similar in both groups. For both groups, the amount of crystalloid and blood infused was similar in the first 6 or 12 hours but the women with a subsequent creatinine of ≥3 had a significantly lower UOP during this interval, and eventually received more blood therapy. An analysis of the 37 patients based on a maximum creatinine of <1.4 or ≥1.4 mg/dl yielded similar results. We speculate that more prompt and adequate correction of intravascular volume may have ameliorated the renal dysfunction in these six women. However, we cannot be certain that the subsequent renal dysfunction had not been determined by events and timing that occurred prior to admission since these six women trended toward a higher creatinine level on admission.

640 **SINGLE DOSE ANTIBIOTIC THERAPY FOR CLINICAL CHORIOAMNIONITIS PRIOR TO VAGINAL DELIVERY.** C. Berry*, K.A. Hansen*, J.F. McCaul, Dept of Ob/Gyn, Naval Hospital, Portsmouth, Virginia.

Intrapartum antibiotics for clinical chorioamnionitis (CHOR) is well established treatment. Anecdotal and retrospective data suggest that vaginal delivery without postpartum antibiotics may be adequate therapy. We hypothesized that patients with CHOR who deliver vaginally do not benefit from postpartum antibiotics in the absence of persistent fever. 41 term laboring patients diagnosed with CHOR who subsequently delivered vaginally after a single dose of ampicillin and gentamicin were prospectively randomized. 21 received continuous antibiotic therapy and 19 were assigned a placebo in a double-blinded fashion. One subject in each arm had continued postpartum febrility ($p = 0.74$, by Fischer's exact test). We concluce that patients with CHOR who deliver vaginally can safely be observed for signs of persistent infection without continuing postpartum IV antibiotics.

641 **LEWIS ANTIGEN EXPRESSION IN WOMEN WITH PRETERM LABOR OR PRETERM PROM.** William F. O'Brien, German Leparc*, Jodi Holbrook*. Univ of South Florida, Tampa, FL

Lewis antigens are polysacharides produced by a number of cell types which are transported in the circulation by adsorption to red cell membranes. The inclusion of Lewis antigens into the cellular membrane interferes with the attachment of gram negative bacterial pili to the cell resulting in a natural defense against colonization in individuals who express the Lewis antigen. Expression of Lewis antigens has been shown to be an important risk factor in women with recurrent urinary tract infection with a higher frequency of non-expression (a-b-) in women with recurrent infection. In view of the importance of genital tract infection in preterm labor (PTL) preterm premature rupture of the membranes (PROM) we investigated the possible association of these complications with Lewis antigen phenotype as expressed on red blood cell membranes.

	White			Black		
LEWIS	PROM	PTL	Control	PROM	PTL	Control
a-b+	18 (60)	15 (75)	38 (58)	15 (42)	15 (56)	21 (38)
a+b-	7 (23)	3 (15)	16 (24)	6 (17)	3 (11)	9 (16)
a-b-	5 (17)	2 (10)	12 (18)	15 (42)	9 (33)	26 (46)

Although the incidence of women who failed to express Lewis antigens was significantly higher when compared to a non-pregnant population, when the results were adjusted for race there was no evidence of an excessive rate of a-b- women in the PROM or PTL groups. It appears that Lewis antigen expression and therefore bacterial attachment to vaginal epithelium is not an important component in the risk of PROM or PTL.

642 **PREVALENCE OF SEXUALLY TRANSMITTED DISEASE IN HIV SEROPOSITIVE PREGNANT WOMEN.** Sharon L. Patrick, M.D.* and Harold E. Fox, M.D., Department of Obstetrics and Gynecology, Sloane Hospital for Women, Columbia Presbyterian Medical Center, New York, NY

Pregnant women infected with the human immunodeficiency virus (HIV) are more likely to contract sexually transmitted diseases (STDs); the magnitude of this problem varies among populations. We compared the prevalence of STDs in pregnant HIV seropositive (HIV+) women with pregnant HIV seronegative (HIV-) and non-pregnant HIV+ individuals. In a retrospective case-controlled study, thirty-three pregnant women who were HIV+ underwent routine prenatal screening for syphilis, hepatitis B surface antigen (HBsAg) and PAP smear analysis. These women were matched for age and socioeconomic status with both pregnant HIV- women and non-pregnant HIV+ women. Results were analyzed using Chi square contingency table analysis. The HIV+ gravidas had a syphilis prevalence of 36% which was four times higher than the pregnant HIV- women ($p<0.05$). Pregnant HIV+ women had a higher prevalence of both HBsAg seropositivity (29% vs. 3%, $p<0.01$) and cervical intraepithelial neoplasia (CIN) on PAP smear (34% vs. 3%, $p<0.005$) when compared with pregnant HIV- counterparts. Similarly, HIV+ non-pregnant women had prevalence rates of syphilis (28%), HBsAg seropositivity (25%), and CIN (31%) which were significantly higher than their pregnant HIV- counterparts but not statistically different from the HIV+ pregnant cohort. HIV+ women, pregnant and non-pregnant, had significantly higher rates of STDs in our population. We conclude that factors other than pregnancy status contribute to the high prevalence of STDs among women infected with HIV. Thus, pregnant women with HIV infection require aggressive surveillance with regard to STDs.

644 UTILITY OF BLOOD CULTURES IN POSTPARTUM ENDOMYOMETRITIS. C. King,[x] P. Charache,[x] J. Repke, Depts. Gyn/Obs and Infect. Dis., The Johns Hopkins Univ. Sch. of Med., Balto., Md. 21205

This study was undertaken in an effort to evaluate the utility of blood culture information in the management of patients with postpartum endomyometritis. An 18 month period was evaluated during which positive blood culture results were reviewed. Variables included assessment of the appropriateness of antibiotic treatment before and after blood culture results were available, effect of blood culture results on antibiotic selection, and effect of blood culture results on duration of use of antibiotics. During this period of time, 16 confirmed positive blood cultures were reported, while an estimated total of 288 sets of blood cultures were obtained. Positive blood cultures, therefore, were present in 5.5% of patients with postpartum endomyometritis. Among these patients, there were no cases identified where additional antibiotics were necessary after blood culture identification and sensitivities were made available. There were eight cases where an antibiotic was judged to be superfluous based on blood culture results. In conclusion, given the high incidence of postpartum endomyometritis, the low incidence of blood culture positivity, and the broad spectrum antibiotics used in treatment, and given the cost of blood cultures ($28 per set), we recommend a reevaluation of the effectiveness of blood cultures, as currently utilized, in the management of postpartum endomyometritis in otherwise uncompromised healthy obstetric patients.

645 MULTICOMPARTMENT MOLECULAR IN UTERO EVALUATION FOR CONGENITAL HERPES SIMPLEX VIRUS (HSV) AND CYTOMEGALOVIRUS (CMV) INFECTIONS BY CHORIONIC VILLUS SAMPLING (CVS) AND POLYMERASE CHAIN REACTION (PCR). NB Isada, MP Johnson[x], SM Berry, R Whitley[x], W Britt[x], W Holzgreve, MI Evans. Ctr for Fetal Diagn & Ther, Hutzel Hosp, Wayne St U, Detroit, Mi., Institute für Humangenetik, Münster, FRG & Div Ped Infect Dis, Dept Peds, U Alabama, Birmingham.

Congenital infections are difficult to evaluate prenatally. CMV is associated with IUGR and CNS defects. Primary HSV may be teratogenic. PCR is a recently idescribed molecular genetic technique which amplifies minute amounts of genetic material. We used a multicompartment evaluation to assess all possible routes and sites of infection. Viral cultures, histology and viral-specific PCR were used to analyze the CVS sampla. Viral cultures and PCR were used to analyze the amniotic fluid (AF). Cordocentesis for CBC, immune globulins and liver enzymes were performed. We evaluated two gravidas for congenital infections. Patient 1 developed primary HSV with meningoencephalitis in thje first trimester. She had a negative evaluation that included CVS, amniocentesis and cordocentesis. Nested PCR primers encompassing HSV glycoprotein B region were used to analyze the CVS tissue. She delivered vaginally at term elsewhere and developed genital HSV 12 hours postpartum. The neonate developed HSV & required IV acyclovir. Concerns have been raised regarding time of acquisition of infection. Patient 2 was a health-care worker seropositive for CMV IgM. She had positive PCR in CVS and AF samples using primers from the conserved region of the gB gene. Shell vial cultures from CVS, amniocentesis and cordocentesis were neg. PCR on WBCs from cordocentesis was neg. She delivered at 37wks a 6 lb healthy male infant. We conclude that multi-compartment evaluation can be useful in excluding in utero infection and that the presence of viral genetic material does not necessarily indicate fetal morbidity.

647 GROUP B STREPTOCOCCUS DETECTION: COMPARISON OF RAPID IMMUNOASSAY AND CULTURE. Jeffrey S Greenspoon, M Morgan[x], Stuart G Smith[x], Regta L Greenspoon[x], Malcolm L Margolin[x] Depts. Ob-Gyn and Pathology and Laboratory Medicine, Cedars-Sinai Medical Center, Los Angeles, California

The reliability of an immunoassay, ICON Strep B Test[R] (Hybridtech, San Diego, CA), was assessed by comparison with the standard culture for Group B Streptococcus (GBS). A simple, rapid means to identify GBS colonized patients has been sought in order to permit selective and expeditious administration of chemoprophylaxis to the colonized patients and to avoid unnecessary treatment of those not colonized. At the time of evaluation for preterm or term labor, premature rupture of membranes, or antepartum surveillance, two vaginal swabs were simultaneously obtained from 174 patients. One swab was cultured using standard techniques for identification of GBS. Colonization was defined as light (1+ growth on culture plate), moderate (2+ or 3+), or heavy (4+). The second swab was used to perform the rapid test according to the manufacturer's recommendations. The prevalence of any GBS vaginal colonization was 10 of 174 (5.7%, 95% CI, 2.8% to 10.3%). Five of 174 (2.9%, 95% CI, 0.9% to 6.6%) had moderate or heavy colonization. Five of the 6 patients with false negative rapid tests had fewer than 20 colonies per plate.

	Culture			
Rapid test	Positive	Negative		
Positive	4	1	Sens. 40%	PPV 80%
Negative	6	163	Spec. 99.3%	NPV 96.4%

Previous reports whose study design distinguished parturients with light growth on culture from those with heavy growth noted that the infants of mothers with light colonization were less likely to develop EOGBS, although the risk was not zero. This test will be especially useful for identifying patients heavily colonized with GBS who are likely to benefit from timely chemoprophylaxis.

648 IMMATURE LECITHIN/SPHINGOMYELIN (L/S) RATIOS AND PERINATAL OUTCOME IN HIGH RISK PREGNANCIES. M.A. Harper, Dept. Ob/Gyn, Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, NC

Nine hundred thirty-seven L/S ratios (single-dimension thin-layer chromatography) were reviewed from the three year period preceding the initiation of surfactant therapy in premature neonates in our institution. Six hundred eight were less than 2.5 with no phosphatidylglycerol. Of these, 104 singletons without congenital anomalies delivered within 72 hours from the collection of fluid [amniocentesis (n=42) or vaginal fluid (n=62)] for L/S determination and are the data set for this analysis. The values of the immature L/S ratios correlated significantly with length of hospital stay (r=-.41, p=.0001), total days on supplemental O_2 (r=-.25, p=.009), total days ventilated (r=-.29, p=.003). Seventy-one percent of babies with a L/S less than 1.0 required some respiratory support (O_2, CPAP, ventilator) compared to 28% of babies with a L/S between 2.0 and 2.5.

Conclusion: The absolute value of an immature L/S ratio can be helpful in predicting perinatal outcome in high risk pregnancies and therefore is of benefit in timing of delivery in these patients.

649 **IS TWIN PREGNANCY DESTINED TO BE A BIOLOGICAL DISADVANTAGE? A STUDY OF PERINATAL OUTCOME IN PRIVATE AND INDIGENT TWIN POPULATIONS.** J. Gandhi, W. Cohen, S. Yeh. Department of OB/GYN, Albert Einstein Medical Center/Temple University, Philadelphia and Albert Einstein College of Medicine, New York.

This report analyses perinatal outcome and contributing maternal factors in 132 indigent (A) and 199 middle class (B) women from the municipal and private services of the same institution. Mothers in group A were younger and of higher parity (age 25.4 vs 29.4, p<0.001, parity 2.4 vs 1.6, P<0.001). Hispanic and black women comprised 84% of group A and 52% of group B. 84% of the group A and 100% of the group B received prenatal care. First prenatal visit was later in A than B (24.7±7.4 vs 12±6 weeks, p<0.001). First prenatal visit was at ≤ 12 weeks in 5.3% of A and 61.6 % of B. 75% of twins in A and 90% in B were diagnosed prior to 28 weeks. Antenatal testing was performed in 61% of A and 67% of B. Lower mean birth weight in A (2167±823 gms vs 2449±710 gms, p<0.001) occurred as a result of more babies weighing <1500 gms (21% vs 9.4%). Mean gestational age at birth was lower in A (34.4±4.4 vs. 36.2±3.9 weeks, p<0.001) due to greater number of babies of <32 weeks (26.4% vs 7.1%). 40% of A and 20% of B babies required NICU care, with average NICU days being 9.3±20 in A and 2.3±9 in B. PNM was 53/1000 in A and 31/1000 in B, (p<0.001). This excess PNM and morbidity of twins in the municipal sector was accounted for by the excess number of preterm babies born prior to 32 weeks and weighing <1500 gms. This adverse perinatal outcome was not associated with increased maternal complications, IUGR or late gestational age at diagnosis. Early prenatal care rather than early diagnosis appeared to have an association with better outcome. **In conclusion,** these data suggest that preventing premature labor prior to 32 weeks in twin gestation in indigent patient may be important in reducing extreme preterm birth and associated perinatal mortality and morbidity.

650 **COCAINE USE IN PREGNANCY: THE EFFECTS OF RESIDENTIAL TREATMENT ON PERINATAL OUTCOME.** Isaac Delke, Drew Leavitt[x], Luis Sanchez-Ramos, Mark T Cullen. University of Florida, Jacksonville, FL.

The perinatal impact of residential treatment of cocaine-using gravida is little known. The purpose of this study is to evaluate the effects of a comprehensive residential treatment program on the perinatal outcome among cocaine-using pregnant women. During an 18-month period, 394 cocaine-exposed infants were reported to Florida Health and Rehabilitative Services from Duval County. Data were available on 320 cases: Group 1 (N=39, residential treatment + prenatal care), Group II (N=138, prenatal care only), and Group III (N=143, no care). Maternal, obstetrical and neonatal data were collected from medical and drug treatment records. The statistically significant differences between the groups included: STDs, gestational age at delivery, preterm birth, birth weight, low birth weight (<2500 grams), small for gestational age, microcephaly (HC<10%ile), Apgar score at one minute, NICU admission and positive urine toxicology at birth. The statistically significant differences between groups I and II were: Low birth weight (p<0.01), microcephaly (p<0.02) and positive urine toxicology at birth (p<0.0001). **Conclusion:** Residential treatment contributed to reduction in low birth weight and cocaine-exposed infants at birth.

651 MANAGEMENT OF PREMATURITY: THRESHOLD FOR OBSTETRICAL INTERVENTIONS BASED ON NEONATAL OUTCOMES. R.T. DePalma, M.D., K.J. Leveno, M.D., M.A. Kelly,[x] M.L. Sherman,[x] UT Southwestern Medical Center at Dallas

We sought to determine the preterm birthweight for which obstetrical interventions intended to delay delivery might potentially improve neonatal morbidity and mortality. 550 singleton and twin livebirths weighing 1000 to 2199 grams and delivered at Parkland Hospital from January 1990 through May 1991 were retrospectively analyzed. The only pregnancy complications included were spontaneous preterm labor and preterm rupture of the membranes. Neonatal mortality and several indices of morbidity are summarized below:

Birthweight (grams)

	1000-1299	1300-1599	1600-1899	1900-2199
No. of infants	58 (%)	87 (%)	142 (%)	263 (%)
Deaths	6 (10)	4 (5)	0 (-)	0 (-)
Resp. Distress Syndrome	23 (40)	23 (26)	8 (6)	4 (2)
Intraventricular Hemorrhage	7 (12)	3 (3)	0 (-)	0 (-)
Necrotizing Enterocolitis	4 (7)	7 (8)	5 (4)	4 (2)
ICN days Mean (SD)	18.1 (24.7)	5.8 (11.5)	1.6 (3.7)	0.4 (1.3)

The table includes only respiratory distress requiring mechanical ventilation and Grade 3 or 4 intraventricular hemorrhage. Conclusion: These results suggest that there are few significant potential benefits in attempting to delay delivery of fetuses weighing 1600 grams or more.

652 VAGINAL POOL PHOSPHOLIPIDS AND NEONATAL OUTCOME. JA Spinnato, CA Marcell,[x] KK Ralston,[x] ER Greenwell,[x] JA Spinnato, III,[x] OB/GYN Dept., Univ. of Louisville School of Medicine, KY

The Lecithin/Sphingomyelin (L/S) ratio and phosphatidylglycerol (PG) value (chloroform extracted-acetone precipitated thin layer chromatography) were assessed on vaginal pool (VP) amniotic fluid (AF) specimens (n=106) from patients with preterm (<37 weeks) rupture of membranes (ROM) and compared to AF values obtained transabdominally (TA) (N=153) from non-diabetic control patients with intact membranes. Neonatal outcomes were compared for patients delivering within one week of AF assessment. Delivery was promptly accomplished in the ROM group if the LS ratio was ≥2 (43/45 within one day) and glucocorticoids were not used in those cases. Between 28 and 32 weeks' gestation the L/S ratio (1.9 ± 0.8, N=56) and PG (13/55 = Present) in the VP group were more mature than in the TA group (L/S = 1.3 ± 1.1, N=41, p<0.01, PG=present, 1/31, p<0.05). After 32 weeks' these differences were not observed. Among patients with an L/S ratio ≥2.0, hyaline membrane disease HMD was noted in 2/45 patients in the VP group versus 0/53 patients in the TA group (P=NS). HMD was not observed in either group (VP=0/23, TA=0/27) when PG was present. Ventilatory support for non-HMD diagnoses was briefly and infrequently required in both groups and no deaths or serious complications occurred when PG was present or L/S ≥2. False negative LS and PG were similarly frequent in both TA and VP groups. The L/S ratio and PG from VP predict neonatal pulmonary performance as well as when obtained TA. The ease of specimen collection and importance to clinical management encourages their use. The neonatal outcomes in this study support prompt delivery when ROM and positive maturity tests coexist.

653 PRETERM RUPTURE OF MEMBRANES BEFORE 25 WEEKS: PERINATAL OUTCOME

Joffe GM, George K[x], Del Valle GO, Izquierdo LA, Gilson GJ, Jones D[x], Vill M[x], Chatterjee S, and Curet LB, Univ. New Mexico Med. Ctr., Albuquerque, NM

Expectant management of PROM before 25 weeks has recently been advocated. An 8 year review of records at our facility reveal 17 cases in 10,500 admissions for an incidence of 0.16%. Six patients elected termination of pregnancy. Of the remaining eleven patients who chose continuation of pregnancy, 4 perinatal deaths occurred for a perinatal mortality rate of 364/1000. Mothers of surviving infants were older (25.3+/-4.5 vs. 21.3+/-3.3 years p=.025) and had higher gravidity (2.43+/-0.79 vs 1.5+/-0.58 pregnancies (p=.025) than mothers of non-surviving infants. There was no difference between survivors and nonsurvivors in gestational age at PROM (20.4+/-4.03 vs. 19.5+/-3.51 weeks), interval from PROM to delivery (12.8+/-5.69 vs 8.75+/-6.38 wk), and delivery weight (1788+/-356 vs 1600+/-453 gm) (p=.10). Neonatal morbidity included pneumonia (4), RDS (5), pneumothorax (1), persistent fetal circulation (1), pulmonary hypertension (3), sepsis (2), IVH (1), limb contractures (3). Expectant management may be offered, if patients are cautioned that it is currently not possible to predict which infants will survive prolonged PROM, and that there may be significant perinatal morbidity.

654 ELEVATION OF TOTAL PLASMA CORTISOL WITH PROM

L. Nelson, M.D.[x] and R.B. Kurzel, M.D. U.C.L.A /L.A.C.-Olive View Medical Center, Sylmar, CA

The role of cortisol in the onset of term or preterm labor in humans is still unknown. Total plasma cortisol (C_T) was determined for patients with preterm premature rupture of the membranes (PPROM) without labor, relative to historical controls (normal patients not in labor, gestationally matched). The gestational dependence of C_T was studied at the time of PPROM, and longitudinally for each patient following that event. Venous C_T obtained at 8 A.M. was assayed by RIA. (10 patients with PPROM between 23-35 wks; 6 serial determinations). All pregnancies were singleton, not in preterm labor, had no evidence of infection, and none were given glucocorticoids to induce fetal lung maturity. A mean of 2.4 days transpired from the last C_T determination to the onset of labor. RESULTS & CONCLUSIONS: (1) C_T was elevated for all patients with PPROM (mean C_T=48.2± 16.2 µg/dl; control C_T=32.0± 3.3 µg/dl), which is significant ($p<.0005$). (2) C_T values appear to be independent of the gestation at which PROM occurs, and serial values show no tendency to increase as long as labor does not ensue. (3) The rise in C_T may reflect the process in parturition.

655 **DECREASING CESAREAN SECTION RATES IN VERY LOW-BIRTH WEIGHT INFANTS: EFFECT ON PERINATAL OUTCOME**

Luis Sanchez-Ramos MD, Carol Walker RN[x], Donna Briones RN, Mark T. Cullen MD University of Florida, Jacksonville, FL

There is little evidence that the use of cesarean section for the delivery of very low-birth weight infants improves overall survival. Our specific objective in this study was to determine within the very low-birth weight category (500-1499 gms) whether a reduction in cesarean deliveries was associated with an increased risk of adverse perinatal outcome. The data used in this analysis were obtained from a review of 23,529 livebirths delivered at our institution from 1986 to 1990. Examination of these data revealed a significant decrease in the use of cesarean section for very low-birth weight infants from 55% to 40% ($p<0.05$) during the five year period. Concomitantly, the cesarean section rate for all birth weight categories decreased from 27% to 8% ($p<0.0001$). The neonatal death rate in the very low-birth weight category decreased from 33/1000 to 18/1000 ($p<0.01$). There was no significant change in the incidence of low Apgar scores, cord blood gas values, intraventricular hemorrhage, and median length of stay in NICU. Our results suggest that the cesarean delivery rate can be significantly reduced in very low-birth weight infants without adversely affecting perinatal outcome.

656 LAMELLAR-BODY NUMBER DENSITY PREDICTION OF FETAL LUNG MATURITY.

Jeffrey S Greenspoon, Stuart B Dubin[x], Kaye E Roll[x] Depts. Ob/Gyn & Pathol. & Lab. Med., Cedars-Sinai Medical Center, Los Angeles, CA

The reliability of amniotic fluid lamellar-body number density (LBND) for the identification of the immature fetus was determined. The outcome predicted by LBND was compared to the clinical outcome of 15 infants delivered within 72 hours of amniocentesis. LBND was compared to other fetal lung maturity (FLM) tests performed on 65 samples. Lecithin-sphingomyelin (L/S), phosphatidylglycerol (PG), absorbance at 650 nm (A_{650}), and the foam stability index (FSI) were determined by standard methods. LBND was measured by resistive-pulse counting of uncentrifuged amniotic fluid (Dubin SB *Clin Chem* 1989;35:612). A "positive" FLM test predicts the development of hyaline membrane disease (HMD). A "negative" test predicts the absence of HMD. The sensitivity (Sens), specificity (Spec), positive predictive value (PPV), and negative predictive value (NPV) of LBND are shown in the table. The relation of LBND <40,000/microL to "positive" (immature) FLM test results is also shown.

LBND <40,000/microL	Clinical HMD	L/S <2	PG <3%	A_{650} <0.15	FSI <47
Sens n(%)	2/3 (67)	12/27 (44)	17/33 (52)	6/9 (67)	7/16 (44)
Spec n(%)	11/12 (92)	33/38 (87)	32/32 (100)	44/53 (83)	20/21 (95)
PPV n(%)	2/3 (67)	12/17 (71)	17/17 (100)	6/15 (40)	7/8 (88)
NPV n(%)	11/12 (92)	33/48 (69)	32/48 (67)	44/47 (94)	20/29 (70)
Prevalence of immature result n(%)	3/15 (20)	27/65 (42)	33/65 (51)	9/62 (15)	16/37 (43)

Every FLM had one clinical HMD false negative (FN) result; A_{650} had 2 FN results. LBND is similar to other FLM tests, but can be measured immediately on uncentrifuged amniotic fluid without interference from blood or pigments.

657 CLINICAL CHARACTERISTICS AND OUTCOME OF PATIENTS WITH RESEALED, PRETERM, PREMATURE RUPTURE OF MEMBRANES. S.J. Carlan, W.F. O'Brien, J.L. Glock[x], U of S Fl, Dept. OB/GYN, Tampa, FL.

From March 1, 1989 to March 1, 1991, a total of 386 women (2.5% of total number of deliveries) with preterm, premature rupture of membranes (PPROM-rupture of membranes prior to labor before 37 weeks gestation) were admitted to Tampa General Hospital. Nineteen women electively terminated the pregnancy, and, of the remaining 349 patients, 14 (4%) resealed. All patients with rupture were documented with a positive history of a gush of fluid from the vagina, and either fern, nitrazine, pooling or a combination. All patients classified as "resealed" reported that the leaking stopped and then were confirmed with amniocentesis and injection of indigo carmine. If no seepage of blue dye was noted from the vagina, they were classified as "resealed". There was no significant difference between the groups in racial makeup, GTPAL, or positive cervical cultures for Gc, Chlamydia, or GBBS. There were no multiple gestations in the resealed group and nine in the group that did not seal.

CLINICAL CHARACTERISTICS OF RESEALED VS SEALED (±1 SD)

	ReSealed (N=14)	Not Sealed (N=335)	P
Age (mean years)	20.0 ± 3.6	23.9 ± 6.2	<.05
EGA at ROM (mean weeks)	29.6 ± 4.6	31.7 ± 3.8	<.05
Hx previous PPROM (%)	14.3	10.1	NS
Initial US deepest pocket (mean cm)	4.6 ± 4.6	2.9 ± 1.6	<.05
ROM to delivery (mean d)	67.1 ± 37.6	5.3 ± 10.3	<.05
EGA at delivery (mean weeks)	38.6 ± 1.3	32.8 ± 3.7	<.05
C-Section (%)	14.3	16	NS
Neonatal wt (mean grams)	3280 ± 454	1952 ± 683	<.05
Cord pH (mean)	7.28 ± .08 (N=12)	7.3 ± .08 (N=280)	NS
NICU admissions (%)	0	52.8	<.05
Total neonatal days in hospital (mean)	2.4 ± 0.8	17.6 ± 23.1	<.05

We conclude that the patients that are more likely to reseal are younger and at an earlier gestational age and have larger pockets of amniotic fluid on initial ultrasound. After resealing the pregnanies apparently procede normally with no higher incidence of re-rupture.

658 **PREVIOUS SPONTANEOUS AND INDICATED PRETERM BIRTH AS RISK FACTORS FOR PREMATURITY**

M.B. DuBard[X], J.C. Hauth, R.L. Goldenberg, R.L. Copper[X], R.O. Davis, R. Creasy[X], J. Iams[X]
The March of Dimes Multicenter Study Group
University of Alabama Hospitals, Birmingham

We reviewed the obstetric history of 33,430 women who were evaluated at the time of the March of Dimes Preterm Birth Prevention Project. As the number of prior PTDs (due to any etiology) rose from 0 to 1 to ≥2, the rate of PTD ≤37 weeks rose from 10 to 21 to 31% (p≤.0001). Similarly, the rate of PTD ≤34 weeks rose from 5 to 13 to 20% (p≤.0001). We then evaluated the risk of PTD as related to the etiology of the prior PTD. As prior spontaneous preterm delivery (SPTD) (following labor or PROM) rose from 0 to 1 to ≥2, the rate of SPTD ≤37 weeks in the current pregnancy rose from 7 to 17 to 26% (p≤.0001) and the rate of SPTD ≤34 weeks rose from 4 to 10 to 17% (p≤.0001). As the number of prior indicated PTD (IPTD) increased from 0 to 1 to ≥2, the rate of IPTD in the current pregnancy ≤37 weeks rose from 2 to 11 to 28% (p≤.0001) and the rate of IPTD ≤34 weeks rose from 2 to 7 to 24% (p≤.0001). One or more prior IPTD did not predict SPTD. Of 445 women with twin gestations, 53% delivered ≤37 weeks and 35% delivered ≤34 weeks. However of women with twins and 1 or more prior SPTD, the rate of SPTD ≤37 weeks was 53% (NS) and ≤34 weeks was 44% (p≤.03). This data will enable those planning studies of PTD intervention strategies to choose groups at highest risk for PTD and allow more precise power calculations.

659 **ESTIMATION OF FETAL WEIGHT BY ULTRASOUND IN PRETERM PREGNANCIES**

D.K. Phillips MD[X], A.B. Knight MD, P.E. Martinez BS[X], T.J. Kuehl PhD[X]. Scott & White Memorial Hospital & Clinic, Texas A&M University College of Medicine, Temple, Texas.

Estimation of fetal weight (EFW) or gestational age in the preterm pregnancy often directs management of high risk patients. Mode of delivery of preterm breech presentation is currently based on EFW; aggressive tocolysis may be limited by EFW and even, consideration of operative intervention requires an assessment of age or EFW. These difficult decisions are most often made in a Labor and Delivery setting by physicians of varying expertise with ultrasound on patients with minimal historical information to allow gestational dating. This study determined the accuracy of fetal weights calculated from ultrasound measurements using the Shepard and 13 other formulas. 172 neonates whose birth weights were < 2000 gm were prospectively evaluated prior to delivery; all had ultrasound measurements (BPD, HC, AC, FL) within 7 days of delivery. The accuracy of each formula was assessed by a ratio of Estimated Fetal Weight(EFW) to Actual Birth Weight (ABW) and 95% Confidence Intervals. Only 3 formulas had 95% CIs that included 1.00, i.e. EFW not significantly different from ABWs: Hadlock #3, 1.004 ± 0.019; Hadlock #4, 1.010 ± 0.099; Woo #2, 0.992 ± 0.019. Errors tended to be exaggerated at ABWs < 500 gm. EFW significantly altered clinical management in a significant number of cases.

660 LONG-TERM INTRAVENOUS TOCOLYTIC THERAPY. J. Bruner, A. Bruner,* A. Sarno, Dept. of OB/GYN, Vanderbilt Univ. Medical Center, Nashville, Tennessee.

Eighteen women in preterm labor who received continuous intravenous tocolytic therapy for greater than 48 hours (108.6 ± SD 156.9 hrs; range 48.5-729 hrs) were compared to a similar group of women treated for less than 48 hours (12.9 ± SD 6.7 hrs; range 4-38.5 hrs) in this retrospective case-control study. The groups were well-matched in regard to age, race, weight, gravidity, parity, marital status, social status, level of prenatal care, and prior medical and surgical diagnoses. The only identifiable risk factors for preterm labor significantly associated with an increased need for long-term intravenous tocolytic therapy were uterine and cervical anatomic defects (fibroids, prior conization, incompetent cervix) and multiple gestation. The mean gestational age at the time of diagnosis was 30 weeks for both groups, and there were no significant differences in mean cervical dilatation or effacement on initiation of therapy. Tocolytic selection was similar in both groups, although the dosage/hr was significantly greater with long-term therapy. The mean interval from initiation of therapy until delivery was 41 days in the study group, compared to 39 days among controls (NS). The mean gestational age at delivery was 37 weeks in both groups. There was no significant difference in the incidence of fetal distress, mode of delivery, or neonatal Apgar scores. No statistically significant maternal or neonatal complications were noted in either group. These data demonstrate that long-term tocolytic therapy is a safe and efficacious means of prolonging gestation in those women who fail to respond to conventional treatment.

662 COMPARISON OF MAGNESIUM AND NIFEDIPINE FOR PRIMARY TOCOLYSIS AND IDIOPATHIC PRETERM LABOR. R.C. Floyd,[X] B.N. McLaughlin,[X] R.W. Martin, W.E. Roberts, W.L. Wiser,[X] J.C. Morrison, Dept. Ob/Gyn, Univ. Mississippi Med. Ctr., Jackson, MS

Objective: To compare nifedipine (N) with magnesium (M) as primary tocolytic agents for idiopathic preterm labor (PTL). Patient Population: In this prospective study, 67 patients between 20 and 34 weeks' gestation with documented PTL over a 12-month period were randomized to receive 2 mg of oral N q 8 hours versus intravenous M (sulfate) followed by oral M (gluconate), 2 gm q 4 hours orally. The diagnosis of PTL was established by repetitive contractions usually q 5 minutes with documented cervical change from a previous exam or cervix > 2 cm/> 50% effaced. Multiple gestation, chorioamnionitis, rupture of the membranes, fetal distress, growth retardation, or allergy to M or N were exclusion factors. Main Outcome Measured: Pregnancy prolongation index (days prolongation from diagnosis of PTL/ideal prolongation [to 37 weeks] from PTL), number delivering < 37 weeks, birth weight, maternal complications for tocolytics and duration to delivery after treatment. Results: There was no difference in the number of patients delivering < 37 weeks, the duration of treatment, interval to delivery, PPI, PTB, or BW.

Group	Number	Treatment Interval* (weeks)	PPI*	PTB*	BW* (gm)
M	29	7.0 ± 5.2	0.96 ± 0.55	11	2565 ± 763
N	39	5.7 ± 3.9	0.97 ± 0.59	13	2768 ± 662

*not significant

Conclusions: The results of this study show that N is a useful agent as a first-line tocolytic with an effectiveness comparable to that of M. No evidence of fetal or neonatal compromise was noted and there was no statistically significant difference between pregnancy prolongation or preterm births.

663 UMBILICAL BLOOD SAMPLING. IS IT IMPORTANT WHERE TO SAMPLE ? B. Peskin[X], N. Lazebnik, J. Blankstein[X]. Dept. Ob/Gyn, Case Western Reserve University, Mt. Sinai Med Ctr, Cleveland, OH.

Umbilical cord blood sampling at birth greatly enhances assessment of the newborn's respiratory status. This study was conducted in order to address two questions. 1) Does the cord blood gas result depend on the cord segment sampled ? 2) Does fetal distress play any roll in choosing the cord segment to be studied ? Three groups of patients were studied with 10 patients in each group. Group I Elective cesarean section with apgar score of > 9 at 1 and 5 minutes. Group II Normal spontaneous vaginal deliveries with no evidence of fetal stress as shown by fetal heart tracings and apgar score of > 7 at 1 and 5 minutes. Group III newborns delivered by forceps / vacuum extractor / cesarean section due to abnormal fetal heart tracings and scalp pH sample of < 7.20. For each group the cord was clamped immediately in 3 different sites. Near the placenta, mid portion and about 5 cm from the newborn. Blood gas samples within sites in the same newborn and between the 3 groups were compared by analysis of variance (ANOVA). The 3 groups were statistically different in cord artery pH results regardless of the site sampled (7.27+ 0.049 vs 7.26 + 0.033 vs 7.17 + 0.06 $p < 0.001$ for groups I, II , and III respectively). In groups I and II where no fetal distress was present no difference was found in cord artery pH between the different sampling sites. However in group III where biochemical evidence of fetal distress was present a significant difference was found in the arterial pH between the three sites sampled. In the site closer to the newborn the mean pH was 7.17 + 0.06, in the mid section of the cord the pH was 7.18 + 0.067 and in the site near the placenta the cord pH was 7.21+ 0.079. The same was found when the pCO2 was studied . Ana ysis of the the cord vein blood gases showed significant differences between groups but no difference within groups. In conclusion, the site sampled may play a roll in documenting the respiratory status if acidosis is present.

664 CLINICAL APPLICATION OF THE KLEIHAUER-BETKE TEST. A.R. Dupre,[X] J.N. Martin, Jr., R.C. Floyd,[X] P.G. Blake,[X] W.E. Roberts, J.C. Morrison, Dept. Ob/Gyn, Univ. Mississippi Med. Ctr., Jackson, MS

Objective: Determine the accuracy of quantitation of fetomaternal hemorrhage by Kleihauer-Betke (KB) testing to predict the maternal/neonatal outcome. Population: All women > 20 weeks' gestation at risk for fetomaternal hemorrhage (abdominal trauma, cocaine ingestion, placenta previa, and abruptio placenta) were consecutively evaluated in the labor and delivery suite. A case series study design was utilized. The analysis of maternal whole blood for the presence of fetal cells was accomplished by the KB procedure using a commercially available kit (Sure-Tech Diagnostics, Inc.). If positive, it was repeated at 6-hour intervals (if the patient remained undelivered) for 24 hours. Main Outcome Measured: The presence or absence of abruption at delivery, the estimated gestational age, as well as neonatal hematocrit, weight, pH, and Apgar score were assessed in women who had positive and negative KB tests. Results: Seventy-six patients were enrolled during the study period and a total of 109 KB tests were performed.

	Abdominal Trauma	Placenta Previa	Substance Abuse	Suspected Abruption
N	37	8	15	16
+ KB	4	2	5	7
+ Abruption	0	1	1	5
NN Hct < 45	0	0	0	1

The presence of a positive KB test was not of assistance in identifying significant fetomaternal hemorrhage. Neonatal (NN) outcome was good. There was no correlation between the KB tests either initially or on serial examination with Apgar scores or cord blood pH. Of the 18 patients with positive KB tests, only 1 infant had a hematocrit of < 45%. Even when positive, the amount of estimated fetomaternal bleeding by KB testing did not correlate with any outcome parameter. Conclusion: Significant fetomaternal bleeding or neonatal morbidity is not predicted by a positive KB test.

Amniotomy	6
Antepartum Fetal Evaluation	32, 154, 164, 198, 205, 255, 293, 332, 366, 394, 468, 471, 489, 498, 500, 501, 504, 507, 508, 510, 511, 512, 513, 515, 518, 521, 523, 524, 525, 566, 569, 572, 573, 606, 623, 630, 663
Antepartum Fetal Evaluation-Acoustic Stimulation	371, 500, 511, 516, 517, 521, 568, 572
Antepartum Fetal Evaluation-Amniotic Fluid Volume	32, 110, 151, 162, 164, 347, 495, 496, 497, 499, 503, 514, 519, 523, 527, 566, 574, 623
Antepartum Fetal Evaluation-Biophysical Profile	366, 492, 500, 572
Antepartum Fetal Evaluation-Doppler	62, 105, 200, 201, 202, 206, 212, 350, 351, 520, 524, 574, 630
Antepartum Fetal Evaluation-Fetal Movement	62, 186, 387, 391, 507, 517, 518, 573
Antepartum Fetal Evaluation-Non-Stress Testing	485, 492, 498, 501, 504, 515, 517, 526, 566, 574
Antepartum Fetal Evaluation-Other	293, 303, 385, 471, 509, 571, 664
Antiphospholipid Antibodies	13, 14, 81, 224, 363, 375, 379, 395, 474
Atrial Natriuretic Hormone	372
Birth Trauma	28, 153, 438, 439, 443, 447, 450, 462, 469, 478, 484, 584
Cardiovascular Hemodynamics	42, 101, 112, 330, 345, 349, 350, 389, 559, 588, 636, 639
Cervical Examination	193, 235, 463, 581, 609
Cervical Ripening	8, 217, 223, 227, 397, 453, 546, 575

Subject	Abstract Number
Cesarean Section	4, 27, 31, 69, 85, 173, 225, 226, 228, 231, 234, 390, 411, 412, 422, 437, 438, 439, 444, 448, 454, 455, 458, 460, 469, 475, 476, 481, 487, 488, 493, 546, 577, 578, 587, 607, 655
Computers	65, 235, 236, 237, 238, 239, 240, 241, 242, 243, 311, 342, 515, 569, 606, 607, 608, 618
Congenital Anomalies	19, 152, 156, 174, 191, 194, 241, 245, 253, 259, 264, 265, 276, 280, 284, 285, 469, 571, 589, 590, 592, 597, 622
Cordocentesis	368, 374, 400, 601, 645
Cordocentesis-Diagnositic	23, 24, 40, 281, 287, 290, 291, 369, 393, 400, 540, 549, 592
Cordocentesis-Intrauterine Transfusion	40, 290, 291, 380, 531, 601
CT Scanning	462
Diabetes	11, 78, 79, 81, 83, 84, 87, 88, 89, 95, 98, 106, 115, 117, 121, 132, 178, 275, 547, 548, 551, 553, 554, 564
Diabetes-Pathophysiology	90, 96, 122, 337, 384, 553
Diabetes-Complications	81, 89, 90, 120, 127, 132, 179, 554, 561
Diabetes-Fetal Evaluation	84, 91, 189, 302, 502, 548, 663
Diabetes-Management	78, 85, 87, 88, 91, 113, 117, 120, 121, 179, 564
Diabetes-Other	41, 51, 106, 117, 122, 159, 273, 335, 545, 547, 564
Diabetes-Other Screening	11, 78, 95, 102, 103, 115, 548, 561
Diabetes-Testing	79, 91, 106, 115, 131, 132
Doppler	204, 205, 207, 208, 209, 211, 213, 539, 629
Doppler-Drug Effects On	54, 55, 56, 199, 201, 539, 627
Doppler-Fetal Echocardiography	163, 199, 201, 210, 510, 628
Doppler-Fetal Well Being	202, 206, 208, 209, 628, 629, 630
Doppler-Findings/OB Complications	128, 198, 209, 524, 623
Doppler-IUGR	203, 212, 294, 494, 520
Doppler-Preeclampsia	48, 49, 52, 54, 56, 66, 70, 71, 76, 77, 203, 389, 600
Doppler-Regional Blood Flow	55, 199, 200, 208
Epidural Anesthesia	77, 433, 434, 587

Subject	Abstract Number
Exercise in Pregnancy	364, 376, 377
Fetal Anomalies	149, 160, 165, 168, 174, 220, 250, 251, 252, 256, 263, 264, 266, 268, 270, 274, 282, 286, 289, 449, 522, 590, 597, 611
Fetal Growth	30, 43, 96, 150, 168, 176, 181, 182, 186, 190, 228, 242, 340, 342, 352, 354, 378, 382, 385, 482, 493, 530, 533, 535, 602, 618
Fetal Growth Abnormalities	88, 161, 178, 204, 251, 257, 451, 482, 529, 530, 551, 559, 585, 595, 612
Fetal Growth Abnormalities-IUGR	30, 48, 120, 148, 175, 212, 242, 261, 280, 331, 332, 336, 382, 445, 529, 530, 533, 585, 594, 602,
Fetal Growth Abnormalities-Macrosomia	79, 87, 131, 153, 180, 189, 213, 451, 561, 612
Fetal Lung Maturity	9, 60, 83, 84, 289, 299, 302, 305, 383, 386, 468, 471, 525, 571, 648, 652, 656
Fetal Therapy	23, 24, 255, 286, 288, 289, 290, 293, 390, 400, 425, 611, 629
Genetics	20, 21, 22, 191, 195, 196, 245, 248, 250, 253, 254, 255, 256, 258, 261, 263, 264, 268, 269, 271, 272, 273, 274, 275, 276, 279, 282, 283, 562, 589, 590, 593, 597, 600
Genetics-Diagnostic Technique	19, 20, 22, 149, 184, 185, 244, 246, 251, 258, 259, 260, 265, 266, 271, 277, 278, 279, 281, 284, 285, 286, 383, 589, 591, 592, 593, 616, 624, 645
Glucose Metabolism	41, 46, 102, 103, 122, 214, 354, 371, 384, 387, 545
Hematology	13, 74, 80, 90, 108, 260, 363, 375, 379, 383, 452, 544, 563
Hemodynamic Monitoring	93, 119, 326
Hemolytic Disease of the Fetus	40, 111, 287, 291, 531, 565
Hemorrhage-Postpartum	452, 458, 460, 563
Hydrops Fetalis-Nonimmune	246, 282
Hypertensive Disease in Pregnancy	15, 16, 17, 25, 46, 47, 48, 49, 50, 51, 52, 53, 57, 58, 59, 60, 61, 63, 64, 66, 67, 68, 69, 70, 71, 72, 73, 75, 76, 77, 83, 94, 101, 207, 330, 333, 349, 389, 494, 543, 627, 633, 637, 638
Hypertensive Disease in Pregnancy-Complications/Fetal	65, 69, 70, 142, 637
Hypertensive Disease in Pregnancy-Complications/Maternal	16, 42, 71, 119, 452, 544, 555, 634, 637, 639

Subject	Abstract Number
Hypertensive Disease in Pregnancy-Evaluation & Diagnosis	18, 49, 53, 54, 55, 56, 57, 58, 59, 60, 64, 72, 338, 555, 638
Hypertensive Disease in Pregnancy-HELLP	53, 544
Hypertensive Disease in Pregnancy-Treatment	15, 16, 50, 63, 66, 74, 207, 627, 633, 634, 636
Hypoxia & Asphyxia-Fetal	10, 39, 136, 137, 139, 141, 143, 229, 344, 357, 358, 370, 382, 516, 528, 532, 584, 604
Incompetent Cervix	86, 397, 446
Infections-Maternal	36, 89, 109, 396, 398, 399, 401, 402, 403, 404, 405, 406, 407, 408, 411, 412, 413, 414, 420, 421, 422, 423, 424, 425, 426, 427, 429, 431, 443, 481, 488, 640, 641, 642, 644, 647
Infections-Maternal/Chlamydia	421, 426
Infections-Maternal/Chorioamnionitis	35, 37, 233, 396, 397, 398, 415, 418, 419, 423, 429, 461, 464, 591, 640
Infections-Maternal/Endometritis	415, 422, 640, 644
Infections-Maternal/Group B Streptococcus	37, 413, 424, 430, 647
Infections-Maternal/Other	33, 38, 109, 225, 391, 393, 394, 395, 402, 403, 404, 407, 408, 409, 410, 411, 412, 414, 416, 417, 420, 427, 428, 457, 601, 642
Infections-Maternal/Preterm Labor-PROM	2, 37, 214, 224, 295, 313, 321, 365, 398, 415, 418, 419, 420, 421, 423, 430, 450, 552, 591, 657
Intrapartum Fetal Assessment	133, 134, 135, 136, 137, 138, 139, 140, 142, 143, 144, 218, 345, 357, 434, 454, 455, 477, 664
Labor	6, 7, 8, 31, 35, 85, 134, 135, 137, 140, 214, 215, 216, 217, 218, 219, 220, 221, 222, 223, 225, 226, 227, 228, 229, 230, 232, 233, 234, 295, 323, 365, 424, 432, 433, 437, 438, 439, 447, 448, 450, 458, 459, 462, 476, 478, 479, 481, 491, 506, 512, 536, 546, 575, 576, 578, 581, 585, 660
Meconium	35, 140, 429, 454, 472
Medical Complications	11, 12, 13, 33, 38, 64, 76, 80, 93, 94, 97, 99, 100, 101, 102, 103, 104, 107, 108, 112, 114, 121, 124, 125, 127, 128, 129, 130, 131, 370, 393, 409, 414, 417, 427, 431, 433, 549, 551, 553, 555, 559, 644
Medications in Pregnancy	100, 104, 179, 355, 377, 401, 407, 432, 435, 563
Medications in Pregnancy-Antiepileptics	65

Subject	Abstract Number
Medications in Pregnancy-Antihypertensives	252
Medications in Pregnancy-Calcium Channel Blockers	15, 17, 74, 327, 634, 636, 662
Medications in Pregnancy-Cocaine	44, 61, 82, 92, 126, 144, 280, 341, 361, 367, 373, 426, 435, 456, 473, 650
Medications in Pregnancy-Corticosteroids	148, 297
Medications in Pregnancy-Other	113, 116, 335, 416, 432, 537, 549, 557, 588
Medications in Pregnancy-Prostaglandin Inhibitors	3, 14, 50, 67, 163, 200, 210, 304, 350, 351, 356, 372, 520
Medications in Pregnancy-Prostaglandins	2, 26, 216, 220, 227, 449, 453
Medications in Pregnancy-Tocolytics	3, 171, 296, 304, 315, 325, 348, 356, 658
Multiple Gestation	28, 31, 154, 176, 177, 186, 222, 244, 301, 305, 325, 339, 381, 436, 459, 466, 470, 486, 518, 534, 649
Oligohydramnios	248, 388, 483, 496, 497, 499, 505, 506, 514, 595, 653
Oxytocin	221, 230, 233, 298, 440, 449, 576
Perinatal Outcome	4, 5, 10, 12, 21, 27, 28, 29, 30, 33, 38, 80, 97, 98, 99, 100, 108, 109, 111, 116, 128, 130, 133, 135, 136, 141, 143, 158, 172, 194, 197, 198, 221, 222, 229, 230, 249, 257, 283, 301, 308, 309, 312, 317, 336, 357, 358, 376, 384, 392, 394, 395, 401, 410, 416, 417, 425, 428, 431, 436, 442, 446, 447, 455, 459, 464, 466, 467, 472, 482, 485, 486, 489, 491, 493, 509, 513, 519, 522, 526, 529, 531, 532, 533, 534, 537, 554, 562, 565, 573, 580, 583, 607, 633, 649, 650, 655, 659
Perineal Trauma	234, 443, 457, 490
Physiology	7, 25, 26, 44, 59, 73, 82, 123, 334, 337, 353, 360, 362, 364, 365, 367, 378, 386, 536, 604
Physiology-Fetal	24, 39, 43, 139, 142, 150, 344, 345, 346, 347, 352, 354, 356, 359, 361, 362, 366, 368, 369, 371, 372, 374, 380, 381, 387, 388, 390, 392, 511, 514, 540, 568, 569
Physiology-Maternal	17, 18, 41, 42, 47, 51, 52, 58, 67, 72, 73, 97, 107, 211, 215, 223, 232, 349, 355, 363, 364, 368, 369, 370, 375, 376, 377, 379, 385, 477, 537, 543, 557, 588, 638
Physiology-Membranes/Placenta/Cord	7, 14, 25, 26, 36, 75, 123, 262, 288, 331, 332, 333, 334, 335, 337, 338, 340, 341, 348, 352, 360, 474, 541, 545
Placenta Previa	173, 323

Subject	Abstract Number
Placental Pathology	36, 75, 165, 166, 203, 261, 272, 330, 333, 336, 338, 339, 340, 410, 461, 600
Polyhydramnios	110, 183, 188, 502, 523
Post-Dates-Prolonged Pregnancy	180, 202, 217, 343, 347, 451, 453, 485, 496, 499, 504, 505, 512, 519, 581
Premature Labor	1, 2, 5, 138, 163, 171, 295, 296, 298, 300, 303, 304, 306, 307, 310, 313, 315, 316, 317, 318, 319, 320, 322, 324, 325, 326, 327, 328, 329, 331, 396, 441, 446, 465, 486, 580, 609, 641, 651, 654, 658, 660, 662
Premature Rupture of Membranes	8, 297, 301, 306, 309, 312, 321, 346, 399, 413, 418, 419, 430, 441, 464, 467, 483, 492, 495, 497, 552, 641, 647, 651, 652, 653, 654
Prematurity	1, 4, 9, 10, 29, 86, 155, 224, 294, 297, 299, 300, 302, 305, 306, 307, 308, 309, 310, 311, 313, 314, 316, 317, 318, 319, 320, 321, 322, 324, 326, 328, 329, 428, 436, 441, 442, 465, 466, 470, 495, 528, 534, 552, 609, 648, 649, 651, 652, 653, 654, 655, 656, 657, 658, 659
Prenatal Care	29, 98, 110, 111, 112, 124, 125, 127, 130, 170, 172, 235, 243, 279, 294, 303, 311, 314, 318, 319, 320, 322, 329, 373, 402, 403, 404, 405, 406, 408, 442, 456, 463, 465, 467, 470, 476, 480, 489, 494, 507, 547, 557, 565, 582, 583, 642
Psychosocial Aspects of Pregnancy	92, 314, 445, 480, 558, 583
Respiratory Distress Syndrome	9, 93, 299, 386, 468, 525, 648, 656
Selective Fetal Reduction	292
Sickle Cell Hemoglobinopathy	105
Substance Abuse in Pregnancy	44, 61, 82, 92, 116, 123, 124, 125, 126, 144, 146, 247, 249, 262, 267, 270, 341, 361, 367, 373, 378, 405, 406, 445, 456, 473, 594, 650
Teratology	146, 247, 249, 252, 254, 256, 262, 267, 269, 270, 359, 594, 645
Thyroid	12, 57, 94, 104
Tocolytics	3, 5, 138, 210, 296, 298, 300, 307, 310, 315, 323, 327, 348, 355, 580, 660, 662
Ultrasound	34, 118, 129, 145, 146, 150, 152, 156, 160, 165, 166, 167, 170, 172, 175, 176, 177, 182, 187, 190, 193, 195, 196, 236, 241, 243, 258, 277, 278, 285, 343, 409, 508, 521, 535, 587, 593, 606, 613, 616, 621, 625
Ultrasound-Contraction Monitoring	215, 324, 328

Subject	Abstract Number
Ultrasound-Estimated Fetal Weight	147, 153, 158, 169, 180, 181, 188, 192, 613, 618, 620, 659
Ultrasound-Fetal Anomalies	20, 34, 118, 149, 152, 155, 157, 159, 160, 174, 183, 184, 191, 194, 195, 196, 197, 245, 250, 253, 254, 259, 265, 266, 274, 281, 284, 540, 595, 611, 616, 621, 622, 624, 625
Ultrasound-Fetal Echocardiography	34, 145, 171, 622
Ultrasound-Fetal Growth	96, 147, 157, 159, 161, 168, 169, 177, 178, 181, 184, 187, 189, 380, 543, 608, 612, 613, 624
Ultrasound-Fetal Well Being	151, 154, 156, 162, 391, 503, 510, 527, 568
Ultrasound-Gestational Age Assessment	147, 157, 158, 182, 192, 236, 343, 535
Ultrasound-IUGR	148, 161, 166, 169, 175, 205, 620
Ultrasound-Multiple Gestation	23, 204, 288, 292, 339
Ultrasound-Other	21, 129, 170, 173, 185, 187, 192, 268, 474, 480, 488
Ultrasound-Technical	145, 237, 346, 608, 620
Ultrasound-Vaginal Sonography	190, 193, 232, 292, 316, 625
Uterine Rupture	231, 440, 475, 487
Vaginal Birth After Cesarean Section	27, 226, 231, 437, 440, 448, 475, 487, 576

Artist's enhancement of scanning electron microscopy: *C albicans* 24 hours posttreatment with butoconazole nitrate.*

When you diagnose vulvovaginal candidiasis (VVC)

FEMSTAT® Prefill (butoconazole nitrate) Vaginal Cream 2% is clinically effective against a broad spectrum of important pathogens, including *Candida albicans* and other *Candida* species, such as *C tropicalis.*

Artist's enhancement of scanning electron microscopy: *C albicans* one week posttreatment with butoconazole nitrate.*

Prescribe the efficacy of 3-day therapy†

FEMSTAT achieves a microbiological cure rate of 95% with the original 3-day therapy[1] that is not confirmed to be associated with flu-like symptoms. The most common complaint with the use of FEMSTAT in clinical trials was vulvar/vaginal burning (2.3%).

FEMSTAT® PREFILL

(butoconazole nitrate) VAGINAL CREAM 2%

3-day Rx control of VVC

1. Droegemueller W, Adamson DG, Brown D, et al. Three-day treatment with butoconazole nitrate for vulvovaginal candidiasis. *Obstet Gynecol.* 1984;64:530-534. *Micrographs on file, Syntex Laboratories, Inc. †In pregnant patients (second and third trimesters only), therapy should be extended to 6 days. Committed to the OB/GYN and women's healthcare

BRIEF SUMMARY

INDICATIONS: FEMSTAT® (butoconazole nitrate) vaginal cream 2% is indicated for local treatment of vulvovaginal mycotic infections caused by Candida species. Confirm the diagnosis by KOH smears and/or cultures. FEMSTAT can be used with oral contraceptives and antibiotics. It is effective in non-pregnant women and during the second and third trimesters of pregnancy.

CONTRAINDICATIONS: FEMSTAT is contraindicated in patients hypersensitive to any of the ingredients.

PRECAUTIONS: General: If clinical symptoms persist, repeat microbiological tests to rule out other pathogens and confirm the diagnosis. Discontinue drug if sensitization or irritation occurs.

Information for the Patient: Do not discontinue prematurely during menstruation or because of symptomatic relief.

Carcinogenesis: Animal studies have not been done.

Mutagenesis: Mutagenicity studies were negative.

Impairment of Fertility: Animal studies showed no impairment of fertility.

Pregnancy Category C: Adverse effects were noted in animals treated with high oral doses. No studies were done in women during first trimester. Patients in the second or third trimester have shown no adverse effects attributable to the drug.

Nursing Mothers: Use with caution.

Pediatric Use: Safety and efficacy have not been established.

ADVERSE REACTIONS: Vulvar/vaginal burning in 2.3% of patients, vulvar itching in 0.9%, discharge, soreness, swelling, itching of fingers each in 0.2%. Complaints caused 1.6% to discontinue drug.

DOSAGE AND ADMINISTRATION: Non-pregnant Patients: The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for three days. Treatment can be extended for an additional three days if necessary.

Pregnant Patients (second and third trimesters only): The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for six days.

CAUTION:
Federal law prohibits dispensing without prescription.

Mosby Year Book

Provide vital information to those who need it most . . .
with article reprints from Mosby–Year Book periodicals

Article reprints are your best means of distributing the information published in Mosby–Year Book's medical, dental, and nursing periodicals. These papers will enhance the value of your information programs.

Not just for authors, reprints are an effective tool for health care professionals, sales and marketing staffs, and advertisers.

Use reprints to:

- Train and educate your sales and marketing staff
- Support your seminar topic
- Inform your health care staff of new developments
- Reach your product users with vital information

Article reprints . . . another valuable service from Mosby–Year Book.

Orders (minimum of 100 copies) of all previous and future articles in Mosby–Year Book periodicals are available from the Publisher.

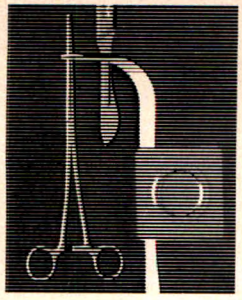
CEFOTAN® IM/IV



(cefotetan disodium)

In intra-abdominal and gynecologic infection due to indicated organisms

For Intravenous or Intramuscular Use
(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT.)

INDICATIONS AND USAGE
Treatment: CEFOTAN is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:
Urinary Tract Infections caused by *E coli, Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis,* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris, Providencia rettgeri,* and *Morganella morganii*).
Lower Respiratory Tract Infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), *E coli, Proteus mirabilis,* and *Serratia marcescens.**
Skin and Skin Structure Infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus pyogenes, Streptococcus* species (excluding enterococci), *E coli, Klebsiella pneumoniae,* and *Peptococcus** and *Peptostreptococcus* sp.*
Gynecologic Infections caused by *Staphylococcus aureus* (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus* species (excluding enterococci), group B streptococci, *E coli, Proteus mirabilis, Neisseria gonorrhoeae, Bacteroides* species (excluding *B distasonis, B ovatus, and B thetaiotaomicron*), *Fusobacterium* species,* and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species).
Intra-abdominal Infections caused by *E coli, Klebsiella* species (including *K pneumoniae*), *Streptococcus* species (excluding enterococci), *Bacteroides* species (excluding *B distasonis, B ovatus,* and *B thetaiotaomicron*), and *Clostridium* species.*
Bone and Joint Infections caused by *Staphylococcus aureus.**
*Efficacy for this organism in this organ system was studied in fewer than ten infections.

Specimens for bacteriological examination should be obtained in order to isolate and identify causative organisms and to determine their susceptibilities to cefotetan. Therapy may be instituted before results of susceptibility studies are known; however, once these results become available, the antibiotic treatment should be adjusted accordingly.

In cases of confirmed or suspected gram-positive or gram-negative sepsis or in patients with other serious infections in which the causative organism has not been identified, it is possible to use CEFOTAN concomitantly with an aminoglycoside. Cefotetan combinations with aminoglycosides have been shown to be synergistic in vitro against many Enterobacteriaceae and also some other gram-negative bacteria. The dosage recommended in the labeling of both antibiotics may be given and depends on the severity of the infection and the patient's condition.
Note: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycosidic antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.
Prophylaxis: The preoperative administration of CEFOTAN may reduce the incidence of certain post-operative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS
CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS
Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile.* Other causes should also be considered.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity and, possibly, subsequent bleeding. Those at increased risk include patients with renal or hepatobiliary impairment or poor nutritional state, the elderly, and patients with cancer. Prothrombin time should be monitored and exogenous vitamin K administered as indicated.

PRECAUTIONS
General: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.
Information for Patients: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc.) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.
Drug Interactions: Although to date nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.
Drug/Laboratory Test Interactions: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels by Jaffe reaction and produce false increases in the levels of creatinine reported.
Carcinogenesis, Mutagenesis, Impairment of Fertility: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approximately 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approximately 2-4 times the usual human dose) only 1 of 10 treated animals was affected, and the degree of degeneration was mild.

Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.
Usage in Pregnancy: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
Usage in Nursing Mothers: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.
Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
In clinical studies, the following adverse effects were considered related to CEFOTAN therapy.
Gastrointestinal symptoms occurred in 1.5% of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).
Hematologic laboratory abnormalities occurred in 1.4% of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).
Hepatic enzyme elevations occurred in 1.2% of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).
Hypersensitivity reactions were reported in 1.2% of patients and included rash (1 in 150) and itching (1 in 700).
Local effects were reported in less than 1.0% of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

During postmarketing experience with CEFOTAN, agranulocytosis, anaphylactic reactions, fever, hemolytic anemia, leukopenia, prolonged prothrombin time with or without bleeding, pseudomembranous colitis, and transient thrombocytopenia have been reported.

DOSAGE AND ADMINISTRATION
Treatment: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

Prophylaxis: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.
Impaired Renal Function: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dosage*	Every 12 hours
10-30	Usual Recommended Dosage*	Every 24 hours
<10	Usual Recommended Dosage*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Alternatively, the dosing interval may remain constant at 12 hour intervals, but the dose reduced to one-half the usual recommended dose for patients with a creatinine clearance of 10-30 mL/min, and one-quarter the usual recommended dose for patients with a creatinine clearance of less than 10 mL/min.

When only serum creatinine levels are available, creatinine clearance may be calculated from the following formula. The serum creatinine level should represent a steady state of renal function.

$$\text{Males:} \quad \frac{\text{Weight (kg)} \times (140 - \text{age})}{72 \times \text{serum creatinine (mg/100 mL)}}$$

$$\text{Females:} \quad 0.9 \times \text{value for males}$$

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

CLINICAL SECTION

Clinical Opinion

Selection bias in in vitro fertilization programs 1
A. Hershlag, MD, E.H. Kaplan, PhD, R.A. Loy, MD, A.H. DeCherney, MD, and G. Lavy, MD
New Haven, Connecticut

Selection biases at the point of entry and between cycles might explain differences in reported pregnancy rates among in vitro fertilization–embryo transfer programs.

Clinical Articles

Main clinical types and subtypes of eclampsia 4
Mario López-Llera M., MD
Mexico City, Mexico

The clinical analysis of 990 patients with eclampsia showed that a complete and more precise classification of this disease must consider seven differential facts.

Prognosis in fetal diaphragmatic hernia 9
Gurleen K. Sharland, BSc, MB, Susan M. Lockhart, RGN, RM, Annabel J. Heward, RGN, RM, and Lindsey D. Allan, MD
London, England

Left heart underdevelopment detected by fetal echocardiography may be a useful predictor of outcome in fetal diaphragmatic hernia.

Obstetrics and Gynecology Review Course
March 23-28, 1992 – San Francisco June 8-13, 1992 –Pittsburgh
Oct. 5-10, 1992 – Nashville †Nov. 30-Dec. 5, 1992 – Chicago
Now, your course for exams has practice tests and case-list reviews

OBJECTIVES
- Increase basic knowledge and clinical skills in ob-gyn
- Assist residents and fellows to organize their study
- Prepare candidates to take their examinations
- Provide practicing gynecologists with an update

METHODS
- HOME STUDY MATERIALS with questions and answers
- SEMINAR with projection slides and lecture-note syllabus
- LABORATORY with microscope and glass slides
- PRACTICE EXAMS for your written and oral exams

†Plus extra mock oral days December 6-8.

*"The faculty was outstanding. The most pleasant thing was learning a tremendous amount, not only from world-famous authorities, but from people who are relatively unknown as well."**

*"The course was extremely helpful to me."**

COURSES: Fall courses are more clinically oriented. The course includes lectures with syllabus as well as an opportunity for you to buy an unlimited number of 25-minute, one-on-one sessions with faculty to review your case lists or perform mock oral exams. The optional extra days, Dec. 6-8, include a pathology laboratory session, one mock oral exam and observation of seven or more hours of other exams. Past participants recommend repeating the course for half price immediately before exams.

*"Accommodations were comfortable...."**

LOCATION: The course hotel will be selected in competitive bidding for the best possible combination of good rates and excellent study environment.

*"...and those little extras...."**

DISCOUNT AIR FARES: Please call toll-free (800) 548-8185 for group discounts.

*"...the most education for the money."**

FEES FOR 60 HOURS:
- Practicing Gynecologist: $780
- Resident or Fellow: $520
- Repeating course within 2 years: $390
- Optional extra days, December 6-8 (per day fee): $150
- **Add 10% within 10 days of the course.**
- Attendees not in course hotel add $20/day.
- A deposit of $50 will reserve your position.

*"...home study material was extremely helpful."**

ACCREDITATION: Jointly sponsored by Penn State's College of Medicine at The Milton S. Hershey Medical Center. Penn State is accredited by the Accreditation Council for Continuing Medical Education (ACCME) to sponsor continuing medical education for physicians.

CREDIT: Penn State designates this continuing medical education activity for 60 credit hours in Category 1 of the Physician's Recognition Award of the American Medical Association.

Abruptio placentae associated with perforated appendicitis and generalized peritonitis 14

Yuval Yaron, MD, Joseph B. Lessing, MD, and M. Reuben Peyser, MD

Tel Aviv, Israel

A case of abruptio placentae at 35 weeks of pregnancy, a sequela of generalized peritonitis after acute appendicitis, is presented.

The effect of continuous subdermal levonorgestrel (Norplant) on carbohydrate metabolism 15

Justin C. Konje, MD, Emmanuel O. Otolorin, MD, and Oladapo A. Ladipo, MD

Ibadan, Nigeria

The effect of continuous low-dose subdermal levonorgestrel on carbohydrate metabolism was studied in 20 women over a 12-month period.

Familial occurrence of thrombotic thrombocytopenic purpura in two sisters during pregnancy 20

Arnon Wiznitzer, MD, Moshe Mazor, MD, Joseph R. Leiberman, MD, Yaron Bar-Levie, MD, Gavriel Gurman, MD, and Marek Glezerman, MD

Beer-Sheva, Israel

A genetic predisposition can trigger the appearance of thrombotic thrombocytopenic purpura during pregnancy.

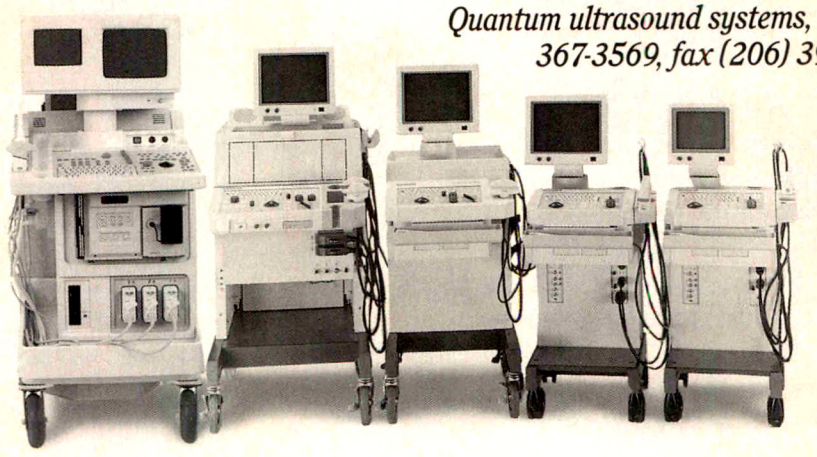
You Have All Kinds Of Reasons To Stay At The Forefront Of Ultrasound

We Have The Technology To Keep You There.



In offices, clinics and hospitals worldwide, Siemens Quantum is changing the way doctors look at their patients.

Our imaging systems and state-of-the-art diagnostics are pushing the limits of ultrasound. Providing more and better information at every level. Performing more types of obstetric and gynecologic studies than ever before.

The Siemens Quantum alliance joins two powerful forces: Siemens, the world's largest medical imaging company, and Quantum, a pioneer and technological leader in ultrasound.

Together, we're committed to maintaining our leading edge. Which means keeping our systems—and our customers—at the forefront of diagnostic imaging.

The Siemens SONOLINE® SI-200 & 250 are versatile, affordable, compact and easy to use.

And they come with the most advanced, multi-frequency, patient-friendly endovaginal probe on the market.

The Siemens SONOLINE® SI-450 offers superb image quality and a comprehensive set of reports and measurement packages. For complete transabdominal, endovaginal and spectral Doppler capabilities, there's no better equipment for the price.

The Quantum 2000 is a high-performance, high-end, all-purpose system that's unsurpassed for high-definition gray scale and ultra-sensitive color flow. Its advanced technology lets you see subtle differences in tissue, accurately image the tiniest flows, and detect even the smallest details at depth.

To receive more information on Siemens Quantum ultrasound systems, call 1-800-367-3569, fax (206) 391-9161, or write us at 1040 12th Ave. N.W., Issaquah, WA 98027.

Numeric analysis of heart rate variation in intrauterine growth–retarded fetuses: A longitudinal study 22
Rosalinde J.M. Snijders, MSc, Lucia S.M. Ribbert, MD, Gerard H.A. Visser, MD, PhD, and Eduard J.H. Mulder, MSc, PhD
Groningen, The Netherlands

Computer analysis of heart rate variation in growth-retarded fetuses showed that reduced variation coincided with antenatal heart rate decelerations.

Eosinophilic cystitis during pregnancy 28
Robert O. Chamberlin, MD
St. Petersburg, Florida

The first reported case of eosinophilic cystitis during pregnancy is presented.

Upper vaginectomy for in situ and occult, superficially invasive carcinoma of the vagina 30
Mitchel S. Hoffman, MD, Steven L. DeCesare, MD, William S. Roberts, MD, James V. Fiorica, MD, Michael A. Finan, MD, and Denis Cavanagh, MD
Tampa, Florida

Upper vaginectomy was efficacious both for the diagnosis of occult invasive carcinoma of the vagina and for the treatment of grade 3 vaginal intraepithelial neoplasia.

Transient symptomatic subendocardial ischemia during intravenous magnesium sulfate tocolytic therapy 33
David M. Sherer, MD, Paul R. Cialone, MD, Jacques S. Abramowicz, MD, and James R. Woods, Jr., MD
Rochester, New York

Acute chest pain with associated electrocardiographic evidence of transient subendocardial ischemia occurred during intravenous magnesium sulfate tocolytic therapy at 35 weeks' gestation.

Possible transplacental transmission of human papillomaviruses 35
Chih-Jen Tseng, MD, Chieh-Yu Lin, BS, Ruey-Ling Wang, BS, Li-Ju Chen, BS, Ya-Li Chang, MS, T'sang-T'ang Hsieh, MD, and Chia C. Pao, PhD
Taipei, Taiwan, Republic of China

Human papillomavirus type 16 deoxyribonucleic acid was found in cord blood of neonates born to mothers with cervicovaginal or peripheral blood mononuclear cell human papillomavirus infections.

Use of urinary luteinizing hormone immunoassays in the assessment of luteal function in infertile women 41
Gregory H. Corsan, MD, Ekkehard Kemmann, MD, Michael Bohrer, MD, Michael Blotner, MD, Paul Smilow, MD, and Robert Shelden, PhD
New Brunswick, New Jersey

A home urinary luteinizing hormone immunoassay kit did not aid in the assessment of luteal function in infertile women.

Contents

Intracerebral, aortic, and umbilical artery flow velocity waveforms in the late-first-trimester fetus 46

Juriy W. Wladimiroff, MD, PhD, Tjeerd W.A. Huisman, MD, and Patricia A. Stewart, PhD

Rotterdam, The Netherlands

In the late-first-trimester human fetus, high umbilical-placental vascular resistance is associated with relatively low cerebral vascular resistance.

Ovarian metastases in stage IB carcinoma of the cervix: A Gynecologic Oncology Group study 50

Gregory P. Sutton, MD, Brian N. Bundy, PhD, Gregorio Delgado, MD, Bernd-Uwe Sevin, MD, PhD, William T. Creasman, MD, Francis J. Major, MD, and Richard Zaino, MD

Indianapolis, Indiana, Buffalo, New York, Washington, D.C., Miami, Florida, Charleston, South Carolina, Denver, Colorado, and Hershey, Pennsylvania

The frequency of ovarian metastases in clinical stage IB cervical carcinoma is low, and no significant difference between squamous carcinoma and adenocarcinoma is appreciated.

Describing and interpreting 24-hour blood pressure patterns in physiologic pregnancy 54

Pietro Cugini, MD, Loredana Di Palma, MD, Paola Battisti, MD, Giuseppe Leone, MD, Antonio Pachí, MD, Rosalba Paesano, MD, Cristiana Masella, MD, Giovanni Stirati, MD, Alessandro Pierucci, MD, Anna Rachele Rocca, MD, and Santo Morabito, MD

Rome, Italy

Twenty-four–hour blood pressure patterns change in time structure along the course of a physiologic pregnancy, showing specific arrangement in each gestational trimester.

Derivation of new mathematic formulas for determining whether a D-positive father is heterozygous or homozygous for the D antigen 61

Michael H. Kanter, MD

Los Angeles, California

For the woman sensitized to the D antigen, new, more accurate formulas are derived to determine if her husband is homozygous or heterozygous for the D antigen.

Insulin-like growth factor I and II binding in human myometrium and leiomyomas 64

Yallampalli Chandrasekhar, PhD, James Heiner, MD, Collin Osuamkpe, MS, and Manubai Nagamani, MD

Galveston, Texas

Leiomyomas of the uterus have increased binding sites for insulin-like growth factor I but not insulin-like growth factor II, indicating a possible role of insulin-like growth factor I in the generation and growth of this tumor.

Impairment of counterregulatory hormone responses to hypoglycemia in pregnant women with insulin-dependent diabetes mellitus 70

Michael P. Diamond, MD, E. Albert Reece, MD, Sonia Caprio, MD, Timothy W. Jones, MD, Stephanie Amiel, MD, Nancy DeGennaro, RN, Andrea Laudano, RN, Mario Addabbo, Robert S. Sherwin, MD, and William V. Tamborlane, MD

New Haven, Connecticut

Pregnant insulin-dependent diabetic women receiving intensive insulin therapy have impaired counterregulatory hormone responses to hypoglycemia.

Contents continued from page 11A

Intrapartum amniotic fluid index and its relationship to fetal distress 78
Stephen C. Robson, MD, Robin A. Crawford, MD, John A.D. Spencer, MD, and Angela Lee, PhD
London, England

A low intrapartum amniotic fluid index (defined as <6.2 cm) was associated with an increased incidence of suspected fetal distress but not with umbilical artery acidemia or low Apgar scores.

Colposcopy to establish physical findings in rape victims 83
Laura Slaughter, MD, and Carl R.V. Brown, PhD
San Luis Obispo, California

Colposcopic evaluation of 131 rape victims provided evidence of genital changes in 114 (87%); application of this new technology may be the best way of seeing and documenting the findings associated with rape.

Natural killer cell activity from pregnant subjects is modulated by RU 486 87
Keith A. Hansen, MD, Michael S. Opsahl, MD, Lynnette K. Nieman, MD, James R. Baker, Jr., MD, and Thomas A. Klein, MD
Washington, D.C., and Bethesda, Maryland

A potent antiprogesterone, RU 486, augments natural killer cell activity isolated from gravid subjects.

Prenatal diagnosis of fetal cytomegalovirus infection 91
Monique E. Lamy, MD, Kipanga N. Mulongo, MD, Jean-François Gadisseux, MD, Gilbert Lyon, MD, Véronique Gaudy, MD, and Michel Van Lierde, MD
Brussels, Belgium

Seven pregnant women with primary cytomegalovirus infection were investigated at 22 weeks; amniotic fluid culture proved to be a sensitive test to diagnose fetal infection.

Endothelin-1,2 levels are increased in the amniotic fluid of women with preterm labor and microbial invasion of the amniotic cavity 95
Roberto Romero, MD, Cecilia Avila, MD, Samuel S. Edwin, MS, and Murray D. Mitchell, DPhil
New Haven, Connecticut, Detroit, Michigan, and Salt Lake City, Utah

Normal amniotic fluid contains immunoreactive endothelin-1,2, and its concentration is increased in preterm labor associated with microbial invasion of the amniotic cavity.

Incidence of pelvic inflammatory disease after first-trimester legal abortion in women with bacterial vaginosis after treatment with metronidazole: A double-blind, randomized study 100
Per-Göran Larsson, MD, Jens-Jörgen Platz-Christensen, MD, Henning Thejls, MD, Urban Forsum, MD, PhD, and Carl Påhlson, PhD
Skövde, Gothenburg, Gävle, Linköping, and Uppsala, Sweden

A double-blind, randomized study of 174 women with bacterial vaginosis showed that treatment with metronidazole leads to a significant reduction in postabortion pelvic inflammatory disease.

Contents

Depressive symptoms in women in the six months after miscarriage 104
Richard Neugebauer, PhD, MPH, Jennie Kline, PhD, Patricia O'Connor, PhD, Patrick Shrout, PhD, Jim Johnson, PhD, Andrew Skodol, MD, Judith Wicks, BA, and Mervyn Susser, MB, BCh, DPH
New York, New York

Women experience threefold increases in depressive symptoms in the 6 months after miscarriage; however, structured interviews administered even by lay personnel via telephone may provide substantial psychotherapeutic benefits.

Alloimmune thrombocytopenia may be associated with systemic disease 110
Helen H. Kay, MD, Marvin L. Hage, MD, Joanne Kurtzberg, MD, and Kimberly P. Dunsmore, MD
Durham, North Carolina

Recent studies identifying cell surface molecules similar to the Pl^{A1} antigen suggest that alloimmune thrombocytopenia may be associated with systemic disease.

Spontaneous abortion and subsequent adverse birth outcomes 111
David H. Thom, MD, PhD, Lorene M. Nelson, PhD, and Thomas L. Vaughan, MD, MPH
Seattle, Washington

Compared with primigravid women, women with three or more prior spontaneous abortions were at increased risk of several adverse birth outcomes in a subsequent pregnancy.

Prolonged effects of a novel, low-dosage continuous progestin–cyclic estrogen replacement program in postmenopausal women 117
Earl R. Plunkett, MD, and Bernard M. Wolfe, BM, BCh(Oxon)
London, Ontario, Canada

Combined hormonal therapy with 17β-estradiol and *dl*-norgestrel relieved vasomotor symptoms, virtually eliminated vaginal bleeding and spotting, and reduced mean plasma low-density lipoprotein cholesterol by 23%.

Attitudes toward reproduction in a nonpatient population 121
Marianne Wikman, MD, Lars Jacobsson, MD, and Bo von Schoultz, MD
Umeå and Stockholm, Sweden

Attitudes toward reproduction in a Swedish population are dominated by two conflicting views: Children mean existential satisfaction and lack of freedom.

Acute posttraumatic fetal anemia treated with fetal intravascular transfusion 127
Gerardo O. Del Valle, MD, Gary M. Joffe, MD, Luis A. Izquierdo, MD, James F. Smith, MD, Tracey Kasnic, RNC, BSN, George J. Gilson, MD, Molly S. Chatterjee, MD, and Luis B. Curet, MD
Albuquerque, New Mexico

Fetal intravascular transfusion may be an alternative in the management of posttraumatic fetal anemia.

Infection and labor. VII. Microbial invasion of the amniotic cavity in spontaneous rupture of membranes at term 129
Roberto Romero, MD, Moshe Mazor, MD, Rafaella Morrotti, MD, Cecilia Avila, MD, Enrique Oyarzun, MD, Alvaro Insunza, MD, Manuel Parra, MD, Ernesto Behnke, MD, Francisco Montiel, MD, and Gail H. Cassell, PhD
New Haven, Connecticut, Detroit, Michigan, and Birmingham, Alabama

Microbial invasion of the amniotic cavity occurs in 34.3% of women with spontaneous rupture of membranes at term.

Serum levels of macrophage colony-stimulating factor in patients with ovarian cancer undergoing second-look laparotomy 134
Steven A. Elg, MD, Yin Yu, MD, Linda F. Carson, MD, Leon L. Adcock, MD, Leo B. Twiggs, MD, Konald A. Prem, MD, and Sundaram Ramakrishnan, PhD
Minneapolis, Minnesota

Regardless of tumor status, macrophage colony-stimulating factor serum levels tend to be elevated at the time of second-look laparotomy in ovarian cancer.

Population differences of fetal biophysical and behavioral characteristics 138
Mary Jo Johnson, MD, Lisa L. Paine, CNM, DrPH, Helma H. Mulder, MD, Carey Cezar, RNC, Carolyn Gegor, CNM, MS, and Timothy R.B. Johnson, MD
Baltimore, Maryland

Doppler real-time ultrasonographic examination of 14 black and 15 white fetuses was undertaken to explain a population difference in nonstress test reactivity.

May-Hegglin anomaly: A rare case of maternal thrombocytopenia in pregnancy 143
Ashwin Chatwani, MD, Nancy Bruder, BS, Todd Shapiro, MD, and E. Albert Reece, MD
Philadelphia, Pennsylvania

A case report and a review of the literature on May-Hegglin anomaly, which is a rare cause of thrombocytopenia, are presented.

Oral magnesium and the prevention of preterm labor in a high-risk group of patients 144
Rick W. Martin, MD, Kenneth G. Perry, Jr., MD, L. Wayne Hess, MD, James N. Martin, Jr., MD, and John C. Morrison, MD
Jackson, Mississippi

Prophylactic oral magnesium gluconate given to patients at risk for preterm delivery did not reduce the incidence of low birth weight or preterm labor.

Pelvic abscess complicating transcervical embryo transfer 148
Mark V. Sauer, MD, and Richard J. Paulson, MD
Los Angeles, California

Although uncommon, severe pelvic infections may occur after transcervical embryo transfer.

Contents

Urinary excretion of prostacyclin and thromboxane metabolites in threatened preterm labor: Effect of indomethacin and nylidrin 150
Tapio Kurki, MD, Lasse Viinikka, MD, and Olavi Ylikorkala, MD
Helsinki, Finland

Threatened preterm labor is accompanied by increases in prostacyclin and thromboxane A_2 synthesis, which is suppressed by maternal indomethacin.

Substance P in peritoneal fluid 155
Joseph S. Sanfilippo, MD, R. Stanford Williams, MD, Marvin A. Yussman, MD, Christine L. Cook, MD, and Francois Bissonnette, MD
Louisville, Kentucky

The first observation of substance P isolated in peritoneal fluid is reported; the patient population comprised individuals undergoing infertility evaluation.

Partial hydatidiform moles have impaired differentiated function (human chorionic gonadotropin and human placental lactogen secretion) in response to epidermal growth factor and 8-bromo-cyclic adenosine monophosphate 160
Donald W. Morrish, MD, PhD, Louis H. Honoré, MB, and Damyanti Bhardwaj, MD
Edmonton, Alberta, Canada

Most partial hydatidiform moles were found to lack human chorionic gonadotropin and human placental lactogen secretory responsiveness to epidermal growth factor and 8-bromo-cyclic adenosine monophosphate/theophylline compared with normal first-trimester placentas.

Rapid growth of leiomyoma in patient receiving tamoxifen 167
P.V. Dilts, Jr., MD, Michael P. Hopkins, MD, Alfred E. Chang, MD, and Robert L. Cody, MD
Ann Arbor, Michigan

A case report is presented of rapid growth of a leiomyoma while a patient was taking tamoxifen for treatment of breast malignancy.

Transient severe unilateral and subsequent bilateral primary fetal hydrothorax with spontaneous resolution at 34 weeks' gestation associated with normal neonatal outcome 169
David M. Sherer, MD, Jacques S. Abramowicz, MD, Paula C. Eggers, RDMS, and James R. Woods, Jr., MD
Rochester, New York

Severe unilateral primary fetal hydrothorax at 28 weeks' gestation, with subsequent bilateral involvement, spontaneously resolved at 34 weeks' gestation with normal neonatal outcome.

Current Development

Meconium aspiration syndrome: Reflections on a murky subject 171
Vern L. Katz, MD, and Watson A. Bowes, Jr., MD
Chapel Hill, North Carolina

Recent investigations suggest that the pathologic condition of meconium aspiration syndrome is caused primarily by asphyxia with subsequent pulmonary vascular disease.

(Contents continued on page 16A)

Contents continued from page 15A

BASIC SCIENCE SECTION

Rapid identification of deoxyribonucleic acid sequence differences in cytochrome P-450 21-hydroxylase (CYP21) genes with denaturing gradient gel blots 184

Richard H. Reindollar, MD, Brian C.J. Su, MD, Steven R. Bayer, MD, and Mark R. Gray, PhD

Boston, Massachusetts

Denaturing gradient gel electrophoresis demonstrates significant polymorphisms within the 21-hydroxylase genes and is potentially useful in the molecular analysis of patients with 21-hydroxylase deficiency.

Transforming growth factor-α and epidermal growth factor messenger ribonucleic acid and protein levels in human placentas from early, mid, and late gestation 192

Francois Bissonnette, MD, Christine Cook, MD, Thomas Geoghegan, PhD, Marlen Steffen, BS, John Henry, PhD, Marvin A. Yussman, MD, and Gregory Schultz, PhD

Louisville, Kentucky, and Gainesville, Florida

High levels of messenger ribonucleic acid and protein for transforming growth factor-α were detected in placentas throughout pregnancy, suggesting that transforming growth factor-α influences placental function by an autocrine system.

Oxytocin given in a pulsatile manner to the ewe at 120 to 140 days' gestational age increases fetal sheep plasma cortisol 200

Drew W. Sadowsky, BA, Juliann Martel, MS, Theresa Cabalum, MD, M. Gabriella Poore, DVM, PhD, and Peter W. Nathanielsz, MD, PhD

Ithaca, New York

Pulsatile oxytocin infusion to the pregnant ewe increases plasma cortisol levels in chronically catheterized fetal sheep in late gestation.

Both 17β-estradiol and tamoxifen induce c-*fos* messenger ribonucleic acid expression in human endometrial carcinoma grown in nude mice 206

Katsumi Sakakibara, MD, Nancy C. Kan, PhD, and Pondichery G. Satyaswaroop, PhD

Hershey, Pennsylvania

17β-Estradiol and tamoxifen induce protooncogene c-*fos* expression in human endometrium.

Low-dose infusion of atrial natriuretic peptide in the conscious guinea pig increases blood flow to the placenta of growth-retarded fetuses 213

Thomas B. Jansson, MD, PhD

Göteborg, Sweden

Physiologic doses of atrial natriuretic peptide selectively increase blood flow to placentas of growth-retarded fetuses and may be of therapeutic value in pregnancies complicated by intrauterine growth retardation.

Contents

The effect of preovulatory peritoneal fluid from cases of endometriosis on murine in vitro fertilization, embryo development, oviduct transport, and implantation 219

William G. Dodds, MD, Frederick A. Miller, MS, Chad I. Friedman, MD, Brad Lisko, BS, Jeffrey M. Goldberg, MD, and Moon H. Kim, MD

Columbus, Ohio

Preovulatory peritoneal fluid from superovulated patients with and without endometriosis demonstrated an equal dose-dependent type of inhibition of murine in vitro fertilization.

Attenuation of the vasoconstrictor effects of thromboxane and endothelin by nitric oxide in the human fetal-placental circulation 224

Leslie Myatt, PhD, Anthony S. Brewer, BS, Gretchen Langdon, BA, and Diane E. Brockman, MS

Cincinnati, Ohio

The endothelium-derived relaxing factor nitric oxide attenuates the action of the vasoconstrictors thromboxane and endothelin-1 in the perfused human fetal-placental circulation.

Influence of terbutaline on ovine uterine response to prostaglandin E_2 challenge 231

Deborah L. Reid, PhD, Susan R. Davidson, MD, Terrance M. Phernetton, BS, and John H.G. Rankin, PhD

Madison, Wisconsin

Both electric and contractile uterine responses to prostaglandin E_2 were diminished during terbutaline infusion in pregnant sheep, with subsequent decreased contractility during normal electric activity.

Catecholamines modulate epidermal growth factor–induced prostaglandin E_2 production in amnion-like (WISH) cells by means of a cyclic adenosine monophosphate–dependent pathway 236

Hsing-Chih Su, BS, Richard H. Fertel, PhD, and Douglas A. Kniss, PhD

Columbus, Ohio

Physiologic concentrations of catecholamines modulate epidermal growth factor–induced prostaglandin E_2 production in human amnion by means of a cyclic adenosine monophosphate–dependent pathway.

Circulating hyaluronic acid in nonpregnant, pregnant and postpartum guinea pigs: Elevated levels observed at parturition 242

Mohammad R. Rajabi, MD, PhD, Edward W. Quillen, Jr., PhD, Bahij S. Nuwayhid, MD, PhD, Ragnhild Brandt, MSc, and A. Robin Poole, PhD, DSc

Montreal, Quebec, Canada, and Uppsala, Sweden

Circulating hyaluronic acid increases at parturition in the guinea pig.

Change in electrocardiogram T-wave amplitude during umbilical cord compression is predictive of fetal condition in sheep 246
Takanori Watanabe, MD, Kunihiro Okamura, MD, Shingo Tanigawara, MD, Yoshiyuki Shintaku, MD, Kozo Akagi, MD, Hidetaka Endo, MD, and Akira Yajima, MD
Sendai, Japan

The T/QRS ratio in the electrocardiogram during umbilical cord compression correlated well with arterial pH, P_{CO_2}, catecholamine concentrations, and duration of elevated blood pressure in the fetal lamb.

Changes in human platelet angiotensin II binding sites associated with early pregnancy 255
Philip N. Baker, DM, Fiona Broughton Pipkin, DPhil, and E. Malcolm Symonds, DM
Nottingham, England

In a longitudinal study of platelet angiotensin II binding in early primigravid pregnancy, the binding of angiotensin II by platelets falls significantly from 5 to 8 weeks' gestation.

The maternal and fetal effects of milrinone and dopamine in normotensive pregnant ewes 257
A.C. Santos, MD, A.L. Baumann, DO, D. Wlody, MD, H. Pedersen, MD, H.O. Morishima, MD, PhD, and M. Finster, MD
Stony Brook, Brooklyn, and New York, New York

Milrinone, a new inotropic agent, had no adverse effects on uterine blood flow or fetal well-being when administered to pregnant ewes.

Editors' note

The AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY introduces a new format for abstracts accompanying regular articles, society articles, and Current Investigation articles. Authors submitting these manuscripts to the JOURNAL should provide an abstract of no more than 150 words structured according to the following headings: Objective(s), Study Design, Results, and Conclusion(s). Exceptions to this requirement include Clinical Opinion, Current Development, case report, and brief communication articles. Abstracts for these articles will continue to follow the standard abstract format. Please consult the Information for Authors for details.

The JOURNAL is abstracted and/or indexed in *Index Medicus, Science Citation Index, Current Contents/Clinical Medicine, Current Contents/Life Sciences, Excerpta Medica, BRS Colleague,* and MEDLINE.

Authorization to photocopy items for internal or personal use is granted by Mosby–Year Book, Inc., for libraries and other users registered with the Copyright Clearance Center (CCC) Transactional Reporting Service, provided that 10¢ per page per copy is paid directly to CCC, 27 Congress St., Salem, MA 01970; phone (508)744-3350. The U.S. Government retains a nonexclusive, royalty-free license in and to any copyright on articles authored by government employees. 0002-9378/92 $00.00 + .10.

You think it's good medicine.

She thinks it's wonderful.

Thanks to you and Premarin®, she could make these years the best years of her life

Hot flashes–Now part of the past for millions of women
Premarin® can dramatically reduce the incidence of hot flashes, night sweats, and related sleep disturbances.

Osteoporosis–No longer part of the future for many women
Premarin® is the first estrogen product proven to prevent postmenopausal osteoporosis in women at risk. And it's the *only* estrogen product proven in studies to reduce the risk of osteoporosis-related fractures by as much as 62%.[1]

Contraindications
Estrogens should not be used in women (or men) with any of the following conditions: known or suspected 1) pregnancy, 2) breast cancer, 3) estrogen-dependent neoplasia, 4) undiagnosed abnormal genital bleeding, 5) active thrombophlebitis or thromboembolic disorders.

Note: Estrogens have been reported to increase the risk of endometrial carcinoma in postmenopausal women.

Nothing else is

PREMARIN®

(conjugated estrogens tablets)

The appearance of this tablet is a trademark of Wyeth-Ayerst Laboratories.

Please see brief summary of prescribing information on last page of this advertisement.

BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION AND PATIENT INFORMATION, SEE PACKAGE CIRCULARS.)*

PREMARIN® Brand of conjugated estrogens tablets, USP
PREMARIN® Brand of conjugated estrogens Vaginal Cream, in a nonliquefying base

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA. Close clinical surveillance of all women taking estrogens is important. Adequate diagnostic measures including endometrial sampling when indicated should be undertaken to rule out malignancy in all cases of undiagnosed persistent or recurring abnormal vaginal bleeding. There is currently no evidence that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.
2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.
Estrogen therapy during pregnancy is associated with an increased risk of congenital defects in the reproductive organs of the male and female fetus, an increased risk of vaginal adenosis, squamous-cell dysplasia of the uterine cervix, and vaginal cancer in the female later in life. The 1985 DES Task Force concluded that women who used DES during their pregnancies may subsequently experience an increased risk of breast cancer. However, a causal relationship is still unproven, and the observed level of risk is similar to that for a number of other breast cancer risk factors.
There is no indication for estrogen therapy during pregnancy. Estrogens are ineffective for the prevention or treatment of threatened or habitual abortion.

DESCRIPTION: PREMARIN (conjugated estrogens, USP) contains a mixture of estrogens, obtained exclusively from natural sources, blended to represent the average composition of material derived from pregnant mares' urine. It contains estrone, equilin, and 17α-dihydroequilin, together with smaller amounts of 17α-estradiol, equilenin, and 17α-dihydroequilenin as salts of their sulfate esters. Tablets are available in 0.3 mg, 0.625 mg, 0.9 mg, 1.25 mg, and 2.5 mg strengths of conjugated estrogens. Cream is available as 0.625 mg conjugated estrogens per gram.

INDICATIONS AND USAGE: Moderate-to-severe vasomotor symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression which might occur during menopause and they should not be used to treat these conditions.) Prevention and management of osteoporosis (abnormally low bone mass). Atrophic vaginitis. Atrophic urethritis. Hypoestrogenism due to hypogonadism, castration or primary ovarian failure.

PREMARIN (conjugated estrogens) Vaginal Cream is indicated in the treatment of atrophic vaginitis and kraurosis vulvae.

PREMARIN HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

CONTRAINDICATIONS: Estrogens should not be used in women (or men) with any of the following conditions: 1. Known or suspected pregnancy (see Boxed Warning). 2. Known or suspected cancer of the breast except in appropriately selected patients being treated for metastatic disease. 3. Known or suspected estrogen-dependent neoplasia. 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thromboembolic disorders. 6. Estrogen replacement therapy has not been reported to increase the risk of thrombophlebitis and/or thromboembolic disease. However, there is insufficient information regarding women who have had previous thromboembolic disease.

PREMARIN Tablets and Vaginal Cream should not be used in patients hypersensitive to their ingredients.

WARNINGS: Some studies suggest a possible increased incidence of breast cancer in women taking higher doses of estrogen for prolonged time periods. The majority of studies have not shown an association with usual estrogen replacement doses. Endometrial cancer risk among estrogen users was about 4-fold or greater than in non-users, and appears dependent on treatment duration and estrogen dose. In patients on combined estrogen-progestin therapy, this risk appears to be decreased. (See PRECAUTIONS below.)

Estrogen therapy during pregnancy is associated with an increased risk of fetal congenital reproductive tract disorders.

A 2.5-fold increase in the risk of surgically confirmed gall bladder disease in women receiving postmenopausal estrogens has been reported.

Large doses of estrogen such as those used to treat prostate and breast cancer have been shown to increase the risk of non-fatal myocardial infarction, pulmonary embolism, and thrombophlebitis in men. This cannot necessarily be extrapolated to women. However, to avoid theoretical cardiovascular risk caused by high estrogen doses, the doses for estrogen replacement therapy should not exceed the recommended dose.

Blood pressure should be monitored with estrogen use, especially if high doses are used.

Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases.

PRECAUTIONS: The addition of a progestin for 7 or more days of a cycle of estrogen administration reportedly lowers the incidence of endometrial hyperplasia. Studies of endometrium suggest that 10 to 13 days of progestin are needed to provide maximal endometrial maturation and elimination of hyperplastic changes. Additional risks, such as adverse effects on carbohydrate and lipid metabolism, may be associated with the inclusion of progestin in estrogen replacement regimens. The choice of progestin and dosage may be important in minimizing these adverse effects.

Physical examination and a complete medical and family history should be taken prior to the initiation of any estrogen therapy with special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolaou smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed. Conditions influenced by fluid retention, such as asthma, epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patients may develop manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding and mastodynia. Pre-existing uterine leiomyomata may increase in size during estrogen use. Estrogens should be used with care in patients with impaired liver function, renal insufficiency, or metabolic bone diseases associated with hypercalcemia.

The following drug/laboratory test interactions have been reported, some only with estrogen-progestin combinations (oral contraceptives):

1. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.
2. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by T_4 levels determined by column or by radioimmunoassay. Free T_3 resin uptake is decreased, reflecting the elevated TBG; free T_4 concentration is unaltered.
3. Impaired glucose tolerance.
4. Reduced response to metyrapone test.
5. Reduced serum folate concentration.

MUTAGENESIS AND CARCINOGENESIS: Long-term, continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver.

PREGNANCY CATEGORY X: Estrogens should not be used during pregnancy. See **CONTRAINDICATIONS** and Boxed Warning.

NURSING MOTHERS: As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

ADVERSE REACTIONS: The following have been reported with estrogenic therapy: changes in vaginal bleeding pattern and abnormal withdrawal bleeding or flow, breakthrough bleeding, spotting, increase in size of uterine fibromyomata, vaginal candidiasis, change in amount of cervical secretion; tenderness or enlargement of breasts; nausea, vomiting, abdominal cramps, bloating, cholestatic jaundice; chloasma or melasma that may persist when drug is discontinued, erythema multiforme, erythema nodosum, hemorrhagic eruption, loss of scalp hair, hirsutism; steepening of corneal curvature, intolerance to contact lenses; headache, migraine, dizziness; mental depression, chorea; increase or decrease in weight; reduced carbohydrate tolerance; aggravation of porphyria; edema; changes in libido.

ACUTE OVERDOSAGE: May cause nausea and vomiting.

DOSAGE AND ADMINISTRATION:

PREMARIN® Brand of conjugated estrogens tablets, USP

1. *Given cyclically for short-term use only.* For treatment of moderate-to-severe vasomotor symptoms, atrophic vaginitis, or atrophic urethritis associated with the menopause (0.3 mg to 1.25 mg or more daily). The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible. Administration should be cyclic (eg, three weeks on and one week off). Attempts to discontinue or taper medication should be made at three- to six-month intervals.
2. *Given cyclically:* Hypoestrogenism. Osteoporosis.
Hypoestrogenism due to: Female hypogonadism—2.5 mg to 7.5 mg daily in divided doses for 20 days followed by 10 day rest period. If bleeding does not occur by the end of this period, the same dosage schedule is repeated. Female castration or primary ovarian failure—1.25 mg daily, cyclically. Adjust upward or downward according to response of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.
Osteoporosis—0.625 mg daily. Administration should be cyclic (eg, three weeks on and one week off).

PREMARIN® Brand of conjugated estrogens Vaginal Cream

Given cyclically for short-term use only. For treatment of atrophic vaginitis or kraurosis vulvae.

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.

Attempts to discontinue or taper medication should be made at three- to six-month intervals.

Usual dosage range: 2 g to 4 g daily, intravaginally, depending on the severity of the condition.

Patients with an intact uterus who are treated with either PREMARIN Tablets or Vaginal Cream should be monitored for signs of endometrial cancer and appropriate measures taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

Revised August 21, 1989

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors (N Engl J Med 1991;324:424-8). Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL.

Manuscript submission. Manuscripts should be submitted to one of the two Editors in Chief as follows:

1. **Dr. Zuspan**—manuscripts from the eastern and southeastern United States and from England, Israel, and Italy, manuscripts written for Clinical Opinion and Current Development, Letters to the Editors, and all manuscripts presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation. *Manuscripts from The Society of Perinatal Obstetricians should be submitted to Dr. J. Peter Van Dorsten, P.O. Box 34, MCV Station, Richmond, VA 23298.*
2. **Dr. Quilligan**—manuscripts from states west of Pennsylvania, West Virginia, Kentucky, Tennessee, and Mississippi; manuscripts from Hawaii, Alaska, Canada, and abroad (except England, Israel, and Italy). Dr. Quilligan is responsible for manuscripts from the Society for Gynecologic Investigation. *Manuscripts from the Society for Gynecologic Investigation should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033.*

Author's suggested reviewers. When authors submit their manuscripts, they must provide the names and addresses of at least three reviewers for consideration by the Editors.

Copyright statement. The specified copyright statement that follows the Information for Authors in each issue of the JOURNAL must be completed, signed by all authors, and submitted with the manuscript. If not completed in full, it will be returned to the author for completion. The copyright statement and checklist form may be torn from the JOURNAL or photocopied for submission.

Checklist. The checklist that appears with the copyright statement in each issue of the JOURNAL must be fully completed by the author(s) and sent with each submitted manuscript. A more complete description of each item that must be checked is provided under the appropriate heading in the Information for Authors, which is published in each issue of the JOURNAL. *If the checklist is not completed in full, the deficiencies will be noted, and the form, as well as the manuscript when necessary, will be returned to the author for completion.*

Previous publication. If a report by the same author(s) or some of the same authors has been previously published in any medium that deals in any respect whatsoever with the same patients, same animals, same laboratory experiments, or same data, in part or in full, as those reported in the manuscript being submitted, two reprints of the article(s) or two copies of the manuscript, be it a full-length report or an abstract, must be submitted with the manuscript. Two copies of a new manuscript being prepared for possible publication also must be submitted. The author(s) should inform the Editor of the circumstances, similarities, and differences of the reports. This requirement also applies to the submission of a manuscript in which a few different patients, animals, laboratory experiments, or data were added to those reported in a previous publication or in a submitted or accepted manuscript. Articles previously published in another language will not be considered.

Human and nonhuman experimentation. It is assumed by the Editors that manuscripts emanating from a particular institution are submitted with the approval of the

requisite authority. Human experimentation that requires local institutional approval must have this approval *before the experiment is started* and approval must be so indicated in the *Material and Methods* section of the submitted manuscript. Reports of experiments on nonhuman animals or other species must *state in the* Material and Methods *section of the manuscript* that the guidelines for the care and use of the animals *approved by the local institution* were followed. The type of nonhuman animals or other species used in an investigation must be named in the title, abstract, key words, and *Material and Methods* section of the manuscript.

Authorship. For manuscripts with two or more authors, each author must qualify by having participated actively and sufficiently in the study that is being performed and reported. The inclusion of each author in the authorship list of a report is based only (1) on substantial contributions to (a) concept and design, or analysis and interpretation of data and (b) drafting the manuscript or revising it critically for important intellectual content; and (2) on final approval by each author of the version of the manuscript. Conditions 1 (a and b) and 2 must both be met. Others contributing to the work should be recognized separately in an Acknowledgment. *In the covering letter that accompanies the submitted manuscript, it must be confirmed that all authors fulfilled both conditions.*

Conflict of interest. Authors are expected to inform the Editor, in a letter accompanying the submitted manuscript, of any commercial association that might pose a conflict of interest, such as ownership, stock holdings, equity interests and consultant activities, or patent-licensing situations. Such information is confidential, is not given to the consultants, and does not play a part in the decision of the quality or timeliness of the manuscript. If the manuscript is accepted, the author and the Editor will determine how best to release the information. The usual and customary listing of sources of support and institutional affiliations on the title page is proper and does not imply a conflict of interest; only where there is a possible conflict of interest is the author(s) expected to inform the Editor.

Disclaimer. Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher, and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality photocopies of the manuscript and three sets of black-and-white glossy prints of illustrations are required. See "Color figures" and "Computer-generated figures" for special requirements. Manuscripts must be submitted in English.

Manuscripts must be typed double-spaced on one side only of 22 × 28 cm (8½ × 11 inch) white bond paper with 1-inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, condensation, abstract, body of text, acknowledgments, references, figure legends, and tables

Title page. The title page (page 1) should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of each author and each author's highest academic degree (both MD and PhD are acceptable, but honors degrees are not permitted); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; source(s) of financial support; presented line, if applicable; disclaimers, if any; name, address, business and home telephone numbers, and fax number of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name, address, business and home telephone numbers, and fax number of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. *At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).*

Condensation. On page 2 of the manuscript provide a brief, concise condensation, typed double-spaced, that will appear with the title in publication of the Contents pages of the JOURNAL. It should be a single-spaced sentence, limited to a maximum of 25 words, delineating the essential point(s) made in the manuscript.

Abstract page including key words/phrases. On manuscript page 3, type the abstract, double-spaced, with the required margins and headed by the title of the article and name(s) of author(s). Below the abstract, list 3 to 5 *key words or short phrases* for indexing purposes.

A structured abstract is required for certain types of articles and a *standard abstract format* is required for other types of articles; therefore the author(s) should select and prepare the appropriate abstract to be used in the submitted manuscript. This applies to both independently submitted and society manuscripts.

Structured abstract. A structured abstract, limited to 150 words, is to be used for regular articles, society articles, and Current Investigation articles; excluded are Clinical Opinion, Current Development, case report, and brief communication articles. The structured abstract is to contain the following major headings: *Objective(s); Study Design; Results;* and *Conclusion(s).* The *Objective(s)* reflects the purpose of the study, that is, the hypothesis that is being tested. The *Study Design* should include the setting for the study, the subjects (number and type), the treatment or intervention, and the type of statistical analysis. The *Results* include the outcome of the study and statistical significance if appropriate. The *Conclusion(s)* states the significance of the results.

Standard abstract. The standard abstract format is required for Clinical Opinion, Current Development, case report, and brief communication articles. The standard abstracts for Clinical Opinion and Current Development articles are to be 50 to 150 words and standard abstracts for case reports and brief communications are limited to 50 words. Even though the formal names of these four types of articles are not used, an author should determine his/her type of manuscript and prepare the appropriate standard abstract, regardless of whether it is to be submitted independently or as a part of a society's transactions.

Text. Do not hesitate to write your manuscript in the first person and active voice if they are more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations, since the emphasis is on the "action" rather than on the person performing the action.

Only standard abbreviations are to be used. Consult the

Estimating length of manuscripts

With the exception of Current Development articles, the length of text material (introduction through *Comment* section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A text of 4200 words or more can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7-page article in the JOURNAL. The 2000 words of text alone makes approximately 8 pages of manuscript typed double-spaced with the required 1-inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 words in manuscript. Thus, if a greater number of illustrations and tables is used, the length of the text should be adjusted accordingly.

Council of Biology Editors Style Manual or the AMA's *Manual of Style.* Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify *Material and Methods*, *Results*, and *Comment*. Authors may wish to summarize their findings in a short paragraph at the end of the *Comment* section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods* section describe briefly (but in sufficient detail to permit other workers to repeat the study) the plan, the patients, experimental animals or other species, material, and controls, the methods and procedures utilized, and the statistical method(s) employed.

In the *Results* section present the detailed findings. Include mentions of all tables and/or figures. Figures and tables should supplement, not duplicate, the text; presentation of data in either one or the other will suffice. Emphasize only your important observations; do not compare your observations with those of others. Such comparisons and comments are reserved for the *Comment* section.

In the *Comment* section state the importance and significance of your findings but do not repeat the details given in the *Results* section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number (25) is allowed, except in case reports and brief communications (limited to 2) and in manuscripts for the Current Development section (for which there is no limit). Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" (Vancouver style) (N Engl J Med 1991;324:424-8). Journal titles should conform to abbreviations used in *Cumulated Index Medicus.*

Examples (if six or fewer authors, list all; if seven or more authors, list three then et al.):

JOURNAL: Flamm BL, Dunnett C, Fischermann E, Quilligan EJ. Vaginal delivery following cesarean section: use of oxytocin augmentation and epidural anesthesia with internal tocodynamic and internal fetal monitoring. AM J OBSTET GYNECOL 1984;148:759-63.

BOOKS: Ledger WJ. Dystocia and prolonged labor. In: Wilson JR, Carrington ER, eds. Obstetrics and gynecology. St. Louis: CV Mosby, 1987 vol 8:474-93.

Personal communications and unpublished data, if essential, may be used but not as numbered references. If they are used, they are to be referred to, within parentheses, at the appropriate location in the text. If used, the author(s) must obtain written and signed permission for their use from the individual being quoted. *This signed permission must accompany the manuscript when it is submitted to the Editor.* Published abstracts can be used as numbered references; however, reference to the complete published article is preferred.

Figures. The term *figure* includes all types of illustrations such as graphs, diagrams, photographs, flow charts, and line drawings. A reasonable number of figures will be reproduced without charge, but special arrangements must be made with the Editors for color figures at an additional charge to the author. The quoted charge is per page of color, and as many as eight color figures can be included on one page if the color balance is appropriate.

Figures must be cited consecutively in the text in Arabic numerals and identified with a gummed label on the back of the figure with author(s) name(s), title of article, figure number, and top marked clearly. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted. Do not use paper clips or mar the surface of figures in any way. Figures will be returned only on request by the author.

For *black-and-white figures,* submit three sets of 3 × 4 inch (minimum) to 5 × 7 inch (maximum) unmounted, glossy prints. All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy prints with good black-and-white contrast.

For *color figures* submit original transparencies and two sets of unmounted prints on glossy (smooth surface) paper. Polaroid prints are not acceptable. Color transparencies must have a color balance (consistency in lighting and film speed) that is acceptable to the author and Editors before acceptance for publication. Please note that 35 mm transparencies are enlarged to twice their original size. If it is important to deviate from this standard, please so indicate when the material is submitted. The top, first author's last name, and figure number must be indicated on the front of each transparency and the back of each print.

Computer-generated figures must be legible and clearly printed in jet black ink on heavy coated paper with either a glossy or dull finish. Any patterns or shadings must be dark enough for reproduction and must be distinguishable from each other. Lines, symbols, and letters should be both smooth and complete. The legend should not appear on the figure. On the back of each figure the name of the first author and the figure number should be given and the top indicated. Three original individual laser or plotter prints are to be submitted *unmounted* with the manuscript. Laser prints should be full size at 300 dots per inch (DPI) or greater full-page resolution; multiple illustrations on a page cannot be accepted. Dot matrix prints and photographic halftones are not acceptable. *Color figures* are acceptable, but special arrangements must be made with the Editors. The colors used must be dark enough and of sufficient contrast for reproduction. With the exception of fluorescent colors, all colors can be reproduced in four-color figures.The preparation and submitting of color prints should follow the preceding guidelines for black-and-white computer-generated illustrations.

Legends to figures. Legends for all figures must be typed together in numeric order double-spaced on one sheet of paper (or more if necessary) separate from the text of the manuscript. This page must be numbered in sequence after the references. Titles should be included in the legend, not on the print. Original magnifications should be provided. If a figure has been taken from copyrighted material, the legend must give full credit to the original source.

Tables. Tables should be typed on separate sheets of paper, one table to a page, and included at the end of the text. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Titles should be brief yet indicate clearly the purpose or content of each table, and each column should be precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. If a table or any part thereof has been taken from copyrighted material, a footnote to the table must give full credit to the original source. Arrangements must be made with the Editors for elaborate tables because of space limitations.

Permissions. Direct quotations, tables, or figures that have appeared in copyrighted material must be accompanied by written permission for their use from *the copyright owner and original author* along with complete reference information. Photographs of identifiable persons must be accompanied by signed releases. If not, all recognizable features must be masked.

Requirements for certain types of manuscripts

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include *standard abstract format*, of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for regular article. The abstract *must* follow the *structured format.*

Clinical Opinion. Limit of 3000 words. Include *standard abstract format* of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include *standard abstract format* of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Letters to the Editors. *Letters to the Editors* must be submitted in duplicate, typed double-spaced, and the text of the manuscript must be limited to a maximum of 400 words (excluding references, name[s] and address[es] of the signer[s], and the phrase "To the Editors"). The submitted *Letter to the Editors* must be accompanied by a signed copyright statement. If there are two or more signers of the *Letter to the Editors,* one of the authors may sign the copyright statement but must add to the statement the following: "I sign for and accept responsibility for releasing this letter on behalf of any and all cosigners." These requirements apply to all types of *Letters to the Editors.* Letters should be sent to Dr. Zuspan.

Two types of letters will be considered for publication. (1) A *Letter to the Editors* commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. If the original author does not respond, a notation indicating "Response declined" will be published. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a *Letter to the Editors* will be considered for publication.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60 U.S., and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Zuspan. No books will be returned.

Reprints

The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the Publisher with the author's consent.

Business communications

Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, or call Journal Advertising Production Manager (1-800-325-4177, ext. 4306, or 314-453-4306).

CHECKLIST AND COPYRIGHT STATEMENT

Both the checklist and the copyright statement forms **must be completed** and sent with each submitted manuscript. If **not** completed, these forms will be returned to the author for completion.

These items appear in each monthly issue of the JOURNAL. A photocopy may be used. An exposition of the requirements given in the checklist is in the Information for Authors, which is published in each issue of the JOURNAL.

CHECKLIST

General

—The original and two copies of the manuscript are submitted.
—The completed checklist is enclosed. The assignment of copyright signed by **all** authors accompanies the manuscript.
—Human experimentation has been approved by the local institution as stated in the *Material and Methods* section.
—Guidelines for the care and use of *nonhuman* animals or *other species* approved by the institution have been followed as indicated in the *Material and Methods* section. *The species is named in the title, abstract, key words, and* Material and Methods *section.*
—The covering letter with essential information is with the manuscript.
—All elements of the manuscript are typed in English double-spaced on bond paper with 1-inch margins at top, bottom, and sides.
—All pages are numbered in the following order: title page, condensation, structured or standard abstract, body of the text, acknowledgments only of persons who have made substantive contributions to the study, references, legends, and tables.
—Signed, written permission from both the copyright holder and the original author for the use of tables, figures, or quotations previously published and their complete references are enclosed with the manuscript.
—Signed, written permission for the use of quotations of personal communications and unpublished data has been obtained from the person(s) being quoted and is enclosed.

Authorship

—In the covering letter that accompanies the submitted manuscript I/we have confirmed that all authors fulfilled both conditions required for authorship.

Conflict of interest

—In the covering letter that accompanies the submitted manuscript the commercial association of the author or of any coauthors that might pose a conflict of interest is described.

Previous publications

—Enclosed with the submitted manuscript are two reprints each of articles the author and/or some of the coauthors have previously published, have submitted for possible publication, or have in manuscript form dealing with same patients, same animals, same laboratory experiment, or same data, in part or in full, as those reported in the submitted manuscript. Further explanation is provided in the covering letter that accompanies the submitted manuscript.
—Similarities, differences and explanation are provided in the covering letter that accompanies the submitted manuscript.

Reviewers

—Names and addresses of three suggested reviewers are enclosed.

Title page

—These elements are given in the following sequence, and are typed double-spaced.
—Title.
—Author(s) name(s) and highest academic degree(s) are shown.
—City(ies), state(s), and country other than United States in which the study was conducted are given.
—The name(s) of the institution(s) section(s), division(s), department(s) in which the study was performed is provided and the institutional affiliation(s) of the author(s) at the time of the study is indicated.
—Acknowledgment of financial support is cited.
—Name, address, business and home telephone numbers, and fax number of author to whom requests for reprints are to be sent are included.
—If reprints will not be available, this has been stated on the title page.
—If the corresponding author is different from the author to whom reprint requests are to be sent, his/her name, address, business and home telephone numbers, and fax number have been added.
—At the bottom of the page, a running head not exceeding 52 characters (including word spaces) has been typed.

Condensation

—On a separate sheet of paper, page 2 of the manuscript, a single sentence limited to 25 words delineating the essential point(s) is typed double-spaced.

Abstract and key words or short phrases

—The abstract (structured or standard format) is typed double-spaced with required margins on page 3 headed by the title and author(s) name(s). Beneath the abstract 3 to 5 key words or short phrases are typed.
—A *structured abstract,* with 150 words or less, is submitted as required for regular articles, society regular-type articles, and Current Investigation articles. The abstract contains the four required major headings: Objective(s), Study Design, Results, and Conclusion(s), each with a brief adequate presentation.
—A *standard abstract* is submitted as required for Clinical Opinion and Current Development articles with 50 to 150 words and for case reports and brief communications articles with a maximum of 50 words, be they independent or society articles.

References
—Are typed double-spaced.
—Are numbered consecutively in the order they are cited in the text.
—The format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" is used. Examples shown in Information for Authors have been followed.
—Personal communications and unpublished observations are not used as numbered references but are mentioned in the text with the written approval of the person being quoted. The signed approval is enclosed.

Figures
—Each is numbered with an Arabic numeral and cited in numeric sequence in the text.
—Three sets of unmounted glossy prints for *black-and-white* figures are submitted, properly numbered, labeled, and *top indicated* on the back of each print.
—Three sets of original computer-generated figures printed on heavy coated paper with either a glossy or dull finish, unmounted, each one on a page, and properly labeled on the back and *top indicated* are submitted. None are dot matrix or photographic prints.
—Original transparencies of *color photographs* appropriately numbered and identified and *top indicated* are submitted along with two sets of unmounted prints on glossy paper, numbered and identified on the back.

Figure legends
—Are provided for each figure.
—Are numbered and typed together in numeric order on one sheet of paper (more if necessary). The page is numbered in sequence after the References page(s).

Tables
—Each table headed by a title and numbered in Roman numerals is typed double-spaced on a separate page.
—Tables are cited in numeric sequence in the text.

CLINICAL SECTION

Clinical Opinion

Selection bias in in vitro fertilization programs

A. Hershlag, MD,[a] E.H. Kaplan, PhD,[b] R.A. Loy, MD,[a] A.H. DeCherney, MD,[a] and G. Lavy, MD[a]

New Haven, Connecticut

Pregnancy rates per cycle reported from different in vitro fertilization–embryo transfer programs vary widely. While several programs have reported constant pregnancy rates per cycle, others report declining pregnancy rates. Selection biases at the point of entry and between cycles are discussed as possible explanations of these discrepancies. (AM J OBSTET GYNECOL 1992;166:1-3.)

Key words: In vitro fertilization, pregnancies, pregnancy rate, selection

In vitro fertilization–embryo transfer pregnancy rates have been used to monitor in vitro fertilization program success rates and to measure the impact of the assisted reproductive technologies on public health.[1] A virtual lack of standardization in reporting has created substantial confusion in the field, rendering assessment of individual programs difficult and prompting accusations of distortion and abuse.[2] With no acknowledged measure for success, the true differences that exist between individual in vitro fertilization–embryo transfer centers have been clouded. This situation had led to a call for increased supervision of in vitro fertilization clinics and the reporting of clinic-specific statistics.[3] Indeed, results from in vitro fertilization-embryo transfer programs in the United States have been available for the last 3 years through the in vitro fertilization-embryo transfer registry,[4-6] which in 1988, the last year reported, included 135 clinics.[6] Although the registry did not contain clinic-specific data, it provided an acceptable reporting format and mean pregnancy rates from the reporting clinics.

The pregnancy rate continues to be used as the criterion of program success. As shown in Table I, several programs[7-9] have reported nearly constant pregnancy rates per cycle, suggestive of a homogeneous patient population where pregnancy ultimately occurs for those who are able to undergo a sufficient number of trials. By contrast, data from Yale University[10] and other reports[11] reflect declining pregnancy rates per cycle, suggesting a heterogeneous patient population in which patients have various probabilities of success in a given cycle.

Statistical and mathematical analyses may be used to formalize the patterns noted here. For example, Padilla and Garcia[9] and Bustillo et al.[8] used life-table analysis to estimate pregnancy rates per cycle, whereas Guzick et al.[7] and Kaplan et al.[10] presented mathematical models that explicitly characterized heterogeneity of various forms. In both the statistical and modeling approaches, women who discontinue treatment without achieving pregnancy are assumed to drop out independently of the treatment process. This fallacy underlies the statistical methods of essentially all studies to date on the performance of in vitro fertilization programs: Reasonable assurance must exist that the patients who drop out of treatment do not differ significantly from those remaining in treatment from cycle to cycle.

A closer look at the literature raises some real concerns. It appears that almost all of the pregnancies achieved in the available series occur during the first four attempts. Specifically, of all women who become pregnant, the percentages achieved within four cycles at Norfolk, Baltimore, Fairfax, and Yale are 93%, 94%, 93%, and 98%, respectively.[7-10] However, whereas the pregnancy rate per cycle continues unchanged beyond the fourth cycle in the other three programs, this is not the case at Yale (Table I). In what ways might these programs truly differ?

Couples undergoing in vitro fertilization represent a subpopulation of all infertile couples. This subpopulation is formed by the application of nonstandard selection criteria. There are several branch points on the

Table I. Pregnancy rate per cycle in different in vitro fertilization–embryo transfer programs (percent)

	Cycle No.									
	1	*2*	*3*	*4*	*5*	*6*	*7*	*8*	*9*	*10*
Norfolk[7] (per retrieval)	13.6	13.0	17.5	17.0	8.3	15.4	37.5	0	100	—
Yale[10] (per retrieval)	13.1	10.7	6.9	4.3	4.9	0	0	0	0	
Fairfax[8] (per retrieval)	15	13.8	10.2	9	11.8	6	6.4	4.7	16.6	0
Baltimore[9] (per transfer)	25	29	28	33	35	30	40	—	—	—

in vitro fertilization–embryo transfer dendrogram, which may alter the composition of the resulting patient population. Combined with the nonrandom dropout as discussed above, these two selection modalities confound the interpretation of pregnancy rate outcome in in vitro fertilization programs.

Reduced fertility potential is a broad spectrum of conditions, ranging from mild subfertility, where unassisted conception takes somewhat longer than 1 year, to severe infertility, where conception does not occur after many years, in spite of multiple therapeutic attempts, such as controlled ovarian hyperstimulation, artificial insemination, and in vitro fertilization–embryo transfer. The potential patient population is thus composed of patients who are distributed along a clinical continuum. The distinct infertility subpopulation that is selected for in vitro fertilization–embryo transfer will significantly affect the observed success rate.

Clearly, programs that limit the age of patients to <40 years eliminate those with decreased fecundity On the other hand, more liberal entry criteria, for example, at Yale, have allowed women up to 45 years old to participate in the program. In addition, some programs consider in vitro fertilization–embryo transfer an 'end stage" treatment, where only patients with prolonged infertility who have gone through all other reasonable treatments and have not conceived are included. Other programs tend to use in vitro fertilization–embryo transfer much earlier. Recently, Gindoff et al.[12] have reported oocyte retrieval and transfer during a diagnostic laparoscopy for infertility. It is clear that a certain proportion of patients, if they had not been treated by in vitro fertilization–embryo transfer at an early point in the infertility workup, would have conceived with expectant management, whereas additional pregnancies would have resulted from other less agressive, non–in vitro fertilization treatments. Inclusion of these "more fertile" patients would thus increase the reportable pregnancy rates.

Selection bias does not stop at the point of entry to in vitro fertilization–embryo transfer but continues between cycles. The dropout population is determined largely by physicians, either directly or indirectly, by shaping patient decisions via counseling.

If a program is very strict in "dropping" patients who have had poor response to controlled ovarian hyperstimulation or in whom fertilization did not occur, the ongoing population in the next cycle should have a higher conception rate than would occur in a program that allows such patients to continue.

Among in vitro fertilization–embryo transfer programs across the country there is a wide variety of selection biases of the sorts described. Programs that select more fertile patients will have more homogeneous-appearing pregnancy data, especially if patients of lesser or no potential to conceive continue to be "extracted." Programs that include the more infertile patients will have more heterogeneous-appearing conception patterns, owing to the presence of the more diverse population, that is, an admixture of both fertile and infertile women.

In summary, two sources of selection bias plague in vitro fertilization–embryo transfer programs. Different programs enforce different eligibility criteria creating differential patient selection across programs at intake. Also, some programs may encourage patients to discontinue in vitro fertilization–embryo transfer on the basis of poor performance in previous cycles whereas other programs experience random dropout during treatment. The implication of these biases is that pregnancy rates reported by different in vitro fertilization–embryo transfer programs do not provide a basis for fair comparison. A method for the standardization of in vitro fertilization–embryo transfer programs would involve the characterization of patients at intake to the in vitro fertilization program and the characterization of those patients who drop out between cycles, in addition to studying those women who ultimately achieve viable pregnancies.

Main clinical types and subtypes of eclampsia

Mario López-Llera M., MD
Mexico City, Mexico

Eclampsia has been traditionally divided in three types: antepartum, intrapartum, and postpartum. Several authors consider two more subtypes, early cases and intercurrent eclampsia. The clinical analysis of 990 patients with eclampsia divided according to such classification revealed numerous significant differences that could give grounds for the interpretation of conflicting results in medical research. Maternal and perinatal mortality, types and incidence of complications, obstetric and eclamptic profiles, and incidence of underlying diseases were strikingly higher in antepartum eclampsia, especially in early cases. The features of intrapartum eclampsia were closer to those of the postpartum group than to those of antepartum cases, and intercurrent eclampsia was oddly benign for the mother but not for the fetuses. These findings indicate that a more precise classification of eclampsia must consider seven differential facts: (1) timing of convulsions, (2) length of pregnancy, (3) complications, (4) underlying diseases, (5) maternal age, (6) number of index pregnancy, and (7) single or multiple gestation. (Am J Obstet Gynecol 1992;166:4-9.)

Key words: Types of eclampsia, maternal mortality, perinatal mortality

Efforts to understand the hypertensive complications of pregnancy have been directed mainly to the investigation of their pathologic characteristics, early diagnosis, and treatment. The subject of their definition, classification, and nomenclature remains unsettled, although several authors, institutions, and related medical societies have issued recommendations for local and international acceptance.[1-7] Furthermore, most recent publications on this matter focus their interest on the nonconvulsive stages of the disease and seem to leave the problem of eclampsia practically untouched.[6,7]

We thought that, to clarify many important questions and provide a better basis for the interpretation of conflicting results, it was necessary to revise the conventional classification of patients with eclampsia with study of the most important clinical characteristics of each type, to look for the differences that could improve such discrimination. This objective appeared to be worthwhile because eclampsia still is the leading cause of maternal death and perinatal morbidity in nonprivileged populations and will continue to be studied intensively throughout the world. In addition, some of the findings of this study could become useful for the understanding of other obscure aspects of the lesser degrees of this condition.

Material and methods

All patients admitted to the Hospital de Gineco-Obstetricia No. 2 del Centro Médico Nacional del I.M.S.S. in Mexico City with a well-documented diagnosis of eclampsia from July 1, 1963, to Sept. 19, 1985, were included in the study. These patients came from the heterogeneous population of one of the largest cities in the world, but the overwhelming majority belonged to the economically disadvantaged and, for various reasons, they represented the advanced stages of the disease.

Definitions. Three main clinical types and two subtypes of eclampsia were considered, as defined here. Antepartum eclampsia was defined as generalized convulsions starting clearly before the beginning of labor in a pregnant woman with evident hypertension or proteinuria; intrapartum eclampsia included convulsions starting after the beginning of labor in a pregnant woman with evident hypertension or proteinuria; postpartum eclampsia was defined as convulsions appearing within 7 days after delivery of the fetus and the placenta in a patient with hypertension or proteinuria during pregnancy, labor, or the postdelivery period. Early antepartum eclampsia consisted of convulsions, hypertension, and proteinuria appearing ≤28 weeks' gestation, and intercurrent eclampsia consisted of convulsions, hypertension, or proteinuria appearing as in antepartum cases but stopping and subsiding with enough clinical improvement to allow continuation of pregnancy for >7 days. Since generalized convulsions were the leading symptom, all noneclamptic causes

†After exclusion of patients who were moribund on admission.
‡$p < 0.001$.

were thoroughly ruled out. Cases of eclampsia in multiple pregnancy were not included, because they have been already reported.[8]

Methods. The clinical variables for analysis and comparison were maternal and perinatal mortality, incidence of complications, incidence of cesarean operation, obstetric profile (maternal age, parity, amenorrhea, and fetal birth weight), eclamptic symptoms (systolic and diastolic hypertension, average proteinuria, total number of convulsions, blood urea and creatinine, and average number of platelets), and presence of underlying diseases. The treatment given to these patients has been outlined in a previous publication,[9] and it is not a matter for analysis here.

Statistics. Proportions are presented as percentages. All mean values are presented as ±1 SE of the mean. The paired t test, χ^2 test, and Fisher's exact test were used to estimate the statistical significance of the differences. Three p values are reported: <0.05, <0.01, and <0.001.

Analysis of the data

Cases. A total of 990 patients were studied: 620 with antepartum and 187 with intrapartum eclampsia, 160 with the postpartum type, and 23 with the intercurrent variety. There were 54 cases in the antepartum eclampsia group with onset at or before the twenty-eighth week.

Maternal mortality and complications. When total maternal mortality was considered, the highest rate was found in the early eclampsia cases (22.2%) and the lowest one in the intercurrent eclampsia subtype (0%). Significant differences existed between antepartum eclampsia and either intrapartum or postpartum cases (Tables I and II). This significance disappeared when the figures were corrected by the exclusion of moribund patients on admission to the hospital.

As far as the frequency of complications was concerned, the highest incidence of brain hemorrhage belonged to early eclampsia (24.1%) and the lowest one to intercurrent eclampsia (4.3%). The figures for disseminated intravascular coagulation, acute renal failure, and abruptio placentae were significantly higher in antepartum eclampsia in comparison with intrapartum cases, and the frequency of severe postpartum hemorrhage was significantly higher in postpartum eclampsia (10.6%) in comparison with antepartum cases (5.5%). There were no significant differences in the incidence of other less frequent complications (cardiac arrest, bronchial aspiration, acute pulmonary edema, progressive respiratory failure, and liver rupture). Nevertheless, when all complications are considered, it becomes obvious that antepartum eclampsia, especially early eclampsia, carried the worse effects.

Perinatal mortality. Total perinatal mortality was highest in early eclampsia (92.6%) followed by intercurrent cases (47.8%) and antepartum eclampsia (31.4%), and it was significantly lower in intrapartum and postpartum cases (12.8% and 7.9%, respectively). These significant differences persisted for fetuses weighing >1000 gm (Tables III and IV). The highest rates of total fetal mortality were found in the early eclampsia subtype (33.3%) and in antepartum eclampsia (18.3%). Total neonatal mortality was highest in both

subtypes of antepartum eclampsia (early eclampsia, 59.3%; intercurrent, 25%), and the lowest total and corrected figures belonged to intrapartum and postpartum eclampsia (2.4 and 4.1, total; 2.4 and 2.1% corrected figures, respectively). The highest incidence of cesarean operation belonged to antepartum eclampsia (74.3%), it dropped to 51.8% for the early eclampsia subtype, and it fluctuated between 28% and 38% in the remaining groups.

Main clinical profile. There were no significant differences in the ages of the mothers in the three main types of eclampsia. However, maternal age was significantly higher in both subtypes of antepartum eclampsia (27.1 years for early eclampsia and 27.9 for intercurrent cases). Obviously, the most significant differences were found in the length of pregnancy and fetal birth weight in all types and subtypes of patients. The lowest average fetal weight belonged to early eclampsia (943 gm), followed by intercurrent cases (1515 gm), and the highest figures were found in intrapartum and postpartum eclampsia cases (2821 and 2711 gm, respectively) (Tables V and VI).

Systolic and diastolic hypertension and proteinuria were highest in antepartum eclampsia, especially in the early cases. Similarly, plasma urea and blood creatinine levels were highest in this subgroup of patients (Tables V and VI). The figures for total blood hemoglobin and plasma proteins of the three main groups also showed significant differences, but they may reflect more the physiologic or therapeutic blood volume changes as-

‡$p < 0.01$.

sociated with labor and delivery than a direct eclamptic feature. The platelet count was significantly lower in postpartum eclampsia (90,355/mm³). However, this was probably related to the high incidence of postpartum hemorrhage (Table I), in association with various obstetric complications that make it not a true eclamptic thrombocytopenia, as occurred in early eclampsia cases (117,956/mm³), where the incidence of postpartum hemorrhage was only 3.7%, in spite of the highest incidence of disseminated intravascular coagulation (18.5%). Finally, although early eclampsia and antepartum eclampsia patients had more convulsive seizures, the differences were not statistically significant.

Previous underlying diseases. To establish the presence of chronic hypertension, diabetes mellitus, renal disease, or cardiac disease, all patients were followed up for at least 6 months after delivery, and a large majority were followed up through their next pregnancies. The combined incidences of these diagnoses in the three main types of eclampsia were 17.9%, 13.4%, and 16.3% for antepartum, intrapartum, and postpartum eclampsia, respectively. The differences were not significant. However, the figures for early eclampsia and for intercurrent cases were 42.6% and 52.2%, respectively ($p < 0.001$ in comparison with the main antepartum type). Chronic hypertension was by far the commonest diagnosis, because it constituted >50% of all underlying diseases in every group. Again, the incidence of chronic hypertension in early eclampsia and in intercurrent cases was higher (29.6% and 26.1%, respectively); however, because of the small number of patients in the intercurrent subtype, the only

significant difference was between early cases and antepartum eclampsia proper ($p < 0.001$).

Comment

The groups of eclamptic patients in this report were as clearly defined as possible. Hence, their clinical characteristics must be considered representative of their respective categories. However, because the precise diagnosis of the onset of labor is not easily ascertainable and eclampsia per se increases uterine contractility and leads to premature labor, a discrete overlap between antepartum and intrapartum cases may exist. Nevertheless, our data showed that intrapartum eclampsia was closer to the postpartum group than to any of the others.

The most influential factor marking the severity of the disease was the timing of the critical process. Obviously, this was a determinant of all perinatal variables, but it was also associated with important maternal data, except in the small group of intercurrent eclampsia cases, where the findings showed that this disease occasionally may be strangely benign for the mother.

The incidence of underlying diseases and the types and rates of maternal complications in the various groups suggest that the main reason for the severity of eclampsia and for the early or late onset of the problem is, in the large majority of the cases, this previous pathologic condition. However, because the severity of any disease is not usually caused by a single factor but by a combination of very diverse conditions and circumstances, there were large numbers of patients apparently free of underlying disease, even among the earliest and most severe of the cases. Many of the early eclampsia patients and an important number of the women with the worst cases of antepartum eclampsia opted for definitive contraception, and the reallocation of the entire obstetric population that followed the destruction of our institution at the end of 1985 made long-term evaluations extremely difficult. We suspect that many of those women apparently free of underlying disease will show the signs of chronic hypertension in the course of time. It is evident that many diseases will not show all their characteristics until a certain number of cases are studied. If the incidence is rather low, this fact may become an insurmountable problem. The solution offered by collaborative studies has several disadvantages. The most important ones depend on differences in the populations and in the medical criteria, but in many instances they become the best possibility.

The material included in this report belonged to a single institution, thus avoiding some of the limitations of collaborative studies, but it was gathered through a span of 22 years, which may be considered a weakness. However, the fact that these patients were handled practically by the same medical and paramedical staff throughout that period may compensate for it.

One of the limitations of studying diseases through relatively long time lapses is that the morbidity data may show continuous changes as a result of technologic and basic health improvements that make the last cases quite different from the early ones. However, in our material, morbidity was practically constant through the 22 years, and if there was a change, it was toward an increase in the incidence and severity of the problem in the last years.

The data presented in this report, added to those of our former partial observations,[9-12] clearly indicate that a complete and precise classification of eclampsia cannot be based on a single aspect of the disease. At the least, it must account for the following differential facts: (1) timing of convulsions in regard to labor and delivery, (2) length of pregnancy at onset of the condition, (3) presence of significant semispecific complications, (4) presence of underlying diseases, (5) age of the patient, (6) gravidity, and (7) single or multiple gestation. As long as no such classification exists, the results of many investigations on eclampsia will be more conflicting than enlightening. We hope that our study belongs more to the second than to the first category.

Prognosis in fetal diaphragmatic hernia

Gurleen K. Sharland, BSc, MB, Susan M. Lockhart, RGN, RM, Annabel J. Heward, RGN, RM, and Lindsey D. Allan, MD

London, England

The reported mortality for prenatally detected congenital diaphragmatic hernia is high. Polyhydramnios and presentation in early pregnancy have been suggested as high-risk factors adversely affecting outcome. We retrospectively reviewed 55 cases of congenital diaphragmatic hernia diagnosed prenatally in our unit. There was an overall mortality of 73%. The mortality in cases with presentation before 25 weeks' gestation was 74%, if the cases resulting in termination of pregnancy are excluded, compared with a mortality of 60% in those seen after this gestational age. Underdevelopment of left-sided cardiac structures was found to be a helpful prognostic factor. We were unable to confirm the predictive nature of hydramnios. Associated chromosomal anomalies were found in two fetuses and major congenital heart disease in nine. Although diagnosis before 25 weeks' gestation is associated with a higher mortality than in cases detected later, it is not universally fatal. If congenital heart disease and chromosomal anomalies are excluded and there is little or no evidence of left heart underdevelopment, the odds for survival will improve. This should be taken into account when the management of these cases is planned. (AM J OBSTET GYNECOL 1992;166:9-13.)

Key words: Left heart underdevelopment, fetal diaphragmatic hernia

Congenital diaphragmatic hernia has been variously reported as occurring in 1 in 2000 to 1 in 5000 births.[1, 2] The prenatal diagnosis of congenital diaphragmatic hernia is well established,[3] but the outcome related to antenatal detection has been poor.[4, 5] In a

recent report of prenatally diagnosed diaphragmatic hernia[6] there were no survivors of 14 cases seen before 25 weeks' gestation, in spite of intensive neonatal care, including the use of extracorporeal membrane oxygenation. The authors suggested that early diagnosis per se was an important factor influencing the outcome. Polyhydramnios was found to be an additional indicator of a poor prognosis. Its presence was associated with an 82% mortality rate. This experience of the natural history has been used to justify prenatal operative techniques involving hysterotomy.[7] However, as the resource implications of both extracorporeal membrane oxygenation and prenatal operation are very great, it is important to reevaluate the outcome in this condition. We therefore retrospectively examined 55 cases of fetal congenital diaphragmatic hernia seen in our department over a 10-year period. Factors that might help to predict the prognosis for cases detected prenatally were sought, so that a rational protocol for future management of pregnancy could be formulated.

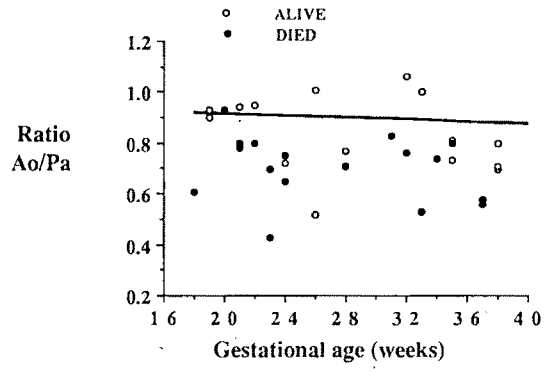

Fig. 3. Scatter of values of ratio of aorta to pulmonary artery *(Ao/Pa)* in 32 cases, compared with normal mean for gestational age.

Patients and methods

Over a 10-year period 55 fetuses with a diaphragmatic hernia have been evaluated by fetal echocardiography in our unit. The diagnosis of fetal anomalies by ultrasonography has been approved by the ethics committee, and each mother gave informed consent to the study. The presence of congenital diaphragmatic hernia found at a routine obstetric scan was the reason for referral in 44 cases. In nine cases a cardiac abnormality had been suspected, and one case was referred after the detection of a pleural effusion. The remaining case was referred for fetal echocardiography because the parents had had a previous child with congenital heart disease.

Each fetus was examined with either a Hewlett Packard 77020 phased array system or an Advanced Technology Laboratories Ultramark 4 system. This was a retrospective study, and a videotape recording of each examination was reviewed. The diagnosis of congenital diaphragmatic hernia was made if there was displacement of the fetal heart associated with an intrathoracic mass having the appearance of stomach or liver. Ultrasonographic diagnosis of polyhydramnios was made when the four quadrant measurements of amniotic fluid were >16 cm.

The structure of the fetal heart was examined for evidence of associated congenital heart disease. The maximum widths of the left and right ventricles were measured in a four-chamber projection, and the ratio of the left ventricle to the right ventricle was compared with the normal range for gestational age.[8] The diameters of the aortic root and the pulmonary valve orifice were measured, and the ratio of aorta to pulmonary artery was compared with the normal mean for gestational age.[9] In 12 fetuses sequential studies were performed during pregnancy. It was possible to sequentially measure the left ventricle/right ventricle ratio in 11 of these, and the aorta/pulmonary artery ratios in nine. Measurements of the cardiac structures

Table I. Associated anomalies

Type of abnormality	*Gestational age (wk)*	*Chromosomal anomaly*	*Outcome*
Cardiac			
Ventricular septal defect	31	Trisomy 18	Intrauterine death
Ventricular septal defect	33	No	Neonatal death
Ventricular septal defect	21	No	Termination of pregnancy
Atrioventricular septal defect	37	Deletion 8	Neonatal death
Atrioventricular septal defect	33	No	Neonatal death
Hypoplastic left heart syndrome	20	No	Termination of pregnancy
Hypoplastic left heart syndrome	22	No	Neonatal death
Tetralogy of Fallot	18	No	Termination of pregnancy
Pulmonary atresia, ventricular septal defect	18	No	Termination of pregnancy
Noncardiac			
Absent kidney, cleft palate	31	No	Intrauterine contraceptive device
Cleft palate	35	No	Alive
Pleural effusion	26	No	Alive
Pleural effusion	37	No	Alive

were performed only in the 39 cases where the pregnancy continued and where there was no evidence of congenital heart disease, so that these could be related to outcome. Images adequate for satisfactory measurements were not recorded on the available videotape in all cases. However, it was possible to obtain a left ventricle/right ventricle ratio in 33 of 39 cases (85%) and the aorta/pulmonary artery ratio in 32 of 39 (82%).

The outcome of each pregnancy was noted and related to the gestational age at the time of presentation. Evidence of associated anomalies, both at the time of ultrasonographic examination and on subsequent examination, was noted. In all cases the diagnosis of diaphragmatic hernia was confirmed either postnatally or at autopsy.

Results

The diaphragmatic defect was left-sided in 53 cases, right-sided in one, and retrosternal in one.

Polyhydramnios. Polyhydramnios was a feature in 16 of the 55 cases (29%). Termination of pregnancy took place in four of the 16, one case resulted in a spontaneous intrauterine death, five of the babies died postnatally, and there are six survivors, three of whom were seen before 25 weeks of pregnancy. Congenital heart disease was present in three cases associated with polyhydramnios.

Ratio of left-to-right ventricular size. The left ventricle/right ventricle ratio obtained in 33 cases is shown in Fig. 1. The majority of survivors (73%) had a left/right ventricular ratio within the normal range, whereas the majority of nonsurvivors (83%) had a reduced ratio. The left ventricle/right ventricle ratio of the survivors (mean ± SD 0.848, ±0.233) was significantly different ($p < 0.01$) from that of the nonsurvivors (mean ± SD 0.666 ± 0.151). In the one case with a high ratio, the diaphragmatic hernia was right-sided and the heart was pushed into the left chest. In this fetus the right-sided heart structures appeared smaller than the left. Sequential observations of the left ventricle/right ventricle ratio were obtained in 11 fetuses (Fig. 2). In three of these the sequential ratio was markedly reduced, and none of the three survived.

Ratio of aorta to pulmonary artery. The aorta/pulmonary artery ratio was obtained in 32 fetuses (Fig. 3). The ratio of the survivors (mean ± SD 0.837 0.149) was significantly different ($p < 0.05$) from that of the nonsurvivors (mean ± SD 0.704 0.128). A sequential value was obtained in nine fetuses, and the changes with gestational age are shown in Fig. 4.

Outcome. The outcome of the 55 cases of diaphragmatic hernia detected prenatally is shown in Fig. 5. The parents elected termination of pregnancy in 11 cases. Of the 44 continuing pregnancies, three resulted in a spontaneous intrauterine death, and 23 babies died in the neonatal period and three in infancy. There are currently 15 survivors, 33% of whom were seen before 25 weeks' gestation and 67% after this gestational age. Two children are <6 months of age, three have survived beyond 2 years, four beyond 3 years, and six beyond 4 years. Of the survivors, one child has had problems with esophageal reflux, one has had problems related to a cleft palate, and one child has scoliosis. There have been no long-term problems in the remaining. Our policy has been to deliver these babies vaginally whenever possible. Of the total group, seven were delivered by cesarean section, four of whom are survivors. In 28 cases antenatal care was transferred for delivery to take place in a unit with specialized pediatric surgical facilities available. In 12 of the 15 survivors delivery took place in a specialized unit.

Associated anomalies. An associated anomaly was present in 13 cases (23.6%). Congenital heart disease was the most frequent associated lesion occurring in nine of these 13 cases (16.4% of the total group). A chromosomal anomaly occurred in two cases (3.6%),

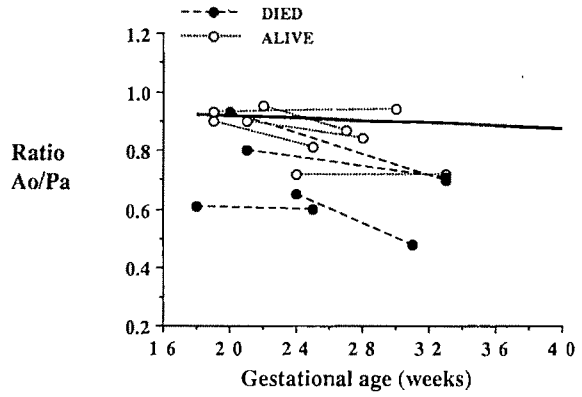

Fig. 4. Sequential values of ratio of aorta to pulmonary artery *(Ao/Pa)* in nine cases, compared with normal mean for gestational age.

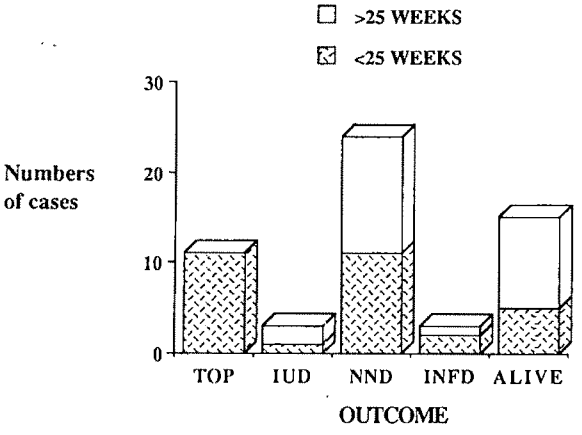

Fig. 5. Outcome in 55 cases of fetal diaphragmatic hernia in cases with presentation before 25 weeks of gestation, compared with cases with presentation after 25 weeks.

both of whom also had congenital heart disease. A breakdown of the different types of anomaly is shown in Table I.

Comment

The mortality associated with congenital diaphragmatic hernia detected prenatally is higher than that reported postnatally, because the spectrum of disease seen in the fetus is different.[2] Several reports have suggested that death occurs in >75% of cases of congenital diaphragmatic hernia that are detected before birth in spite of optimum postnatal care.[4, 6] The overall mortality in our series was 73%, but it fell to 66% if cases that elected termination of pregnancy were excluded and to 62% if those associated with congenital heart disease were also excluded. In cases with presentation before 25 weeks' gestation (n = 30) the overall mortality was 83% but fell to 72% if cases resulting in a termination or those associated with congenital heart disease were excluded. In the group seen after 25 weeks' gestation (n = 25), the overall mortality was 60% and fell to 52% if the four cases that also had congenital heart disease were excluded. Thus, although the mortality associated with the cases in our series was high, it was better than that previously reported.

We were unable to confirm previous reports that polyhydramnios is a predictor of a poor outcome.[6, 7] Hydramnios was a feature of 16 cases (29%), 12 of which had an isolated hernia. Of these 12 cases, termination of pregnancy took place in two and there are six survivors. It has been suggested that the presence of stomach in the chest, especially if it is dilated, may also be predictive of a poor outcome.[7] We were unable to relate this finding to outcome, because in six of our 15 survivors a dilated stomach was identified in the chest.

Left heart underdevelopment has previously been reported as being associated with a poor outcome and cardiac ventricular disproportion seen before 24 weeks was associated with a 100% mortality.[10] Our study confirmed the finding that disproportion, as shown by a reduced left-to-right ventricular size, is predictive of a poor outcome. However, two of our survivors had marked ventricular disproportion, one at 21 weeks' gestation and the other at 24 weeks' gestation, so that although a reduced left-to-right ventricular ratio is likely to be associated with a poor outcome, it is not an absolute prognostic indicator. In addition, three of the cases seen in early pregnancy with a left-to-right ventricular ratio in the normal range did not survive. Sequential observations, however, showed that changes that will alter the prognosis can occur with advancing gestational age. In three of the cases with sequential studies, the left ventricle/right ventricle ratio fell much more dramatically than expected with advancing gestational age, indicating more marked left ventricular underdevelopment. None of the three babies survived. Progression of lesions has been reported with some types of congenital heart disease[11] and emphasizes the need for serial scans during pregnancy for reassessment. Similarly, the ratio of the aorta to the pulmonary artery was generally lower than the mean in the nonsurvivors compared with the survivors, and changes in this ratio were also observed with advancing gestation. Thus examination of the fetal heart may be helpful in distinguishing cases likely to be associated with a good or bad outcome.

The cause of left heart underdevelopment remains uncertain. It has been suggested that herniated organs cause compression of the left ventricle in left-sided diaphragmatic hernias.[12] The development of cardiac chambers is related to the volume of blood flow, so that reduced blood flow will result in underdevelopment. In the presence of a left-sided diaphragmatic hernia, it is likely that reduced blood flow into the left side of

the heart is due to a combination of increased left atrial pressure restricting the normal right-to-left interatrial flow and decreased pulmonary venous flow because of lung hypoplasia. However, the evidence of right heart underdevelopment in the right-sided hernia suggests that direct compression of cardiac structures may play a role in hypoplasia.

The association of congenital heart disease with congenital diaphragmatic hernia is well recognized.[13] In this series there was evidence of congenital heart disease in 16.4% of cases; this was associated with a poor outcome. There were only two fetuses (3.6%) with a karyotype anomaly, which is a much lower rate than that reported in other series.[6, 14] This is presumably because most of our patients were referred after the result of chromosomal analysis was known and the patient was planning to continue the pregnancy.

The main cause for the high mortality associated with this condition is pulmonary hypoplasia.[15] Prenatal therapy has been aimed at trying to prevent this from occurring.[16] It is difficult to assess the critical mass of lung tissue required for survival. Infants survive resection of a malformed or infarcted lung, suggesting that adequate ventilation is possible with 50% of normal lung mass. Infants dying with a large diaphragmatic hernia usually have a lung weight of 15% to 40% of expected weight and it has been sugested that the critical mass is between the two.[17] To date, there have been no accurate methods defined for estimating fetal lung mass prenatally. It has been suggested that the area of the hernia can be measured on ultrasonography and related either to the area of the chest or to the size of the heart.[7, 10] The area of the hernia in the chest is not always clearly defined on ultrasonographic scanning. so that an overestimation or underestimation may occur. Further studies are required to establish whether lung volume can be accurately predicted prenatally. For the present time, it would be easier to assess the secondary effects on the cardiac structures when attempts are made to predict the outcome.

In conclusion, although the overall mortality associated with fetal congenital diaphragmatic hernia is high, the odds for survival are significantly improved if other abnormalities are excluded and there are few or no signs of left heart underdevelopment. Thus examination of the fetal heart is important in the evaluation of each case, both in terms of detecting structural cardiac abnormalities and for assessing the development of the cardiac chambers. Careful counseling of the parents is required, particularly in cases seen in early pregnancy, as the potential for change with advancing gestational age must be taken into account. Termination of pregnancy is an option before 24 weeks of gestation. In cases that continue to term, sequential observations may be helpful in selecting cases likely to be associated with a good outcome. In these cases careful attention to postnatal perioperative management is required, and the influence of this on the outcome needs further assessment before prenatal therapy is contemplated.

Abruptio placentae associated with perforated appendicitis and generalized peritonitis

Yuval Yaron, MD, Joseph B. Lessing, MD, and M. Reuben Peyser, MD
Tel Aviv, Israel

A primigravid woman at 35 weeks' gestation was admitted with abdominal pain, fever, and vomiting. Forceful contractions and signs of fetal distress suggested abruptio placentae. During cesarean section, seropurulent exudate and a perforated appendix were found; an appendectomy was performed. A mechanism linking appendicitis with abruptio placentae is suggested. (AM J OBSTET GYNECOL 1992;166: 14-5.)

Key words: Abruptio placentae, acute appendicitis, peritonitis

A case of abruptio placentae occurring in association with a perforated appendix is described.

Case report

A 26-year-old primigravid women was hospitalized at 35 weeks of gestation because of the sudden onset of abdominal pain associated with copious vomiting. Before admission the clinical and ultrasonographic follow-up indicated an uneventful pregnancy with an appropriate-for-gestational-age, normally developing fetus. There was no hypertension, diabetes mellitus, or history of external trauma. The pateint did not smoke or consume alcohol, nor was she a drug abuser.

On admission, the patient was apprehensive and tachypneic. Temperature was 37.8° C, pulse 92 beats/min and blood pressure 100/60 mm Hg. On examination, the uterine size was appropriate for gestational age with evident tenderness above it and alongside, predominantly on the right. The fetus was in a vertex presentation, and the cervix was 2 cm long, firm, and dilated to 1.5 cm. On ultrasonography, the biophysical profile was normal, and the placenta was at the fundus with no apparent signs of abruptio placentae. On cardiotocography, fetal heart rate was normal and reactive. Hemoglobin was 13 gm/dl, white blood cell count 11,700 mm^3, and blood glucose, urea, electrolytes, and clotting factors were within the normal range. Urinalysis results were normal. Within 4 hours the patient complained of contractions with increasing frequency and intensity. Shortly thereafter the uterine tone ceased to subside between contractions, but the fetal heart rate remained normal and reactive. The cervix was then effaced and dilated to 2 cm. Abruptio placentae was suspected and amniotomy was performed. The fluid was clear, and on direct internal tocography the basal uterine pressure was 30 to 40 mm Hg. Epidural analgesia was established, and ampicillin and gentamicin therapy was initiated. In the following 2 hours the cervix dilated to 3 cm; at that time blood clots first appeared through the cervix. The fetal heart rate pattern then showed late decelerations, and a cesarean section was performed. In the peritoneal cavity 300 ml of odorless, seropurulent fluid was present. A 2425 gm male infant was delivered, with Apgar scores of 7 and 9 at 1 and 5 minutes, respectively. The placenta followed immediately, with numerous blood clots covering about 30% of its surface. Exploration of the abdominal cavity revealed a perforated appendix with a fecalith at the perforation site and leakage of pus. Appendectomy was performed, and the peritoneal cavity was thoroughly rinsed. The postoperative period was uneventful.

Pathologic examination of the appendix was consistent with acute appendicitis. *Escherichia coli* was cultured in specimens from the appendix, peritoneal fluid, and placenta. Culture specimens from the neonate's nose, pharynx, and ear canals were sterile.

Comment

The combination of acute appendicitis and abruptio placentae poses a difficult diagnostic problem. Nevertheless, the presence of both conditions is unlikely to be coincidental. A possible explanation linking the events beginning with acute appendicitis and culminating in a premature separation of the placenta is presented.

With maternal intraperitoneal infection, microorganisms may gain access to the intervillous space by hematogenous dissemination during maternal bacteremia. From there, the infection could spread to the villi and fetal circulation. Bacterial colonization of the decidua and fetal membranes without clinical evidence of infection was reported. Darby et al.[1] reported that histologic chorioamnionitis and funisitis were present

significantly more often in patients with acute, severe preterm abruptio placentae than in normal deliveries. They speculated that direct bacterial colonization of the decidua with resultant tissue inflammation may initiate processes, such as disruption of decidual lysosomes, that ultimately result in abruptio placentae.

Whereas direct bacterial colonization of the decidua is a possibility when generalized peritonitis is present, this need not necessarily occur, as dissemination of bacterial endotoxin is also capable of initiating similar processes. The initiation of normal parturition is dependent on activation of the decidua and the production of prostaglandins by accelerated hydrolysis of glycerophospholipids.[2] It has been shown that the decidua responds to bacterial infection by increased biosynthesis of prostaglandin, stimulated either by bacterial endotoxin or by host signals (tumor necrosis factor, interleukin-1, platelet-activating factor) that were secreted in response to the presence of microbes.[2]

In the case under discussion, generalized peritonitis caused by a ruptured appendix may have been associated with dissemination of bacteria and bacterial endotoxin that stimulated prostaglandin biosynthesis in excess. Both increased prostaglandin biosynthesis and direct colonization of the placental villi with tissue disruption could have resulted in abruptio placentae.

In summary, we suggest that in pregnancy an acute bacterial infection such as generalized peritonitis may cause abruptio placentae.

The effect of continuous subdermal levonorgestrel (Norplant) on carbohydrate metabolism

Justin C. Konje, MD, Emmanuel O. Otolorin, MD, and Oladapo A. Ladipo, MD
Ibadan, Nigeria

Blood glucose and plasma insulin levels during an oral glucose tolerance test were measured in 20 women using continuous subdermal levonorgestrel (Norplant) for contraception over a 12-month period. Changes in carbohydrate metabolism occurred as early as 1 month but were most marked after 6 months. After 1 month the area under the glucose and insulin curves increased by 12.3% and 37.7%, respectively. This increase was more marked by 6 months, but by 12 months it was significantly less marked. Although changes in the blood glucose and plasma insulin levels at different times during the oral glucose tolerance test occurred, they were all within normal limits for normal women. The peak blood glucose and insulin levels after insertion of the implant occurred 60 minutes after the glucose load, as opposed to 30 minutes before insertion. Apart from this, there was a significant delay in the return of these levels to fasting values. We conclude that this product, like any other progesterone-containing contraceptive, alters carbohydrate metabolism, but these alterations are not clinically significant in normal women. It is, however, possible that in potential cases of diabetes it may predispose to frank diabetes. (Am J Obstet Gynecol 1992;166:15-9.)

Hormonal contraceptives remain one of the most effective reversible methods of family planning worldwide. Although first marketed in 1957, it was not until the pioneering work of Waine et al.[1] that attention was drawn to the adverse metabolic effects of these hormones. It is now generally believed that the altered

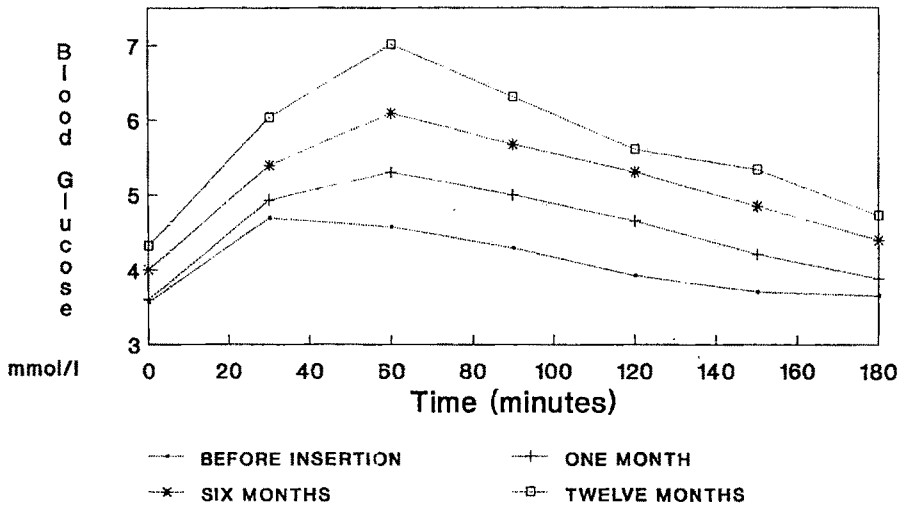

Fig. 1. Mean blood glucose values during GTT in 20 Norplant users over a 12-month period.

carbohydrate metabolism in women using combination oral contraceptives is mainly due to the progestogen component.[2-7] Of the various classes of progestogens used for contraception, the 19-norprogestogens alter carbohydrate metabolism most.[3,5] Levonorgestrel belongs to this potent group and has no doubt been extensively investigated.

As research continues on adverse metabolic effects of various hormonal contraceptives, so too are attempts to develop long-acting preparations and delivery systems that will improve effectiveness, safety, and acceptability. The continuous subdermal implant Norplant is one of these new long-acting contraceptives containing the 19-norprogestogen levonorgestrel. Regulatory approval has been given for its marketing in many developing and developed countries,[8,9] and very recently by the Food and Drug Administration in the United States. Unlike oral contraceptive pills and injectable contraceptives, the release of levonorgestrel peaks to 80 μg/24 hours during the first weeek after insertion and declines steadily to stabilize at 30 μg/24 hours after 12 to 18 months.[10,11] While lipid and coagulation changes have been extensively studied in Norplant users,[12-15] such changes in carbohydrate metabolism have not been properly studied. The aim of this study was therefore to monitor the alterations in carbohydrate metabolism that occur in Norplant users over a 12-month period.

Material and methods

Twenty women voluntarily seeking contraceptive advice at the University College Hospital, Ibadan, Nigeria, family planning clinic, who opted for Norplant after counseling and satisfied the inclusion criteria, were recruited into the study. These criteria were age 20 to 40 years, regular menstrual cycles in the last 12 moths, absence of known or suspected medical disorders, weight between 40 and 80 kg, nonsmoker, and not receiving steroids, antibiotics, barbiturates, and antituberculous drugs. All those who had either been pregnant or used other hormonal contraceptives in the preceding 12 months were excluded. Signed consent was obtained from each patient, and approval for the study was obtained from the Joint Ethical Committee of the University of Ibadan and University College Hospital, Ibadan, Nigeria.

Glucose tolerance test. An average Nigerian diet contains at least 60% carbohydrate; hence no special dietary preparation was required. After a 12-hour overnight fast, an oral glucose tolerance test (GTT) was performed at 8 AM, before Norplant insertion. After the patient rested in a chair for 30 minutes, an intravenous cannula (20 Fr) was inserted into the antecubital vein, and 5 ml of blood was withdrawn. Three milliliters was placed in a heparinized tube and later centrifuged. The serum was then separated and labeled. The remaining 2 ml was placed in an oxalate fluoride bottle and also labeled. Each patient was then given a solution of 250 ml of water containing 75 gm glucose to drink. Repeat venous samples were collected at 30-minute intervals for 3 hours and separated as detailed. The seven samples for glucose estimation were immediately transported to the laboratory, where blood glucose was estimated with the glucose oxidase method on a Beckman glucose autoanalyzer (Beckman Instruments, Inc, Fullerton, Calif.). Serum for insulin was stored at −20° C and later measured with Amersham radioimmunoassay kits (Abbott Laboratories, North Chicago). The measurements for each patient were performed as single assays.

As soon as the oral GTT was completed, six capsules of Norplant were inserted on the medial aspect of the

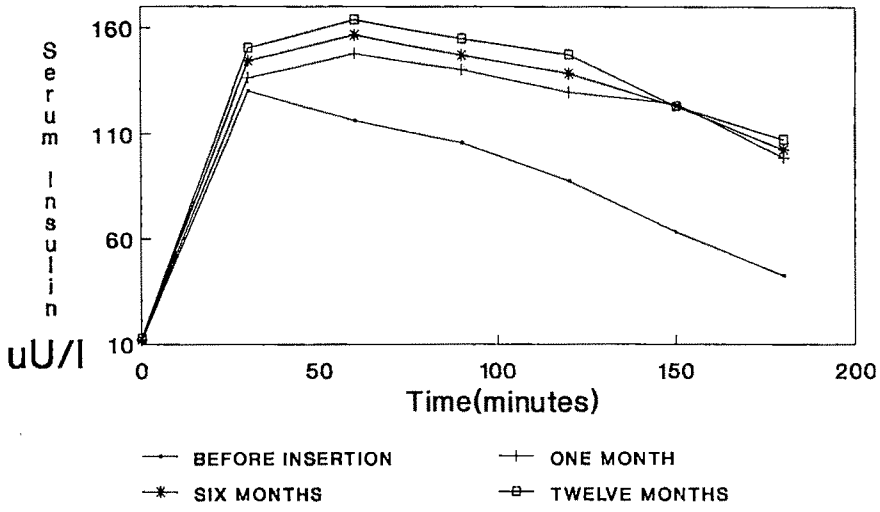

Fig. 2. Mean serum insulin values during GTT in 20 Norplant users over a 12-month period.

Table I. Mean blood glucose values for 20 Norplant users over a 12-month period

Duration of Norplant use (mo)	*Glucose values (mmol/L, mean ± SD) during oral GTT*

12	4.32 ± 0.69 $t = 4.412$ $p < 0.001$	6.03 ± 1.23 $t = 4.295$ $p < 0.001$	7.01 ± 1.02 $t = 0.037$ $p < 0.0001$	6.31 ± 0.77 $t = 9.140$ $p < 0.0001$	5.60 ± 0.78 $t = 6.855$ $p < 0.0001$	5.33 ± 0.65 $t = 7.932$ $p < 0.0001$	4.72 ± 0.67 $t = 4.758$ $p < 0.001$

The p value is statistical significance for glucose value compared with the corresponding value before insertion.

upper arm with the method recommended by Alvarez.[16] The oral GTT was then repeated at 1, 6, and 12 months after insertion. Blood glucose and serum insulin values and the areas under the curves were compared with the paired t test.

Results

The mean age and parity of the 20 patients were 32.9 ± 3.9 (range 25 to 39 years) and 5.8 ± 1.5 (range 4 to 8). The mean weight at admission was 56.7 ± 9.4 kg but changed to 56.6 ± 9.3, 56.8 ± 9.4, and 57.9 ± 9.6 kg at 1, 6, and 12 months after Norplant insertion. These weight changes were small and insignificant.

Blood glucose. The mean blood glucose values during oral GTT over the 12-month period are shown in Table I and depicted graphically in Fig. 1. There was a consistent rise in the various blood glucose values after 1, 6, and 12 months on Norplant. The rise in blood glucose level at various times during the oral GTT was more marked after 6 and 12 months on Norplant than after 1 month. The p values for these changes are shown in Table 1.

The peak blood glucose level during oral GTT occurred at 30 minutes before Norplant insertion, but it occurred at 60 minutes after Norplant insertion. There was also a slower return of the blood glucose value to fasting levels after Norplant insertion.

The area under the oral GTT curve was 247.7 ± 19.4 before insertion (AG_0) but rose to 278.20 ± 23.7 (AG_1), 314.85 ± 31.8 (AG_6), and 347.85 ± 44.3 (AG_{12}) after 1, 6, and 12 months on Norplant, respectively. The changes in area from insertion to 1, 6, and 12 months afterward were 30.50, 67.15, and 100.25, respectively. These represented 12.3%, 25.0%, and 40.4% increases, respectively. The $\Delta AG_{0\text{-}6}$ and $\Delta AG_{0\text{-}12}$ values were statistically greater when compared with $\Delta AG_{0\text{-}1}$ ($p < 0.05$ and $p < 0.01$, respectively).

	$p > 0.5$	$p < 0.0001$	$p < 0.0001$	$p < 0.0001$	$p < 0.0001$	$p < 0.0001$	$p < 0.0001$

The p value is statistical significance for insulin value compared with corresponding value before insertion.

serum insulin levels at various times over 12 months of Norplant use. The changes are also shown graphically in Fig. 2. Again there is a consistent rise in various values at different times of the oral GTT. Unlike blood glucose values, there was a very small rise in fasting insulin levels. The peak insulin value was measured 30 minutes before Norplant insertion and 60 minutes after insertion. The return of serum insulin to fasting levels was slower after Norplant insertion.

The area under the insulin curves rose from 530.6 ± 120.4 (IA_0) at insertion to 730.5 ± 170.6 (IA_1) at 1 month, 768.7 ± 169.5 (IA_6) at 6 months, and 799.9 ± 179.2 (IA_{12}) at 12 months after insertion. The change in area from insertion to 6 months afterward (ΔI_{0-6}) was 238.1 and from insertion to 12 months after was (ΔI_{0-12}) 269.3, representing a 44.9% and a 50.8% rise from the area at insertion (IA_0), respectively. The increase in area was 199.9 from insertion to 1 month afterward (ΔI_{1-0}) and 31.2 from 6 to 12 months after insertion (ΔI_{6-12}), representing a 37.7% and a 4.1% rise, respectively.

Comment

Since the pioneering work of Waine et al.[1], various studies have been conducted to determine the secondary metabolic effects of steroidal contraceptives.[1-6] Most of these have shown that the gonane progestogens are the most potent in altering carbohydrate metabolism.[3,5] Almost all the previous studies have been with oral contraceptives. Administration of these hormones is associated with daily fluctuations in serum progestogen levels. In addition, ever-changing conditions of the gastrointestinal and hepatic systems may affect absorption and metabolism. The daily dose of progestogens in most products varies from 150 μg to 2 mg, but levonorgestrel release from Norplant rises to 80 μg within the first week and drops steadily to 30 μg after 12 to 18 months. We aimed in this study to determine the extent to which continuous levonorgestrel, when given alone, will alter carbohydrate metabolism.

Our results show that alteration in carbohydrate metabolism with continuous low-dose levonorgestrel occurs as early as 1 month after insertion. Although changes in glucose and insulin curves occurred throughout the 12-month period, it was more marked over the first 6 months. This would suggest that the alteration in carbohydrate metabolism is partly dependent on the dose of levonorgestrel released. We feel that these alterations may in fact stabilize by 18 months when levonorgestrel release stabilizes at 30 μg/24 hours.

Although there was an alteration in carbohydrate metabolism, none of the glucose tolerance curves were either diabetic or suggestive of impaired glucose tolerance. This is in contrast with the findings of Spellacy et al.[4] on 19-norgestrel where 18% of the glucose tolerance test results were abnormal after 18 months. This difference may be due to the dose of levonorgestrel administered.

Whereas the rise in fasting blood glucose level after 6 and 12 months on Norplant in our study was statistically significant, others have reported either no rise[17-19] or a statistically insignificant rise.[20,21] Dietary and cultural differences might be responsible. The glucose and insulin curves showed a change in pattern after Norplant insertion. Similar changes have also been noted by others but with other forms of hormonal contraceptives.[4,6]

Although extensive research has been conducted on the alterations in carbohydrate metabolism caused by hormones, the exact mechanism of these alterations is yet to be universally agreed on. We speculate that the delayed peaking of the glucose and insulin curves in our cases might have been due to delayed absorption of glucose from the gastrointestinal tract. It is also possible that decreased gastrointestinal motility induced by the progestogens may be a contributing factor. Other mechanisms that have been suggested for these changes include alteration in liver morphologic characteristics and function,[22] increase in peripheral insulin resis-

tance,[23] and increase in insulin antagonistic hormones such as growth hormone, cortisol, and glucagon.[24] Diaz et al.,[25] however, in studying cortisol, thyroid, and prolactin changes in Norplant users, found no such increases. Whatever the mechanism, 17-estradiol, when administered with progestogens, is said to enhance these changes.[7] Therefore the absence of estrogen in Norplant may be partly responsible for the milder alterations.

Although we have demonstrated that Norplant induces changes that are not clinically significant in normal patients, such changes in diabetes or potential diabetes may have significant clinical implications. There is likely to be a need for increased insulin requirements, and those with impaired carbohydrate metabolism may become overtly diabetic. We therefore suggest that until more studies are carried out on diabetic women and others at risk these conditions should be a relative contraindication. Where there is no alternate form of contraception, Norplant may be used but the diabetic control will need to be monitored more carefully.

We thank Family Health International for the supply of Norplant, B. Adelaja and his colleagues at the Medicine Laboratory University College Hospital, Ibadan, for assaying the hormones, and Mrs. A. Olowe for her invaluable assistance during recruitment and follow-up.

Familial occurrence of thrombotic thrombocytopenic purpura in two sisters during pregnancy

Arnon Wiznitzer, MD,[a] Moshe Mazor, MD,[a] Joseph R. Leiberman, MD,[a] Yaron Bar-Levie, MD,[b] Gavriel Gurman, MD,[b] and Marek Glezerman, MD[a]

Beer-Sheva, Israel

The etiology of thrombotic thrombocytopenic purpura is not fully understood. A genetic predisposition and other inciting factors have been suggested by several studies to bring about the full-blown syndrome. We report two cases of thrombotic thrombocytopenic purpura in two sisters with sudden onset during late pregnancy. (AM J OBSTET GYNECOL 1992;166:20-1.)

Key words: Thrombotic thrombocytopenic purpura, pregnancy, heredity

Thrombotic thrombocytopenic purpura is a well-recognized clinical syndrome associated with diverse conditions. Various studies suggested that genetic factors and immunologic and infectious causes can induce this disorder to appear. A combination of genetic factors with a precipitating event, pregnancy, was previously suggested by Wallace et al.[1] Fuchs et al.[2] described two sisters in whom acute and fatal thrombotic thrombocytopenic purpura occurred during their first pregnancies. We report here the second case of a classic syndrome of thrombotic thrombocytopenic purpura that occurred during late pregnancy in two primiparous sisters. In each sister the disease began suddenly, and one of the sisters is alive.

Case reports

Case 1. In 1980, a 19-year-old patient, gravida 1 para 0, was hospitalized at her thirty-first week of gestation complaining of generalized weakness and vomiting. Her medical history was uneventful.

Physical findings revealed a well-developed and well-nourished woman, appearing pale and diaphoretic with diffused purpura on both legs. Blood pressure was 120/80 mm Hg, pulse was 88 beats/min, and she had no fever. The uterus was appropriate for gestational age, with the fetus in vertex presentation. Immediately after admission she convulsed. The initial laboratory evaluation revealed microangiopathic hemolytic anemia, thrombocytopenia of 10,000/mm^3, hemoglobin of 5.8 gm/dl, and urinalysis showing macrohematuria. Six hours after the grand mal seizure, the fetus died and labor was induced. Thereafter, sudden deterioration in the mother's condition occurred and she subsequently died. Autopsy examination showed thrombi in the small vessels of the heart, brain, lungs, and glomerular capillaries consistent with the diagnosis of thrombotic thrombocytopenic purpura.

Case 2. In 1990 the 26-year-old sister of patient No. 1 was seen during the twenty-seventh week of her first pregnancy in a stuporous state with purpura on both legs. Her prenatal course was complicated by repeated urinary tract infections with *Escherichia coli*. On admission the examination revealed a restless, stuporous, toxic-appearing woman with a temperature of 39.6° C. Blood pressure was 110/80 mm Hg and pulse 120 beats/min. The uterus was appropriate for gestational age, with the fetus in vertex presentation. The uterine cervix admitted a fingertip but was not effaced. Initial laboratory workup revealed a white blood cell count of 4300 cells/mm^3, hemoglobin of 7.6 gm/dl, and platelet count of 66,000/mm^3. Blood coagulation profile was within normal limits. Blood and urine specimens both revealed *E. coli*. Four hours after her admission, two grand mal seizures occurred.

A cesarean section was performed because of severe fetal bradycardia, and a 1100 gm male infant with an Apgar score of 2 at 1 minute was delivered. The infant died within a few minutes.

Amniotic fluid cultures obtained during the cesarean section demonstrated the same serotype of *E. coli* that was isolated from maternal blood and urine. Postoperatively, the patient was bleeding through the nasogastric tube and at the central venous pressure catheter site. Further laboratory evaluation showed a decrease in platelet count to 15,000/mm^3, a few fragmented red blood cells on the peripheral smear, a negative test result for antinuclear antibody, and normal prothrombin time, partial thromboplastin time, and fibrinogen levels. Serum creatinine concentration rose to 8 mg/dl. The patient was transferred to the general intensive care unit, where she was treated for 41 days for multiple life-threatening conditions. At admission she was stuporous, hypothermic (33° C) and rapidly developed septic shock. A bleeding diathesis consistent with disseminated intravascular coagulation improved after

6/1/31812

massive transfusion of blood, plasma, and several clotting factors. Two days after admission to the intensive care unit the patient became fully alert and conscious.

On the fifth day, the patient again became lethargic and stuporous and signs of meningeal irritation and right hemiparesis developed. Brain computed tomographic scan showed a large left frontoparietal infarct without signs of mass effect or edema. On the seventh day, the patient's condition deteriorated into deep coma. There was renal failure with creatinine levels of 10 mg/dl and urea levels of 550 mg/dl.

Eleven days after admission, the patient had a repeated event of septic shock. Pulmonary artery catheterization showed a low-resistance, high-cardiac-output failure. Cultures from the sputum and urine grew *Acinetobacter* and drainage of a large pleural effusion grew *Pseudomonas aeruginosa.*

After aggressive antibiotic and steroid treatment the patient's status gradually improved. She regained consciousness with neurologic and renal function slowly returning to normal.

On the forty-first day of hospitalization, the patient recovered completely and was discharged from the hospital to be followed up monthly at the outpatient clinic. Sixteen months later she is healthy and without any pathologic sequelae.

Comment

Thrombotic thrombocytopenic purpura is an acute disease of unknown cause. In some patients pregnancy appears to exacerbate or trigger the onset.

Hereditary factors may play a role in etiology and pathogenesis. Thrombotic thrombocytopenic purpura has been reported before in siblings.[1] Moreover, Fuchs et al.[2] have reported the classic syndrome of fatal thrombotic thrombocytopenic purpura in two sisters during pregnancy. The authors concluded that this disorder may have a genetic predisposition that is triggered during late pregnancy by various inciting factors, such as sepsis. In both sisters thrombotic thrombocytopenic purpura occurred at almost the same stage of their first pregnancies, the clinical course was similar, and the triggering factor was associated with infections. The recovery of the second sister can be attributed to the early diagnosis and aggressive intensive care.

Physicians and patients should be alerted to the possibility of familial occurrence of thrombotic thrombocytopenic purpura during pregnancy. Aggressive treatment of an infectious disease should be initiated as soon as possible.

Addendum

A third sister became pregnant, and her pregnancy was complicated with thrombocytopenia. Because of the family history and the physician's alertness to this rare disease, a prompt diagnosis of thrombotic thrombocytopenic purpura was made.

Numeric analysis of heart rate variation in intrauterine growth–retarded fetuses: A longitudinal study

Rosalinde J.M. Snijders, MSc, Lucia S.M. Ribbert, MD, Gerard H.A. Visser, MD, PhD, and Eduard J.H. Mulder, MSc, PhD

Groningen, The Netherlands

OBJECTIVE: We attempted to determine changes occurring with time in fetal heart rate and its variation in fetuses with intrauterine growth retardation in whom late antepartum fetal heart rate decelerations eventually develop.

STUDY DESIGN: Thirteen fetuses with intrauterine growth retardation were studied over a median period of 25 days. One-hour fetal heart rate records were made two to five times per week and were analyzed numerically. Fetal movements were recorded by the women.

RESULTS: On average long-term fetal heart rate variation decreased gradually with time and fell below the norm (30 milliseconds) at about the same time decelerations appeared. Mean heart rate showed a slight but statistically significant increase after the occurrence of decelerations. There were large interfetal differences in all parameters studied.

CONCLUSION: In fetuses with intrauterine growth retardation a decrease in long-term fetal heart rate variation is a rather late sign of impairment that coincides with the occurrence of late decelerations. In the surveillance of the fetus with intrauterine growth retardation it might be most appropriate to use each fetus as its own control. (AM J OBSTET GYNECOL 1992;166:22-7)

Key words: Intrauterine growth retardation, fetal heart rate monitoring, fetal hypoxemia, computer analysis

In cross-sectional studies of fetuses with intrauterine growth retardation (IUGR), long-term heart rate variation is usually within the normal range in the absence of antepartum late fetal heart rate (FHR) decelerations, but it is reduced in the presence of late decelerations.[1, 2] Reduced FHR variation and the occurrence of decelerations coincide with hypoxemia, as determined in cord blood obtained by cordocentesis or at elective cesarean section,[2-4] and are assumed to precede the "terminal" state, in which fetal acidemia is present.[5, 6] These data suggest that a reduction in heart rate variation is a rather late sign of impairment of the fetal condition.

The cross-sectional design of these studies has not allowed determination of the actual sequence of changes in FHR patterns with progressive deterioration. In this study therefore heart rate and its variation were measured longitudinally in fetuses with IUGR to determine changes occurring with time and progressive deterioration.

Patients and methods

The study group consisted of 13 women admitted to the obstetric ward. They were selected retrospectively on these criteria: (1) Computerized analyses of 1-hour FHR records were available before and after the occurrence of antepartum late decelerations; (2) cesarean section had been performed because of recurrent late decelerations; (3) the infants had a birth weight below the 10th percentile as corrected for sex and parity[7] and had no congenital malformations. All of the women had been admitted because of the clinical diagnosis of IUGR. Nine had pregnancy-induced hypertension; proteinuria was detected in four women. Four patients were treated with antihypertensive drugs, and two received 80 mg of acetylsalicylic acid daily. No other medication was prescribed.

The clinical data of the infants are shown in Table I. Most were delivered before 35 weeks of gestation. All but one (case number 12) had abnormal umbilical artery blood velocity waveforms, and in seven there was absence of end-diastolic frequencies above filter level (150 Hz). In one there was reversed flow during diastole. In the seven fetuses in whom blood velocity waveforms were measured in the internal carotid artery, the pulsatility index (Peak systolic velocity − Peak diastolic velocity/Mean velocity) was decreased, which probably indicated reduced cerebral vascular resistance. The blood velocity waveforms in the umbilical artery and internal carotid were related to observations made on normal fetuses.

†Absence of end-diastolic velocities.

‡Symmetric IUGR.

§Reversed flow.

Before birth, nine fetuses exhibited asymmetric growth retardation; four were symmetrically growth retarded, according to the head/abdomen circumference ratios.[8] At birth, nine infants weighed <2.3rd percentile. Five of the nine fetuses with measurements had hypoxemia (umbilical arterial $Po_2 < 2.00$ kPa) and in 10 of the 13 fetuses the pH was within the normal range (umbilical artery pH > 7.20).[2] There was one neonatal death. Other complications included intraventricular hemorrhage ($n = 1$), necrotizing enterocolitis ($n = 1$), and hyaline membrane disease ($n = 4$).

In the 13 fetuses 200 1-hour FHR records were made with a Hewlett Packard model 8040A cardiotocograph over a median period of 25 days (range 4 to 44 days) two to five times per week between 10 AM and 6 PM. The records were analyzed numerically with an on-line microcomputer system[9] adapted for use with a personal computer (Apricot Xen). This computer program for FHR analysis is identical to that of the commercially available Sonicaid System 8000. With this system a baseline is fitted to the FHR trace. Accelerations (≥ 10 beats/min lasting ≥ 15 seconds) and decelerations (≥ 10 beats/min lasting ≥ 60 seconds or ≥ 20 beats/min lasting ≥ 30 seconds) are then identified. FHR variation is measured as the range of mean pulse intervals about the baseline calculated minute by minute, with data from decelerations excluded; it is averaged to give a measure of long-term variation ("mean minute range" in milliseconds). Episodes of high and low heart rate variation are identified when 5 of 6 successive minutes have a range of pulse intervals > 32 or < 30 milliseconds, respectively. Basal FHR is calculated as the mean FHR in episodes of low variation or, if no such episodes are present, as the mean pulse interval expressed as beats per minute.

The fetal movements felt by the women were recorded with an event marker. No more than one movement every 1/16 minute was identified. An example of a 1-hour recording is shown in Fig. 1. The number of records differed among the fetuses; therefore data were standardized per fetus per week (Figs. 2 and 3).

It has been shown previously that FHR variation is > 30 milliseconds in 95% to 97% of normal third-

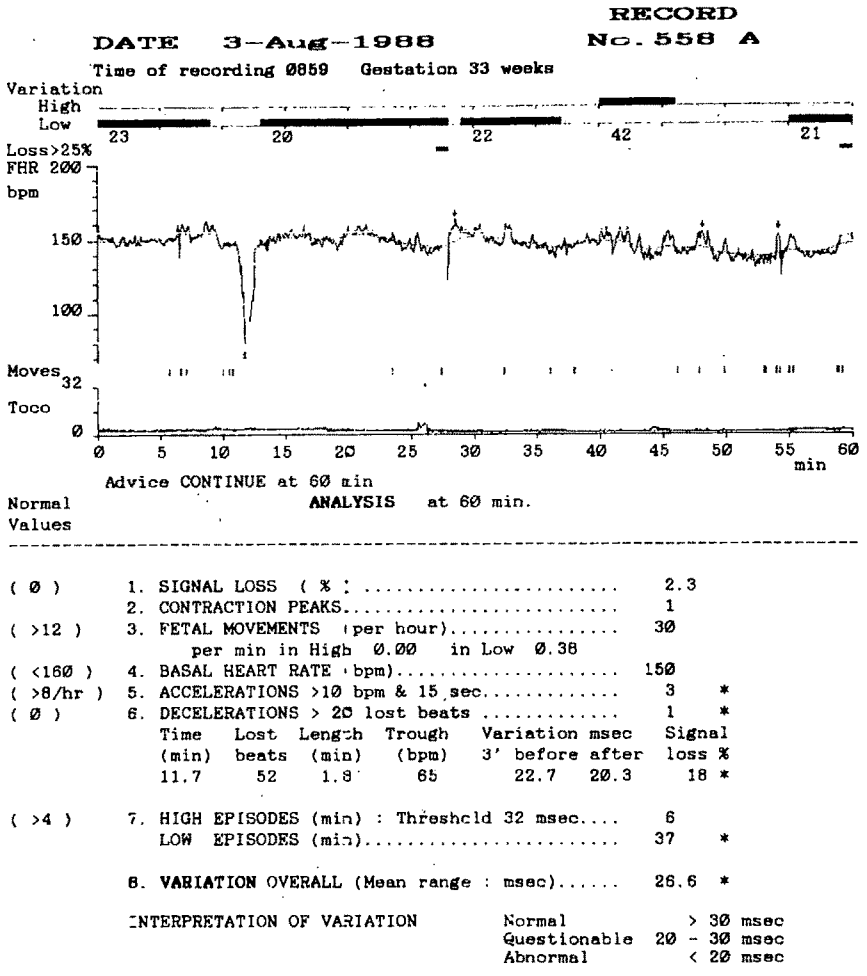

Fig. 1. Example of computer printout of 1-hour record at 33 weeks. Heart rate variation is below normal range (26.6 milliseconds); there is one large deceleration.

trimester fetuses.[9] This value was taken as the lower limit of normality. Because neither this lower limit nor that of the incidence of fetal body movements[2] changes during the third trimester of pregnancy, the data were grouped according to the first occurrence of late decelerations without regard to the differences in gestational age. The occurrence of antepartum late decelerations was assessed visually from the original FHR traces[5, 6] by clinicians not aware of the data from the numeric analysis. The women were delivered of their infants between <1 day and 19 days after the first deceleration occurred (median interval 6 days). On average, visually assessed decelerations were present in 38% of the records made after the occurrence of the first deceleration.

Results

The changes with time in basal heart rate, FHR variation, and the percentage of time that episodes of high FHR variation were present are shown in Fig. 2. There was a slight but significant increase in basal FHR when decelerations occurred (Wilcoxon test, $p < 0.05$). On average, FHR variation decreased gradually with time. The median value fell below the normal range (30 milliseconds) at about the time at which decelerations appeared. A similar gradual decline occurred in the duration of episodes of high FHR variation (Fig. 2) and in the incidence of fetal movements as felt by the women (Fig. 3). The number of accelerations per hour was low initially and remained constant (Fig. 3).

There were no differences among fetuses with symmetric and asymmetric IUGR except for the incidence of movements felt subjectively, which was somewhat higher in the fetuses with symmetric IUGR.

Large interfetal differences were present (Figs. 2 and 3). In Figs. 4 and 5 basal heart rate, FHR variation, and episodes of high variation are shown for two fetuses delivered at 37 weeks and for two delivered at 31 weeks. In spite of similar birth weights there were large differences in FHR variation, which was already low in one fetus weeks before the onset of decelerations; in

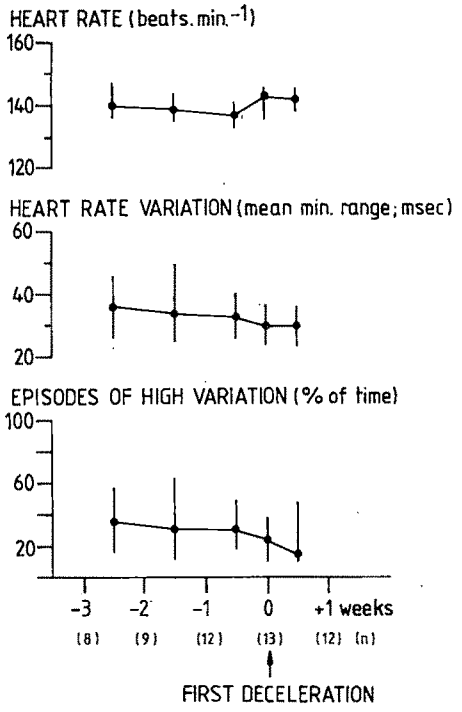

Fig. 2. Changes with time in basal heart rate, heart rate variation, and percentage of time in which episodes of high heart rate variation are present in 13 growth-retarded fetuses. Data are grouped according to first occurrence of late decelerations and are presented as medians and interquartile ranges. Numbers in parentheses are number of fetuses included.

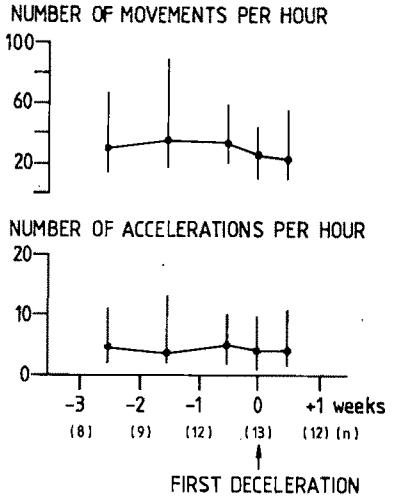

Fig. 3. Changes with time in number of movements felt by women and in number of accelerations (≥ 10 beats/min lasting ≥ 15 milliseconds) in 13 growth-retarded fetuses. Data are grouped according to first occurrence of late decelerations and are presented as medians and interquartile ranges.

the other it was still high after the onset of decelerations (Fig. 4) or decreased when the first deceleration occurred (Fig. 5). All four fetuses in Figs. 4 and 5 had asymmetric growth retardation; no antihypertensive drugs were administered.

There was a gradual increase in the pulsatility index of the umbilical artery (Fig. 6). The pulsatility index was increased (> 2 SD above the mean) in 7 of 10 cases studied 3 weeks before the decelerations occurred, in 7 of 12 cases studied at −2 weeks, in 10 of 13 cases at −1 week, and in 11 of 13 cases at the occurrence of decelerations.

Comment

The results of this longitudinal study demonstrate that in growth-retarded fetuses, who are eventually delivered because of repetitive FHR decelerations, there is a gradual decline in long-term FHR variation. However, variation often remains within the normal range (> 30 milliseconds) until (or even after) late decelerations occur. This finding is in agreement with data from earlier cross-sectional studies[1, 2] and implies that often the FHR variation of fetuses with IUGR cannot be distinguished from that of normal fetuses before late decelerations appear. Furthermore, the coincidence of the decline in FHR variation and the occurrence of late decelerations indicates that both parameters should be considered as a rather late sign of fetal impairment, because antepartum FHR decelerations are associated with adverse neonatal neurologic outcome.[10]

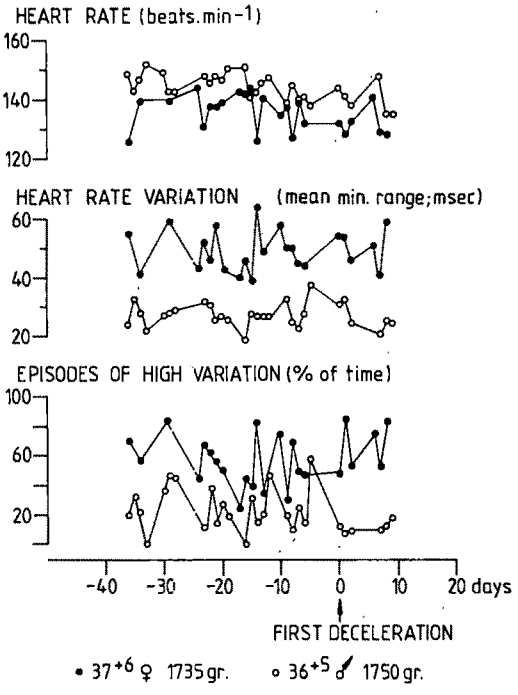

Fig. 4. Basal fetal heart rate, heart rate variation, and occurrence of episodes of high variation in two fetuses with similar birth weights who were delivered at 36 and 37 weeks' gestation, respectively. Data are grouped according to first occurrence of late decelerations. Note interfetal differences.

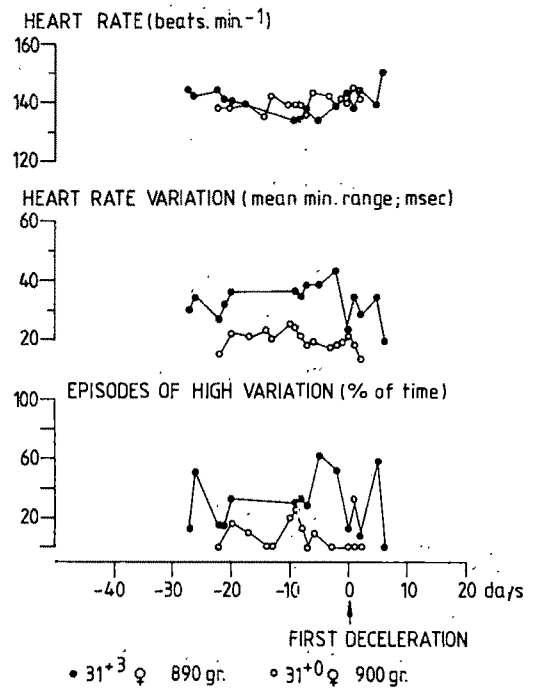

Fig. 5. Basal fetal heart rate, heart rate variation, and occurrence of episodes of high variation in two fetuses with similar birth weights who were delivered at 31 weeks' gestation. Data are grouped according to first occurrence of late decelerations.

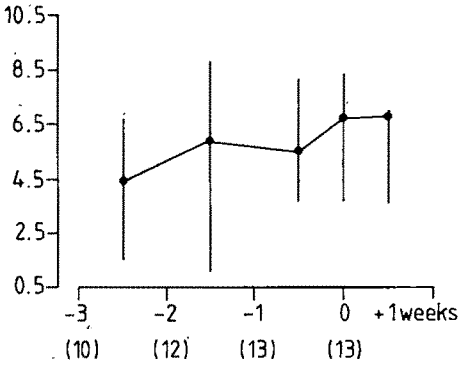

Fig. 6. Changes with time in pulsatility index of umbilical artery in 13 growth-retarded fetuses. Pulsatility index decreases with gestation; therefore data are expressed as number of standard deviations by which measured values differed from appropriate normal mean for gestation. Data are grouped according to first occurrence of late decelerations and are presented as medians and interquartile ranges. Numbers in parentheses are number of fetuses included.

In the rhesus monkey it has been found that with progressive deterioration of the fetal condition, late heart rate decelerations first appeared.[11] This condition was associated with hypoxemia. Heart rate variation (accelerations) decreased later, when the arterial pH also fell. In the human fetus decreased FHR variation occurs (on average) when decelerations appear. Decelerations are, however, dependent on the amount of uterine activity (frequency, duration, and intensity of Braxton Hicks contractions), and with recordings of longer duration or with induced contractions a different time relationship may be found. In this respect it should be noted that in our study decelerations were only present in about 40% of records made after the occurrence of the first deceleration.

It is likely that the initial reduction in FHR variation is mediated by fetal hypoxemia and that evident acidemia is absent until terminal FHR patterns develop. Evidence for this assumption has been provided by reports on associations between decreased FHR variation or development of antepartum FHR decelerations and fetal hypoxemia diagnosed at cordocentesis or at elective cesarean section.[2-4, 12] In addition, maternal hyperoxygenation in pregnancies complicated by IUGR has demonstrated that improved fetal oxygenation results in an increase of FHR variation,[13] whereas variation is temporarily decreased directly after "hypoxemic" events (late decelerations).[14] In fetal acidemia more severe reductions in FHR variation have been described, with simultaneous (shallow) decelerations following each Braxton Hicks contraction (terminal FHR pattern).[4-6]

In this study the interval between the last computerized FHR record and cesarean section varied considerably (1 to 48 hours). The correlation coefficient between FHR variation of the last records and umbilical arterial Po_2 at cesarean section was, however, in the same range ($r = 0.56$, $n = 9$; not significant; see Table I) as described by others ($r = 0.52$ and $r = 0.66$, respectively).[3, 12] In our study and in that of Smith et al.[3] FHR variation was not significantly correlated with pH at cesarean section. In a series including severely compromised fetuses, a significant correlation between mean 1-minute range and pH at cordocentesis has been described ($r = 0.69$).[12]

Although the evolution of the FHR patterns was similar in most fetuses, in some cases decelerations were preceded by reduced FHR variation for up to 5 weeks; in others the variation remained within the normal range even in the presence of decelerations. Differences in the trends in FHR changes could not be explained by differences in head/abdomen circumference ratios, birth weight, or abnormalities in Doppler velocity waveforms. However, they might reflect variations in adaptation to chronic compromise. Further evidence for adaptation to an adverse intrauterine environment can be derived from the finding that the development of decelerations coincided with a small but significant increase in basal FHR, a finding also reported in a previous cross-sectional study.[2]

However, perhaps prolonged low FHR variation in the absence of decelerations should be interpreted as

evidence for an inherently low FHR variation.[15] In normal fetuses there are large interindividual differences in FHR variation; within the same individual variation remains within a much narrower range.[15, 16] The data of this study indicate that this premise also applies to fetuses with IUGR (Figs. 4 and 5). In spite of interindividual differences, most fetuses had a progressive decline in FHR variation. Thus, in the surveillance of the fetus with IUGR, it is better to use each fetus as its own control.[17] This is facilitated by an objective numeric analysis of FHR variation.

In fetuses with IUGR, changes in umbilical artery waveforms usually precede FHR decelerations. In studies in which the latter were taken as an end point, abnormal waveforms had been present for at least 9 days[18] or had been present 17 days on average.[19] A study from our institute showed that the duration of this interval differs considerably (0 to 60 days) and that FHR decelerations occasionally occur when Doppler recordings are still normal.[19] In the present study there were two cases with normal waveforms at the occurrence of decelerations and one with a normal pattern still present just before delivery. To a large extent the considerable differences in time interval between first abnormal waveform and occurrence of FHR abnormalities can be explained by differences in gestational age. In early pregnancy this interval appears to be much longer than it is at late gestation.[19] The variable interval between the first abnormal Doppler recording and abnormality in the FHR indicates, however, that Doppler recordings of the umbilical artery are of limited value with respect to the timing of delivery and that a normal umbilical artery pusatility index cannot be considered a definite proof of fetal well-being.

In summary, with progressive deterioration of the condition of the fetus with IUGR, there is a gradual fall in heart rate variation. Both antepartum decelerations and/or reduceed FHR variation are associated with fetal hypoxemia and/or acidemia. The main additional values of numeric analysis of FHR variation are the identification of those fetuses, in whom reduced variation proceeds the development of decelerations and the provision of objective and longitudinal data on progressive deterioration in fetuses with apparently normal FHR variation or in fetuses with abnormal patterns in whom further maturation in utero is considered.

Eosinophilic cystitis during pregnancy

Robert O. Chamberlin, MD
St. Petersburg, Florida

The first report of a case of eosinophilic cystitis during pregnancy is presented. Premature cervical dilatation was associated with onset of the disease at 19 weeks' gestation. (AM J OBSTET GYNECOL 1992;166:28-9.)

Key words: Eosinophilic cystitis

A case of eosinophilic cystitis during pregnancy is described.

Case report

A 31-year-old, gravida 3, para 2 woman had midline pelvic cramps associated with intermittent loss of a small amount of clear fluid at 19 weeks' gestation. Speculum examination, Nitrazine test, and fern test results were negative. She ambulated with Nitrazine paper on a perineal pad until an episode of cramping occurred that yielded a positive test result. Ultrasonographic examination revealed a normal amount of amniotic fluid, and amniocentesis with instillation of indigo carmine dye ruled out ruptured membranes. However, funneling of the membranes was noted, and digital examination revealed cervical dilatation of 1.5 cm with prolapsed membranes into the endocervical canal. Uterine monitoring did not reveal activity. Urinalysis revealed 5 to 10 red blood cells per high-power field, and a complete blood cell count was normal without eosinophilia.

Her medical history included bronchial asthma, genital herpes, and recurrent urinary tract infections for which she underwent cystoscopic examination with normal findings at age 21 years. Obstetric history was unremarkable except for postpartum *Campylobacter* enteritis after her first delivery. During the index pregnancy she received albuterol inhaler treatments beginning at 7 weeks, miconazole vaginal cream at 11 weeks, and prenatal vitamin supplementation. Genetic amniocentesis performed because of a low maternal serum α-fetoprotein level, revealed a normal 46,XX karyotype.

After preparation of the vulva and vagina with povidone-iodine solution, a McDonald cerclage was placed. Saline solution was instilled into the bladder to assist in reduction of the prolapsed membranes. She received prophylactic tocolysis in the form of terbutaline 2.5 mg orally every 6 hours for 48 hours. She had postoperative urinary spasms with involuntary voiding around the urinary catheter. This did not improve with catheter change, and repeat urinalysis results revealed innumerable red blood cells and a few bacteria. Ampicillin 2 gm was given intravenously every 6 hours for presumed severe cystitis; subsequently 1 gm cefoperazone every 12 hours was added. Because her symptoms did not improve, she had a cystoscopic examination with biopsy revealing marked edema, vascular congestion, lymphangiectasia, and perivascular eosinophilic infiltration consistent with eosinophilic cystitis (Fig. 1). Urine cultures for bacteria, *Chlamydia*, herpes simplex, and tuberculosis were negative. Some improvement was obtained with diphenhydramine 50 mg orally every 8 hours and phenazopyridine 200 mg every 12 hours. She declined a trial of steroids. Her symptoms markedly improved by 23 weeks' gestation but recurred between 24 and 34 weeks. Fern testing was done at each visit and with slides mailed in by the patient three times a week. At 31 weeks, persistent diarrhea developed, sigmoidoscopic examination was normal, and the diarrhea gradually resolved with a lactose-reduced diet. Because of the unknown fetal effects of eosinophilic cystitis, antepartum surveillance in the form of weekly nonstress tests and serial ultrasonography was done. At 36 weeks, external cephalic version was performed for breech presentation. At 39 weeks, ultrasonographic examination showed the fetal weight (3651 gm) to be consistent with a large-for-gestational-age fetus with the Lubchenko curve.[1] The patient had a favorable Bishop score of 7; labor was induced, and the patient was delivered of an 8 pound 4 ounce (3737 gm), large-for-gestational-age female infant with Apgar scores of 8 at 1 and 9 at 5 minutes. Umbilical artery pH was 7.42. Placental weight was 680 gm; there was no evidence of eosinophilic inflammation. The postpartum course was normal; urinalysis results were normal >5 months since delivery.

Comment

In 1988 Castillo et al.[2] reviewed the literature, which contained 42 cases of eosinophilic cystitis since the initial report in 1960.[2] None of the cases involved pregnancy. Although parasites were proved to be the cause in some cases, allergy is the most commonly incrimi-

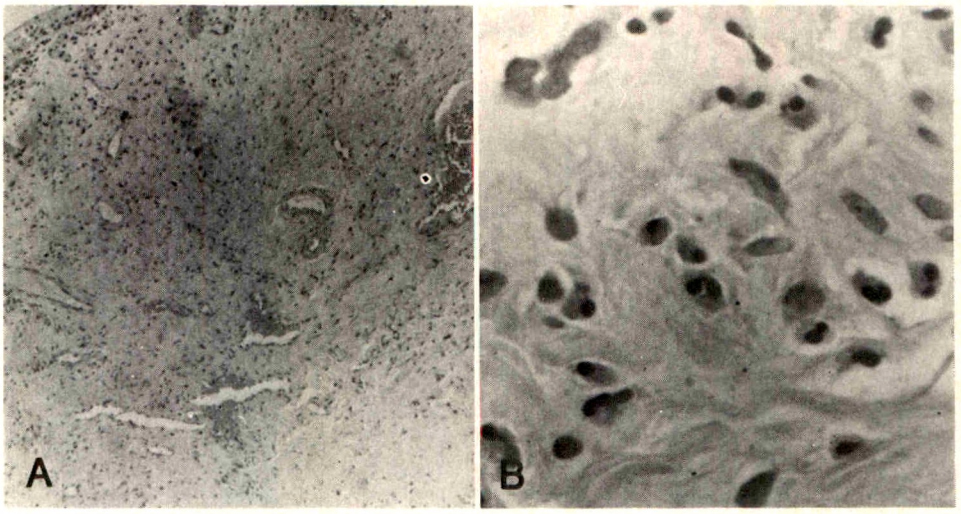

Fig. 1. Low **(A)**– and high **(B)**–magnification photomicrographs of bladder mucosa reveal marked edema, vascular congestion, lymphangiectasia, and perivascular eosinophilic infiltrate consistent with eosinophilic cystitis. (**A,** ×4. **B,** ×40.)

nated factor. The spectrum of disease ranges from mild cystitis to a chronic, relentless cystitis with upper tract damage. Severe blood loss has also occurred. The most common finding is a small-capacity bladder. Urine cultures are sterile in 70%. Treatment regimens include antihistamines, intravesical dimethylsulfoxide, and steroids. Cystectomy and urinary diversion have been required in severe cases. This case of eosinophilic cystitis in pregnancy presented similar to premature rupture of membranes and preterm labor. However, amniocentesis and uterine monitoring ruled out these conditions. The positive Nitrazine test was likely the result of hematuria; the abdominal cramps were believed to originate from the urinary bladder. It is possible that the povidone-iodine vaginal preparation may have entered the bladder through catheterization and served as a potential allergen. Instillation of the saline solution into the bladder may have also aggravated the condition. However, the onset of the symptoms clearly antedated these procedures. Although cervical cerclage was required, further reports will be necessary to determine whether incompetent cervix is a frequent association with eosinophilic cystitis in pregnancy.

Upper vaginectomy for in situ and occult, superficially invasive carcinoma of the vagina

Mitchel S. Hoffman, MD, Steven L. DeCesare, MD, William S. Roberts, MD, James V. Fiorica, MD, Michael A. Finan, MD, and Denis Cavanagh, MD

Tampa, Florida

Between Aug. 1, 1985, and July 31, 1990, 32 patients underwent upper vaginectomy for grade 3 vaginal intraepithelial neoplasia. Thirty-one of these patients had undergone hysterectomy, 25 because of cervical neoplasia. Fourteen patients had undergone treatment for vaginal intraepithelial neoplasia. Nine (28%) had invasive cancer on final pathologic examination. Among the remaining 23 patients, recurrence of vaginal neoplasia developed in four (17%), with a mean time to recurrence of 78 weeks, and one was found to have superficial invasion at the time of recurrence. The remaining 19 patients remain alive with no evidence of recurrent disease at a mean follow-up interval of 152 weeks. In our patients upper vaginectomy was efficacious for the diagnosis of occult invasive carcinoma of the vagina and for the treatment of in situ and superficially invasive carcinoma of the vagina. (AM J OBSTET GYNECOL 1992;166:30-3.)

Key words: Upper vaginectomy, vaginal intraepithelial neoplasia

Vaginal intraepithelial neoplasia accounts for approximately 0.4% of lower genital tract intraepithelial neoplasia.[1] Identifiable risk factors for this condition include cervical intraepithelial neoplasia, human papillomavirus infection, immunosuppression, and possibly previous pelvic radiotherapy.[2-5] The invasive potential of vaginal intraepithelial neoplasia appears to be similar to that of cervical intraepithelial neoplasia.[2, 6] The process most commonly occurs in the upper third of the vagina and frequently is multifocal.[3-11] Vaginal intraepithelial neoplasia is usually diagnosed during an investigation of an abnormal Papanicolaou smear; it is not grossly visible and does not usually produce symptoms. The diagnosis is usually established at colposcopy with directed biopsy. A wide variety of treatments have been used, most commonly consisting of local excision, partial or total vaginectomy, radiotherapy, laser vaporization or topical 5-fluorouracil administration.[12] Each of these treatment methods has advantages and disadvantages, and none has proved superior efficacy over the others. This is a report of our experience with the use of upper vaginectomy for grade 3 vaginal intraepithelial neoplasia.

Material and methods

The charts of all patients with grade 3 vaginal intraepithelial neoplasia managed by our division between Aug. 1, 1985, and July 31, 1990, were reviewed retrospectively. A total of 45 patients were identified. Of these, 32 were treated either primarily or secondarily with upper vaginectomy. It was not possible to define accurately how patients were selected for upper vaginectomy over other forms of treatment. In general, upper vaginectomy was performed for grade 3 vaginal intraepithelial neoplasia when the lesion was confined to the upper one third to upper one half of the vagina, especially when invasive cancer was suspected or could not be adequately ruled out by colposcopically directed biopsy. All upper vaginectomies were performed by an obstetrics and gynecology resident or fellow under the direct supervision of one of the gynecologic oncology attending physicians. All procedures were performed in the operating room with the patient under general or regional anesthesia. An attempt was made to include a 1 cm margin of surrounding normal-appearing mucosa. Patients were generally admitted on the day of surgery and kept overnight in the hospital with a vaginal pack in place. Patients were examined at 2 weeks, 8 weeks, and then every 2 to 3 months after surgery for the first 2 years and then every 6 months thereafter, unless there was recurrence of the disease. Five of the patients included in this study were also the subject of a prior report.[13]

Results

The mean age of the 32 study patients was 64 years, with a range of 36 to 85 years. Thirty-one (97%) pa-

tients had undergone hysterectomy. Twenty-five of these were for squamous cervical neoplasia, four were for benign disease, and two were for unknown reasons. Five patients had undergone pelvic radiotherapy for malignancy. Fourteen patients (44%) had undergone therapy for vaginal intraepithelial neoplasia or vaginal human papillomavirus infection. These treatments included one or two laser vaporizations in eight patients, upper vaginectomy in one patient, 5-fluorouracil administration in two patients, and multiple types of treatment in three patients.

The vaginal intraepithelial neoplasia was located in the apex or upper one third of the vagina in 23 patients, it was multifocal in the upper one half of the vagina in five patients, and it was in a vaginal pocket or inclusion cyst in four patients. The area of the vagina encompassed by the lesions ranged from 1 × 1 to 3 × 5 cm. The mean operative time was 60.5 minutes with a range of 20 to 105 minutes. The mean estimated blood loss was 187 ml with a range of 50 to 1150 ml. The patient who lost 1150 ml had hypersplenism-related thrombocytopenia, and focal, superficially invasive cancer was found on the final pathology specimen. Including this patient, three patients had an intraoperative estimated blood loss of ≥500 ml. Other intraoperative complications included premature ventricular contractions in one patient, which were successfully treated with intravenous lidocaine, and a cystotomy in another patient, which was immediately repaired and healed uneventfully. In one patient severe bleeding estimated to be 1000 ml developed approximately 3 weeks postoperatively. This was successfully managed with vaginal packing containing ferric subsulfate solution. Febrile morbidity developed in one patient and was believed to be related to operative site cellulitis, which responded well to intravenous antibiotics. There were no other postoperative complications.

Of the 32 patients, nine had invasive squamous cell carcinoma in the upper vaginectomy specimen. In all of these patients the lesion was at the vaginal apex in the region of the vaginal cuff scar. Four had undergone hysterectomy for grade 3 cervical intraepithelial neoplasia. Three had undergone radical hysterectomy for invasive squamous cell carcinoma of the cervix, and two had undergone radiotherapy (one with hysterectomy).

Four of the nine were frankly invasive (from 3.5 mm to full-thickness involvement) and were treated subsequently with radiotherapy. One of these four subsequently died of carcinoma 23 months later. The remaining three patients remained alive with no evidence of recurrent disease at 37, 42, and 46 months after radiotherapy.

The other five patients had invasion measuring <2 mm in depth. In one of these patients who was severely immunocompromised, several foci of recurrent, superficially invasive (<2 mm) squamous cell carcinoma developed in the vagina 31 months after upper vaginectomy; she was treated with radiotherapy, which was completed 2 months before completion of this study. The other four with superficially invasive carcinoma of the vagina have received no further treatment and remain alive with no evidence of recurrent disease at 4, 31, 44, and 54 months after upper vaginectomy.

The 23 remaining patients all had grade 3 vaginal intraepithelial neoplasia on the final pathologic examination of the upper vaginectomy specimen. Margins were clear on all but one patient. She received no further treatment and remains without evidence of recurrence at 6 months. Of the 23 patients, 19 (83%) remain without evidence of recurrence at a mean follow-up of 38 months, with a range of 6 to 73 months. In four patients recurrence of vaginal neoplasia developed, with a mean time to recurrence of 19 months and a range of 3 to 32 months. Recurrence developed in one of these patients 64 weeks after upper vaginectomy, and superficially invasive cancer <1 mm was found on pathologic examination of a repeat upper vaginectomy specimen. She remains without evidence of recurrence 7 months later. Recurrence was managed by repeat upper vaginectomy in two of the other patients and simple excision in the office in the fourth patient. Follow-up information regarding anatomy and sexual function was inadequate for reporting. However, of the 15 patients treated with upper vaginectomy only and with no history of radiotherapy, five had a vagina obviously adequate for intercourse and five had an obviously shortened vagina. Such information was not recorded for the other five patients.

Comment

A wide variety of methods have been used to treat vaginal intraepithelial neoplasia, including partial to total vaginal excision, radiotherapy, laser vaporization, and topical 5-fluorouracil.[2, 7, 9, 12-24] In general, good results have been obtained with these methods, although the results have been more variable with laser vaporization.[12, 14-17, 19-24] Laser vaporization for vaginal intraepithelial neoplasia has been variously reported to have a 50% to 100% success rate. Some of these studies included patients who had undergone two laser vaporizations. Partial or total vaginectomy has been considered by many to be the treatment of choice, mainly because it excises the abnormal tissue and provides a specimen for complete histologic review.[13, 18, 19, 25, 26] One of the main detractions of partial vaginectomy is shortening or stenosis of the vagina. Preventive measures include not closing the mucosa and using a dilator with estrogen vaginal cream in the early postoperative period. Covering the excised area with a skin graft is another useful alternative.[2] Several advantages of

laser vaporization and 5-fluorouracil have been cited, including reduced operative morbidity, less operative time, and improved subsequent sexual function.[14-18, 20-23, 26] Laser vaporization or 5-fluorouracil may also be preferable in previously irradiated patients because of the excessive morbidity associated with vaginectomy in these women.

Before treatment with laser vaporization is considered, an accurate appraisal of the extent and severity of the disease must be made. This is facilitated by using colposcopy, Lugol's iodine, palpation, and multiple biopsies. Laser vaporization should not be performed unless the full extent of the abnormal vaginal epithelium can be visualized, there is no suspicion of an invasive process, and there is no gross scarring or distortion of the posthysterectomy vaginal cuff. The last point has been made by several authors, including a prior study from this institution in which some of the patients from the current study are included.[13-21] The results of the current study underlines the problem of occult invasive vaginal carcinoma discovered in the patient diagnosed as having grade 3 vaginal intraepithelial neoplasia. Nine of our 32 patients (28%) had invasive carcinoma on the upper vaginectomy specimen. Any treatment other than excision of this area with histologic evaluation would have led to inappropriate treatment. In all nine of these patients the lesion was at the vaginal apex in the region of the vaginal cuff scar. Vaginal intraepithelial neoplasia in the upper vagina of women who have undergone hysterectomy probably should be excised along with the vaginal cuff scar. This seems especially important for patients whose hysterectomies were performed because of cervical cancer or intraepithelial neoplasia, whose vaginal cuffs are prominent or distorted, or who have treatment failure with laser vaporization or topical 5-fluorouracil. All such patients should undergo a careful bimanual rectovaginal examination to detect the presence of obvious induration or nodularity of the vaginal cuff.

None of the patients in the present study had a preoperative diagnosis of invasive cancer. The standard treatment for invasive carcinoma of the vagina is radiotherapy.[27] On review of the upper vaginectomy specimens of five of the patients, superficial invasion <2 mm was found and was believed to be well cleared. It was thought that these patients received adequate treatment and radiotherapy was not administered. As noted in Results, one of the patients did have recurrent superficially invasive disease in the vagina and was treated with radiotherapy. Other small studies have supported the use of partial or total vaginectomy for the treatment of superficially invasive (<2.5 mm) squamous cell carcinoma of the vagina.[28, 29]

On the basis of the results of this study, we believe that upper vaginectomy is the treatment of choice for grade 3 vaginal intraepithelial neoplasia diagnosed at the vaginal apex in the region of a vaginal cuff scar. Whether upper vaginectomy is efficacious therapy for superficially invasive carcinoma of the vagina will require further study. In the presence of multifocal or extensive grade 3 vaginal intraepithelial neoplasia involving large areas of vaginal mucosa, laser vaporization of the disease away from the vaginal apex could easily be combined with an excision of the vaginal apex and cuff scar area.

Transient symptomatic subendocardial ischemia during intravenous magnesium sulfate tocolytic therapy

David M. Sherer, MD, Paul R. Cialone, MD, Jacques S. Abramowicz, MD, and James R. Woods, Jr., MD

Rochester, New York

Although β-sympathomimetic tocolytic therapy has been associated with transient subendocardial ischemia, magnesium sulfate has rarely been noted to cause acute chest pain and is, in fact, known to improve myocardial perfusion in patients with variant angina. We believe this report represents the first case in which intravenous magnesium sulfate administered as a tocolytic agent caused acute chest pain accompanied by transient electrocardiographic evidence of subendocardial ischemia. (Am J Obstet Gynecol 1992;166:33-5.)

Key words: Preterm labor, magnesium sulfate, myocardial ischemia

Magnesium sulfate is a successful, inexpensive, and relatively nontoxic tocolytic agent with few side effects. The exact mechanism of its tocolytic activity is unclear. The incidence of acute chest pain in association with this therapy is low and has been reported at 1.1%. We report the first documentation of acute chest pain accompanied by electrocardiographic signs of transient subendocardial ischemia occurring in conjunction with this regimen.

Case report

A 29-year-old Oriental woman, gravida 1, para 0, was admitted to labor and delivery at Strong Memorial Hospital because of preterm labor at 35 weeks 1 day of gestation. Her medical history was unremarkable, and her pregnancy was uneventful until she was seen on this occasion. Physical examination 4 hours before her referral disclosed the uterine cervix to be 90% effaced and dilated to 1 cm. On admission, she was noted to be in good general health. Blood pressure was 110/65 mm Hg. The cervix was 90% effaced and dilated to 2 to 3 cm with the vertex presenting at S − 3 station. Although she initially responded to intravenous hydration, the uterine contractions recurred, and intravenous magnesium sulfate was administered at a rate of 3 gm/hr after a loading dose of 4 gm. Ten hours after this treatment was initiated, the patient began complaining of nonradiating substernal chest pain. No respiratory distress was noted, and blood pressure was

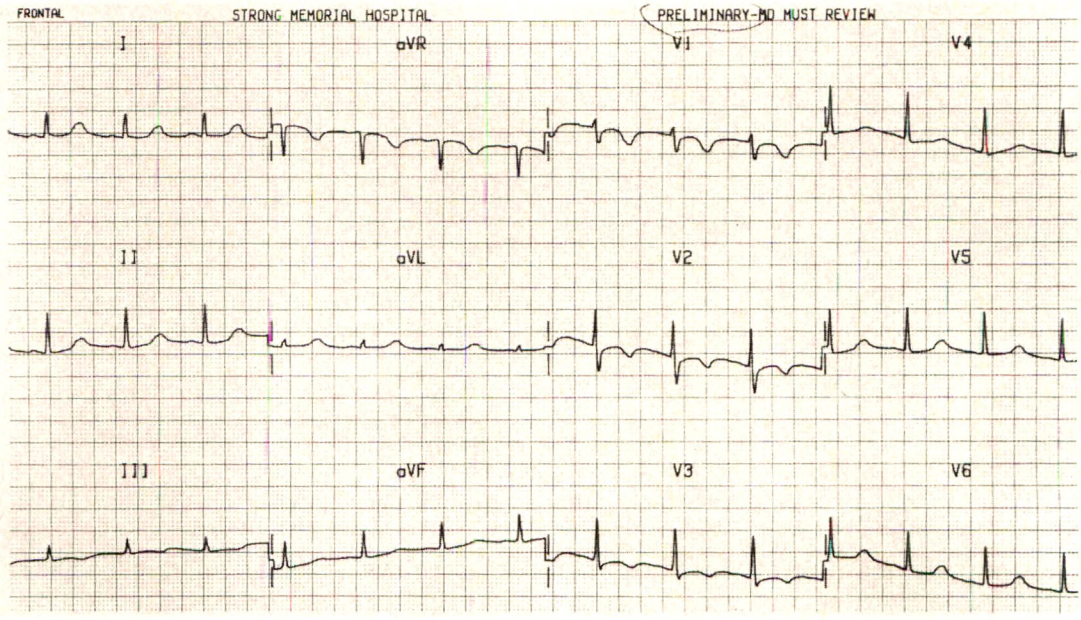

Fig. 1. Electrocardiogram during acute chest pain. Note inverted T waves in leads L_3 and V_1 through V_3 (speed 25 cm/sec, voltage 1 cm = 1 mV).

80/50 mm Hg with a heart rate of 100 beats/min. Electrocardiographic examination revealed a normal sinus rhythm at 84 beats/min with inverted T waves in L_3 and V_1 through V_3 leads (Fig. 1). Chest roentgenogram was normal. Laboratory evaluation revealed hemoglobin 12.2 gm, hematocrit 36%, sodium 135 mEq/L, potassium 3.9 mEq/L, glucose 93 mg/dl, creatine kinase 114 mU/ml (normal 0 to 122), MB (myocardial component) isozyme fraction 5% (normal). Serum magnesium level was 6.3 mEq/L. The intravenous magnesium sulfate was decreased to a rate of 2 gm/hr with resolution of chest pain, although a repeat electrocardiogram continued to demonstrate the inverted T waves. After 30 hours magnesium sulfate was gradually tapered successfully and discontinued with resolution of the electrocardiographic changes. The patient was discharged on day 3 after a normal echocardiogram. At 41 weeks 3 days' gestation, because of an arrest of the second stage of labor, a vacuum extraction was performed, with the delivery of a male infant weighing 3240 gm with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively.

Comment

β-Sympathomimetic therapy for preterm labor has been associated with symptomatic and asymptomatic myocardial ischemia that appears to be localized in the subendocardial region. Subendocardial oxygen supply may be compromised during β-sympathomimetic administration. This is thought to be a result of induced tachycardia resulting in a shortened diastole, i.e., the time of myocardial perfusion, and the placenta's effect on peripheral vascular resistance with diminished aortic diastolic blood pressure. In many centers magnesium sulfate has replaced β-sympathomimetic therapy as the first-line drug for tocolysis of preterm labor. To date, there have been no reported cases of myocardial ischemia during magnesium sulfate administration, when it was used for this purpose.

Intravenous magnesium sulfate is known to have antiarrhythmic effects and has, in fact, been used as a possible protective agent in patients with acute myocardial infarction, reducing conduction disturbances and in-hospital mortality in these patients. Furthermore, intravenous magnesium sulfate suppresses exercise-induced angina.[1] The size of the myocardial perfusion defect as measured by thallium 201 scintigraphy was significantly less in 13 patients with variant angina receiving magnesium sulfate than in 11 control patients receiving placebo.[1] The beneficial effect of magnesium in patients with variant angina is thought most likely to represent improvement of regional myocardial blood flow by suppression of coronary artery spasm. It is therefore of significance that acute chest pain with transient myocardial ischemia and associated electrocardiographic changes occurred during administration of this drug for tocolysis of preterm labor.

This event may have resulted from hypotension as a secondary effect of intravenous magnesium sulfate, compounded by a physiologic reduction in diastolic blood pressure normally occurring in pregnancy, which led to a transient but substantial decrease in subendocardial perfusion. Dandavino et al.[2] have previously shown that bolus administration of magnesium sulfate to control levels occurred within 5 minutes of bolus injection and no change in blood pressure occurred

during subsequent infusion of magnesium sulfate at 2 or 4 gm/hr. In our case symptoms and associated electrocardiographic changes were noted 10 hours into treatment. The mechanism of this drug-related sequela remains to be deciphered. Nevertheless, because of the widespread use of magnesium sulfate in pregnancy, this case is reported to bring attention to this seemingly rare drug event.

Possible transplacental transmission of human papillomaviruses

Chih-Jen Tseng, MD,[a] Chieh-Yu Lin, BS,[b] Ruey-Ling Wang, BS,[b] Li-Ju Chen, BS,[a] Ya-Li Chang, MS,[b] T'sang-T'ang Hsieh, MD,[a] and Chia C. Pao, PhD[b]

Taipei, Taiwan, Republic of China

OBJECTIVE: The objective of this study was to examine the possibility of intrauterine human papillomavirus infection of fetuses by transplacental transmission of human papillomavirus before delivery.
STUDY DESIGN: Specimens of cervicovaginal cells and peripheral blood mononuclear cells were obtained from 52 consecutive pregnant women in the third trimester of pregnancy. Cord blood specimens were also obtained from the neonates born to these mothers. Presence of human papillomavirus types 16 and 18 deoxyribonucleic acid was analyzed by an in vitro enzymatic deoxyribonucleic acid amplification method.
RESULTS: Human papillomavirus type 16 deoxyribonucleic acid was found in 6 (11.5%) cervicovaginal and in 9 (17.3%) peripheral blood mononuclear cell specimens. Seven cord blood specimens from neonates born to mothers who were positive for peripheral blood mononuclear cell human papillomavirus type 16 deoxyribonucleic acid were found to contain human papillomavirus type 16 deoxyribonucleic acid. One cervicovaginal and two peripheral blood mononuclear cell specimens contained human papillomavirus type 18 deoxyribonucleic acid, but none of the cord blood specimens contained human papillomavirus type 18 deoxyribonucleic acid.
CONCLUSION: These results seem to suggest possible transplacental transmission of the virus and the potential association of such transmission with the status of human papillomavirus in peripheral blood mononuclear cells. (Am J Obstet Gynecol 1992;166:35-40.)

Key words: Human papillomavirus, transplacental transmission, polymerase chain reaction (PCR), peripheral blood mononuclear cells

Depending on the detection method used and the type of tissue examined, between 10% and 60% of clinically and histologically normal cervical specimens from a general population were found to contain human papillomavirus (HPV) deoxyribonucleic acid (DNA).[1-5] Although most of these infections are asymptomatic and subclinical in nature and the clinical and biologic significance of these findings is not clear, the prevalence of HPV even among the general population is probably quite high. Management of pregnant patients with HPV infections takes on additional importance because of the possibility of maternal-fetal transmission. The issue of possible maternal-fetal HPV transmission is a pressing concern for pregnant patients because several reports have suggested that the incidence of genital HPV infection is higher in pregnant women than in nonpregnant women.[6-9] Given that the behavior of urogenital human papillomavirus infections during pregnancy is not clear and that the exact mode and risk of the maternal-fetal HPV transmission in clinically

asymptomatic patients are almost completely unknown, it is tempting to speculate that inoculations may occur during passage of the fetus through the birth canal. On the other hand, reports of juvenile laryngeal papillomatosis,[10] congenital condyloma acuminatum,[11] and the presence of HPV DNA in the foreskin,[12] oral cavity, and amniotic fluid[13] of clinically normal neonates delivered by cesarean section suggest the likelihood of intrauterine HPV infection by transplacental transmission before delivery.

We report, in the following text, the results of using an extremely sensitive and specific method of polymerase chain reaction to assess the presence of HPV type 16 and 18 DNA sequences in cord blood of neonates born to women with urogenital or peripheral blood mononuclear cell HPV infection.

Material and methods

Experimental protocol. Blood specimens were obtained from 52 consecutive pregnant women in the third trimester of pregnancy who were receiving routine antepartum care at Chang Gung Memorial Hospital in Taipei, Taiwan. Cervicovaginal cells were also collected from these women at the same time by cervical lavage with 2 to 4 ml of phosphate-buffered saline solution (20 mmol/L, pH 7.0) containing sucrose (200 mmol/L), streptomycin 50 μg/ml), vancomycin (100 μg/ml), and nystatin (25 U/ml). None of the patients had symptomatic or known urogenital HPV infections at the time of sampling. The average age of the patients was 28.5 years (median 28 years). Thirty-two and 14 of the women were pregnant for the first and second times, respectively, and the rest of them were pregnant for the third time or more. Informed consents were obtained from all participants to obtain blood from them and their infants.

Polymerase chain reaction amplification of HPV DNA. The procedures for the amplification and subsequent detection of HPV type 16 and 18 DNA in clinical specimens were those we have described earlier[14, 15] with the following modifications to incorporate an additional round of "nested" amplification. The nested polymerase chain reaction requires a second or inner set of primers that locate inside the initial or outer primers and uses the resulting products from the initial amplification as a template for amplification. The nested amplification both increases the overall sensitivity and enhances the specificity of polymerase chain reaction by minimizing false-positive results.[16, 17] For the nested amplification, 2 μl of the reaction mixture from the initial amplification reaction was amplified with same procedures in a freshly prepared 100 μl reaction mixture containing the same reaction components as the initial polymerase chain reaction and the new set of nested primers. The genomic region within the HPV E6 genes was chosen to amplify because this region of HPV genome is almost always retained in the HPV DNA integrated in cancer tissues.[18] The sequences of the antisense and sense strands of primers that flank the 445 base pair E6 gene of HPV type 16 DNA in the first round of amplification are CGTGTTCTTGATGATCTGC and GAACTGCAATGTTTCAGGACC (the 5′-end bases of these two primers are 540nt and 96nt, respectively on the HPV type 16 genome). The sequences of the corresponding nested primers that cover 422 base pairs of DNA on the HPV type 16 genome are GCAACAAGACATACATCGACCG (523nt) and CAATGTTTCAGGACCCACAGG (102nt). The first and nested sets of primers for HPV type 18 DNA amplification are CTCGTGACATAGAAGGTCAACCGG (676nt) and CACACCACAATACTATGGCGCGCT (91nt) and CAATGTTGCCTTAGGTCCATGC (613nt) and CTACAAGCTACCTGATCTGTGC (137nt), respectively. The sizes of the DNA flanking by the first and nested sets of primers used in this study for the HPV type 18 DNA are 586 and 477 base pairs, respectively. Additional primers complementary to HPV E7 and L1 genes are also used.

Establishment of HPV positivity. After the DNA amplification, one-tenth of the amplification reaction mixture was separated by electrophoresis in 2% agarose gel containing 0.5 μg/ml ethidium bromide and visually inspected under ultraviolet light for the presence of 422 and 477 base pair DNA bands to determine the HPV type 16 and 18 positivity, respectively. Authenticity of this amplified DNA was confirmed by restriction endonuclease analysis and by Southern blot DNA hybridization with an internal oligonucleotide probe.[15, 19] The sequences of oligonucleotide probes are AGCTGCAAACAACTATACATGATATAATATTAGAATGTGT (for type 16) and AACTGAACACTTCACTGCAAGACATAGAAATAACCTGTGT (for type 18). The oligonucleotide probes were labeled at their 5′-end with γ–phosphorus 32–adenosine triphosphate by polynucleotide kinase to approximately 5×10^6 cpm/pmol. Procedures for Southern blot hybridization have been described previously by others[19] and were modified for oligonucleotide probes as follows: After hybridization, the filters were washed sequentially in 2× SSC (1× SSC is 0.1 mol/L sodium chloride and 0.015 mol/L sodium citrate) and 0.1% sodium dodecyl sulfate twice for 10 minutes each at room temperature and then in 1× SSC and 0.1% sodium dodecyl sulfate three times for 20 minutes each at 55° C. Restriction endonucleases were purchased from either Boehringer Mannheim (Mannheim, Germany) or BRL (Gaithersburg, Md.) and used according to manufacturer's recommendations.

Precautions against polymerase chain reaction contamination and false-positive results. Because of the extraordinary power of the amplification procedures, precautions were taken to minimize or eliminate the possibility of contamination during both sampling and subsequent processing. These precautions included ex-

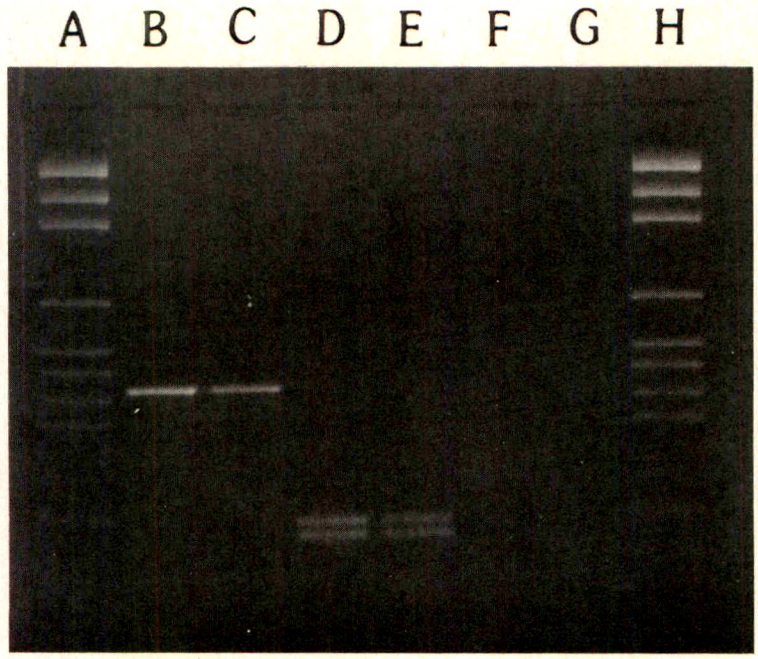

Fig. 1. Agarose gel electrophoresis of amplified HPV type 16 DNA. pGEM-3 DNA digested with a mixture of restriction endonucleases *Hin*fI, *Rsa* I, and *Sin* I was used as size standards in *lanes A* and *H*, and the sizes are (from top to bottom) 2645, 1605, 1198, 676, 517, 460, 396, 350, 222, 179, 126, 75, 65, 51, and 36 base pairs. *Lanes B* and *C* are amplifications of DNA prepared from cervicovaginal cells of a HPV type 16–infected patient and from CaSki cells, respectively. *Lanes D* and *E* are restriction endonuclease *Dra* I–digested amplified DNA in *lanes B* and *C*, respectively. *Lanes F* and *G* are respective amplifications of 50 ng of human DNA and 1 ng of bacterial *E. coli* DNA with HPV type 16 primers.

tensive cleaning of the skin area and umbilical cord before the venipuncture and the use of closed and sterile Vacutainer blood collecting tubes (Becton Dickinson, Rutherford, N.J.). Special measures were also taken to minimize sample-to-sample contamination and polymerase chain reaction product carryover to avoid false-positive results. These precautions include aliquoting of all reagents, physical separation of samples before and after polymerase chain reaction, and meticulous laboratory techniques. Furthermore, all reagents were irradiated with ultraviolet light to inactivate any contaminated double-stranded DNA[20] that may have been present before sample DNA was added and the polymerase chain reaction started. Fifth nanograms of human DNA or 1 ng of *Escherichia coli* DNA was used as a negative control, which always yielded negative results. Multiple reagent controls were also included in each polymerase chain reaction assay and gave negative results. Repeated DNA amplification assays of the same specimens at different times produced the same results. Human *Alu* repeated DNA sequences[21] were also amplified with each assay to ensure that enough sample DNA was used in the amplification reaction.

Results

The presence of HPV type 16 DNA in clinical specimens is indicated by the presence of the 422 base pair DNA after two rounds of amplification (Fig. 1, lanes B and C). The lower limit of detection of the amplification used in this study was estimated to be <0.001 pg of HPV type 16 or 18 DNA or approximately 100 HPV viral genomes equivalent. This number was calculated by amplifying serial dilutions of a purified cloned HPV DNA solution with known concentration (data not shown) and by the amplification of HPV type 16 DNA in CaSki cells, which has been suggested to contain about 500 copies of HPV type 16 per cell.[22] This sensitivity of detection is not adversely affected by the presence of as much as 50 ng of human DNA (equivalent to approximately 10,000 cells) or 1 ng of *Escherichia coli* DNA (equivalent to approximately 200,000 bacterial cells). DNA prepared from *Chlamydia trachomatis, Mycoplasma hominis*, Herpes simplex virus types I and II, cytomegalovirus, Epstein-Barr virus, and other types of HPV (including HPV types 1, 6, 8, 11, 18, 31, and 33) does not cross amplify with the HPV type 16 primers used in this study (data not shown).

The specificity of the primers and the authenticity of the amplified 422 base pair HPV type 16 DNA were confirmed by two independent methods. First, the amplified HPV type 16 DNA was treated with a restriction endonuclease with known restriction site on the amplified DNA according to known DNA sequences. When the 422 base pair DNA from amplifying DNA,

Fig. 2. Autoradiograph of Southern blot hybridization test of amplified HPV type 16 DNA with internal oligonucleotide probe. Arrangements of samples are same as in Fig 1. Probe sequence and hybridization procedures have been described in Material and methods. Top bands in *lanes D* and *E* were results of undigested residual 422 base pair DNA. Exposure time was 40 minutes at room temperature without intensifying screen.

Table I. Presence of HPV type 16 DNA in maternal cervicovaginal and peripheral blood mononuclear cells

Neonate's cord blood HPV type 16 DNA	*HPV type 16 DNA in maternal cervicovaginal cells/peripheral blood mononuclear cells*			
	Positive/positive	*Positive/negative*	*Negative/positive*	*Negative/negative*
Positive	1	0	6*	0
Negative	1	4	1	39

*One of the babies was HPV type 16 positive on follow-up when venous blood was assayed for HPV type 16 DNA 3 months after birth.

prepared from either cervicovaginal cells of an infected patient or CaSki cells (which contain HPV type 16 DNA), was treated with restriction endonuclease *Dra* I, the original 422 base pair DNA disappeared and was replaced with new DNA of 220 and 202 base pairs (Fig. 1, lanes D and E). Second, the Southern blot hybridization showed that both the 422 base pair DNA and the 202 base pair restriction endonuclease fragment resulted from *Dra* I digestion hybridized with the oligonucleotide probe (Fig. 2). The specificity of the amplification of HPV type 18 DNA was confirmed by similar procedures. The amplified 477 base pair HPV type 18 DNA could be converted by restriction endonuclease *Xba* I to two DNA fragments of 292 and 185 base pairs, which agreed exactly with the prediction from the known restriction site and HPV type 18 DNA sequences (data not shown). Amplification of HPV types 16 and 18 with primers complementary to E7 and L1 genes yielded the same results as those obtained with primers of E6 genes.

Tables I and II summarize the presence of HPV type 16 and 18 DNA in neonatal cord blood with respect to HPV DNA in maternal cervicovaginal cells and peripheral blood mononuclear cells. HPV type 16 DNA was found in 6 of 52 (11.5%) cervicovaginal cell specimens and in 9 of 52 (17.3%) peripheral blood mononuclear cell specimens from the same group of women. A total of 7 neonates, all born to mothers with peripheral blood mononuclear cell HPV DNA (6 mothers without and 1 mother with cervicovaginal cell HPV DNA), were found to have HPV type 16 DNA in the cord blood collected at birth. On the other hand, cord

47	−	−	−	+	−	−

Patients 4, 5, 7, 11, 13 to 20, 22 to 24, 27, 28, 30 to 36, 38 to 40, 42 to 46, and 48 to 52 all had negative results.

blood specimens from infants born to two other mothers with peripheral blood mononuclear cell HPV DNA were free of detectable HPV DNA. None of the 39 mothers without cervicovaginal cell and peripheral blood mononuclear cell HPV gave birth to infants who had HPV DNA in cord blood. Follow-up investigation was performed on two babies with cord blood HPV DNA. Venous blood specimens from one of them remained HPV DNA positive 3 months after birth (Table I).

HPV type 18 DNA was found in one cervicovaginal specimen and in two peripheral blood mononuclear cell specimens among the 52 pregnant women. However, none of the cord blood specimens of the neonates born to any of the 52 women was found to contain HPV type 18 DNA, unlike HPV type 16 DNA (Table II).

The presence of HPV DNA and the distribution of HPV types in the maternal cervicovaginal and peripheral blood mononuclear cells and cord blood of neonates born to the 52 pregnant women are summarized in Table III.

Comment

This study seems to have provided information on both the possible transplacental transmission of HPV and the potential association of such transmission with the status of HPV in peripheral blood mononuclear cells.

Although the behavior of HPV in patients with clinically asymptomatic urogenital HPV infections during pregnancy is unclear, our results supported the findings by others, which indicated an increased incidence of genital HPV infection during pregnancy.[6-9] The presence of HPV in both cord and venous blood of infants suggests that the HPV in these infants probably resulted from viral infection before birth through transplacental transmission instead of being acquired from the maternal vaginal secretions at the time of birth. This possibility is supported by the findings that the presence of HPV DNA in cord blood of neonates seems to be more closely related to the status of HPV DNA in maternal peripheral blood mononuclear cells than cervicovaginal cells. Examination of HPV DNA in trophoblastic and villous cells may be able to provide more information on this matter.[23]

We have reported earlier the findings of HPV DNA in peripheral blood mononuclear cells of patients with urogenital HPV infections.[15] We have speculated that HPV in peripheral blood mononuclear cells may serve as a potential source of infection of others or recurrent infection in the same patients and therefore represents route(s) of HPV transmission other than sexual or di-

rect contact.[15] More recently we have succeeded in immortalizing (with Epstein-Barr virus) HPV-infected B lymphocytes from patients, and preliminary results indicated that these B cells produce and secrete HPV virions into culture media (unpublished observations). These findings are consistent with the suggestion that HPV in peripheral blood mononuclear cells may be involved in the possible transplacental transmission of HPV, which may occur during intermittent low-level viremia released from these cells.

The possible association between HPV in peripheral blood mononuclear cells and HPV transmission clearly requires more extensive investigations. Hepatitis type B virus infection of extrahepatic sites, such as peripheral blood mononuclear cells, has been shown to be a major factor in infections of liver grafts.[24] Indeed, a direct transmission of the hepatitis type B virus genome from HBV-positive to HBV-negative peripheral blood mononuclear cells, even in the absence of a detectable hepatitis type B virus virion, has been described.[25]

We believe that the presence of HPV DNA sequences may not in itself indicate the presence of infectious virions, but the findings of HPV DNA in cord blood of neonates born to mothers with HPV in peripheral blood mononuclear cells nevertheless suggest a mechanism by which HPV can be transmitted. Given that HPV growth and host immunologic responses to HPV infection during pregnancy are unclear, longitudinal follow-up investigations on infants with HPV in cord blood is needed for understanding of both the transmission of HPV and any clinical significance it may carry.

We acknowledge the encouragement and support of Dr. Delon Wu and Dr. Chau-Hsiung Chang. We also acknowledge Dr. Huey-Shinn Cheng for some technical assistance.

DEMULEN® 1/35

(ethynodiol diacetate 1 mg, ethinyl estradiol 35 mcg)

Where protection begins

The physician should become familiar with the prescribing information (labeling) for this product, which discusses reported risks, such as thromboembolic disorders (including strokes and heart attacks), risk of estrogen dose, and hepatic lesions, as well as the need to monitor patients for early symptoms of any diseases or medical conditions, so use can be discontinued when appropriate.

Please see adjoining page for a brief summary of prescribing information.

The OC innovator **SEARLE**

DEMULEN® 1/35 Where protection begins

(ethynodiol diacetate 1 mg, ethinyl estradiol 35 mcg)

BRIEF SUMMARY

Demulen® 1/35: Each white tablet contains ethynodiol diacetate 1 mg and ethinyl estradiol 35 mcg. Each blue tablet in Demulen 1/35-28 is a placebo containing inert ingredients. **Demulen® 1/50:** Each white tablet contains ethynodiol diacetate 1 mg and ethinyl estradiol 50 mcg. Each pink tablet in Demulen 1/50-28 is a placebo containing inert ingredients.

Indication and usage: For prevention of pregnancy. Pregnancy rate for products with ≥35 mcg ethinyl estradiol or ≥50 mcg mestranol is ≤1/100 woman-years. With ≤35 mcg ethinyl estradiol, rate is slightly higher; with progestogen-only oral contraceptives (OCs), rate is about 3. Precise comparisons cannot be made. Rates for other methods have been published. *Dose-related Thromboembolic Risk:* Studies showed positive association between OC estrogen dose and thromboembolic risk. It is in keeping with good therapeutics to minimize estrogen exposure. Prescribe product containing least amount of estrogen compatible with acceptable pregnancy rate and patient acceptance. Start new users on ≤50 mcg estrogen.

Contraindications: Thrombophlebitis, thromboembolic disorders, past history of deep vein thrombophlebitis or thromboembolic disorders; cerebrovascular disease, myocardial infarction or coronary artery disease, or past history of these; known or suspected breast carcinoma, estrogen-dependent neoplasia, or pregnancy; undiagnosed abnormal genital bleeding; past or present, benign or malignant liver tumors developing during use of estrogenic products.

Warnings:

Cigarette-smoking increases risk of serious cardiovascular side effects from OC use. Risk increases with age and heavy smoking (15 or more cigarettes/day) and is quite marked in women over 35. OC users should be strongly advised not to smoke. OCs are associated with increased risk of several serious conditions including venous and arterial thromboembolism, thrombotic and hemorrhagic stroke, myocardial infarction, visual disorders, hepatic tumors, gallbladder disease, hypertension, fetal abnormalities. Practitioners should be familiar with the available information relating to these and other risks.

1. *Thromboembolic disorders and other vascular problems:* Increased risk of thromboembolic and thrombotic disease associated with OCs is well established. A British study showed increased risk for fatal venous thromboembolism (TE). British and U.S. studies showed increased risk for nonfatal disease. U.S. studies showed increased risk for stroke. OC users were 2-11 times more likely to manifest these diseases without evident cause. In a study of idiopathic deep vein thrombosis and pulmonary embolism (PE), projected hospitalization rates for ages 16-40 were 47/year/100,000 users and 5 for nonusers. Overall excess mortality from PE or stroke was 1.3-3.4 deaths/year/100,000 users and increased with age. *Cerebrovascular Disorders:* In a study of stroke with and without predispositions, risk of hemorrhagic stroke was 2 times greater and thrombotic stroke 4.0-9.5 times greater in users. Mortality trends in 21 countries indicate that changes in cardiovascular mortality were associated with changes in OC prevalence. The Royal College of GPs (RCGP) reported on its prospective study: "A statistically significant higher rate of reporting of cerebrovascular accidents in Takers is evident, but the numbers are too small to justify an estimation of the degree of risk." A 1981 analysis showed a 4-fold increased mortality in users from circulatory diseases, mainly myocardial infarction (MI) and hemorrhagic stroke. Excess mortality was associated with age and smoking. A 1983 analysis showed elevated cerebrovascular disease, increasing with use to 8 yrs, including cerebral thrombosis or embolism and TIA. Peripheral arterial disease and MI were increased. Women over 30 had more arterial disease, being greatest in smokers. Arterial case-fatality was 2-3 times greater for users who smoked. Family Planning Assoc. (FPA) found significant association between OC use and stroke; increased risk for venous thrombosis and PE was 4-fold and statistically significant. Mortality from nonrheumatic heart disease was greater in ever-users. In the Walnut Creek Study, subarachnoid hemorrhage risk was associated with smoking, age, and OC use. *Myocardial Infarction:* Increased risk of MI associated with OCs was reported in Britain, as previously suspected. The morbidity study found the greater the number of risk factors for coronary artery disease (smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk, regardless of OC use. OCs were an additional risk factor. Excess rate of fatal MI was 3.5/year/100,000 users aged 30-39 and 20 for ages 40-44. (These are based on British statistics with acute MI death rates 2-3 times less than the U.S. Similar estimates for the U.S. are 25.7 for users aged 30-39 with predispositions vs 1.5 without; for ages 40-44, 86.2 vs 5.1.) Excess hospitalization rate for nonfatal MI in Britain was 3.5/year/100,000 users aged 30-39 and 47 for ages 40-44. Smoking is a major predisposing condition to MI. In terms of relative risk, nonsmoking OC users are twice as likely to have fatal MI as nonsmoking nonusers. Smoking users have a 5-fold greater risk than nonsmoking users, but a 10-12-fold greater risk than nonsmoking nonusers. Amount of smoking is an important factor. In determining importance of these risks, give serious consideration to rates in table below. Importance of other predispositions cited above in determining relative and absolute risks has not been quantified; it is likely the same synergism exists, but perhaps to a lesser extent. U.S. studies similarly relate MI, OCs, smoking, and age.

Estimated Mortality Rate from Myocardial Infarction per 100,000 Women/Year

	Aged 30-39	*Users*	*Nonusers*	*Aged 40-44:*	*Users*	*Nonusers*
All smokers		10.2	2.6		62.0	15.9
≥15 cigarettes daily		13.0	5.1		78.7	31.3
<15 cigarettes daily		4.7	0.9		28.6	5.7
Nonsmokers		1.8	1.2		10.7	7.4
Smokers and nonsmokers		5.4	1.9		32.8	11.7

Risk of Dose: Reports of TE after use of OCs with ≥50 mcg estrogen received by drug safety committees in Britain, Sweden, and Denmark were compared with distribution expected from market research sales estimates. A positive correlation was found between estrogen dose and reporting of TE, including coronary thrombosis, in excess of that predicted by sales. OCs with ≥100 mcg estrogen were associated with higher TE risk than those with 50-80 mcg. Estrogen quantity may not be the sole factor; influence of progestogens was not considered, which may be responsible for certain discrepancies in the data. No significant differences were noted between OCs containing same estrogen dose nor between ethinyl estradiol and mestranol. In Britain certain TE conditions were associated with progestogen or estrogen dose. In Sweden reports of TE decreased when higher estrogen doses were no longer prescribed. Studies on TE risk with progestogen-only OCs have not been done. Cases have been reported for these; they are not presumed free of risk. In a U.S. case-controlled study, relative risk of OC use 1 month before hospitalization for various types of TE was calculated. If relative estrogenic potency and possible influence of different progestogens are ignored, OCs may be divided into those with <100 mcg and those with ≥100 mcg estrogen. For all cases combined, larger doses were associated with only slightly higher risk; for idiopathic cases risk was doubled with larger doses, but confidence limits overlapped and differences were not significant. Apparently there was less increased risk for cases with predispositions. In FPA study no nonhemorrhagic strokes occurred with <50 mcg estrogen, vs 13 with higher doses. Latter group also had more venous TE. TE risk in users and nonusers increases with age. OCs have been considered an independent risk factor. Decreased HDL, which relates to increased myocardial ischemia, occurs with high progestational activity. Consider amount of both steroids in choosing OC. *Persistence of Risk* after OC discontinuation was reported for circulatory disease, nonrheumatic heart disease, and cerebrovascular disease, including subarachnoid hemorrhage, cerebral thrombosis, and TIA. *Excess Mortality from Circulatory Diseases:* A U.K. prospective study estimated annual mortality from circulatory diseases for OC users and nonusers by age, smoking, and duration of use. Excess mortality was 23/100,000 users (2 and 10 for ages 25-34, 15 and 48 for ages 35-44, 41 and 179 for ages >44, for nonsmokers and smokers, respectively). Risk was significant only for smokers over 34. Most deaths were due to subarachnoid hemorrhage or ischemic heart disease. Risk for ever-users rose with parity. One study estimated risk of death with various contraceptive methods, each estimate including risk of method (eg, TE for OCs) plus risk due to pregnancy or abortion in cases of method failure. This latter risk varies with effectiveness. It concluded mortality with all methods is low and below that of childbirth, except for OC users over 40 who smoke. Heavy smokers have double the risk of smokers, light smokers about half. Mortality with OC use in nonsmokers over 40 is higher than with any other method in that age group. Lowest mortality is with condom or diaphragm backed up by early abortion. Risk of TE and thrombotic disease with OCs increases with age after 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia, and especially cigarette smoking. Based on current data, the chart gives gross estimates of risk of death from circulatory disorders associated with OCs:

Risk is: A—very high; B—high; C—moderate; D—low.	Age:	<30	30-39	≥40
Heavy smokers (≥15/day)		C	B	A
Light smokers (<15/day)		D	C	B
Nonsmokers, no predispositions		D	C,D	C
Nonsmokers, with predispositions		C	C,B	B,A

Be alert to earliest manifestations of TE disorders (eg, thrombophlebitis, PE, cerebrovascular insufficiency, coronary artery disease, MI, retinal thrombosis, mesenteric thrombosis). Should any be suspected, discontinue OCs immediately. A 4-7-fold increased risk of postsurgery TE was reported in users. If feasible discontinue OCs at least 4 weeks before surgery or in prolonged immobilization. Before resuming OCs, weigh risks of postsurgery TE complications against contraceptive needs. RCGP reported higher incidence of superficial and deep vein thrombosis in users, the former correlated with progestogen dose. Varicose veins have little effect on development of deep vein thrombosis. **2.** *Ocular lesions:* Neuro-ocular lesions such as optic neuritis or retinal thrombosis have been associated with OCs. Discontinue if there is unexplained, gradual or sudden, partial or complete loss of vision; proptosis or diplopia; papilledema or evidence of retinal vascular lesions. Institute diagnostic and therapeutic measures. **3.** *Carcinoma:* Long-term estrogen in certain animals increases carcinomas and/or nonmalignant neoplasms, such as those of breast, uterus, cervix, vagina, ovary, liver, pituitary. Some synthetic progestogens, none currently in OCs, increase incidence of benign and malignant mammary nodules in dogs. Estrogens increase risk of human endometrial carcinoma. In case-controlled studies, increased risk (2.2-13.9 times) associated endometrial carcinoma with prolonged estrogen for menopausal symptoms. Risk was independent of other known risk factors and depended on duration of use and dose. This is supported by increased endometrial cancer incidence since 1969 in areas with cancer-reporting systems, which may be related to expanding estrogen use. There is no evidence that natural estrogens are more or less hazardous than synthetics. Of the first 30 cases of endometrial carcinoma in OC users under 40, those without predispositions occurred nearly always with no-longer-marketed sequential OCs. No statistical association is reported suggesting increased endometri cancer with combination or progestogen-only OCs. Studies show no increased breast cancer with OCs or estrogens. Howeve greater risk was noted in OC users with benign breast disease or long-term (2-4 years) use. One study found greater risk breast cancer with >4 years OC use prior to first full-term pregnancy. Risk of breast cancer with menopausal estrogens ro and further increased with duration of follow-up. OCs or estrogen were related to breast cancer in connection with other ri factors and in various subgroups. Decrease in benign breast tumors in OC users is well known. Some studies suggest increased risk of cervical dysplasia, CIN, erosion, and carcinoma in long-term users. Cervical microglandular hyperplasia h been reported. In summary, there is no consistent evidence from human studies of increased cancer risk with OCs. Clos surveillance is, however, essential. In undiagnosed persistent or recurrent abnormal vaginal bleeding, consider nonfunction causes and take diagnostic measures to rule out malignancy. Carefully monitor users with strong family history of brea cancer or with breast nodules, fibrocystic disease, recurrent cystic mastitis, abnormal mammograms, or cervical dysplasi **4.** *Hepatic adenomas, etc.* have been associated with OCs. In 1 study OC formulations with high "hormonal potency" we associated with higher risk, as was age over 30. Though benign, these lesions may rupture and cause fatal hemoperitoneu in short- or long-term users. Two studies related risk to duration of use, being much greater after ≥4 years. Long-term C users have an estimated adenoma incidence of 3-4/year/100,000. Consider such lesions in users with abdominal pai tenderness, mass, or shock. About 25% present with abdominal masses, up to half with acute hemoperitoneum. Radiolog and lab studies may not be helpful; liver scans may show local defect. Hepatic arteriography or CAT may be usefu Hepatocellular carcinoma risk is increased 7-20 times in users for 8 or more years. Bile duct cancer may occur with OC us **5.** *Use in or immediately preceding pregnancy, birth defects, malignancy in offspring:* Estrogens or progestogens during ear pregnancy may seriously damage offspring. Females exposed in utero to DES and other nonsteroidal estrogens may ha increased risk of vaginal or cervical cancer. Though OCs may not enhance this risk, monitor such patients carefully. From 3 90% of DES-exposed women develop benign vaginal or cervical adenosis, which could be premalignant. DES-expose daughters have more unfavorable pregnancy outcomes. Males so exposed may develop urogenital and sperm defects. Oth estrogens may mimic DES. Reports relate fetal exposure to female sex hormones and congenital anomalies, eg, VACTERL f vertebral, anal, cardiac, tracheoesophageal, renal, and limb defects. There appears preferential expression by males. The was a 4.7-fold increased risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdraw pregnancy tests, or treatment for threatened abortion). Some exposures were very short, being only a few days. Cardiovascul defects in children exposed to female hormones, including OCs, during early pregnancy occurred in 18.2/1,000 birth compared to 7.8 for those unexposed (P<.05). Female hormone exposure in utero was associated with testicular and ovari cancer. More twinning was reported in conceptions shortly after OC discontinuance. Female sex hormones were used f threatened or habitual abortion, but there is considerable evidence estrogens are ineffective and no evidence progestoge are effective. Triploidy and possibly other polyploidy may be increased in abortuses from women becoming pregnant soo post-OC. These almost always abort spontaneously. It is unknown if spontaneous abortion is increased soon after stoppi OCs. Increased chromosome aberrations have been reported. Safety of OCs in pregnancy has not been demonstrated. Ru out pregnancy in using OCs and always consider it if withdrawal bleeding does not occur. If 2 consecutive periods are missi rule out pregnancy before continuing. If user deviates from regimen, consider pregnancy at first missed period and withho OCs. If pregnancy is confirmed, stop OC and apprise patient of potential fetal risks and discuss continuation of pregnanc Users discontinuing for pregnancy should use alternative contraception for 3 months before attempting to conceive, thoug this is not based on precise information. Do not use progestogen-only or progestogen-estrogen drugs as pregnancy test **6.** *Gallbladder disease* risk, surgically confirmed, appeared after 2 years' use and doubled after 4-5 years in 1 study; appeared in 6-12 months' use in another. Bile duct cancer has been reported. **7.** *Carbohydrate and lipid metabolism:* Decrease glucose tolerance occurs in a significant number of users; carefully observe diabetic and prediabetic patients. Triglyceride total phospholipids, and lipoproteins may increase. **8.** *Elevated blood pressure* (BP) occurs in some users in a few month and degree may relate to progestogen dose. Hypertension prevalence in users is not higher in the first year, but increas with longer exposure; in the 5th year it is 2½–3 times the first year. Age is strongly correlated with hypertension in user Those with history of elevated BP (hypertension), preexisting renal disease, history of toxemia or elevated BP in pregnanc familial tendency to hypertension or its consequences, or history of excessive weight gain or fluid retention during menstru cycles may be more likely to develop elevated BP on OCs and should be monitored closely. Even though elevated BP may b in "normal" range, do not ignore implications. Follow closely, particularly those with other risk factors for cardiovascul disease or stroke. High BP may or may not persist after stopping OCs. **9.** *Headache:* Onset or exacerbation of migraine development of headache of a new pattern that is recurrent, persistent, or severe requires stopping OCs and evaluating caus **10.** *Bleeding irregularities:* Breakthrough bleeding (BTB), spotting, and amenorrhea are frequent reasons for discontinuing. BTB, as in all cases of irregular bleeding, consider nonfunctional causes. In undiagnosed persistent or recurrent bleeding, ru out pregnancy or malignancy. If pathology is excluded, time or change to another product may suffice. Change to a highe estrogen OC only when necessary as this may increase thromboembolic risk. Those with history of oligomenorrhea secondary amenorrhea or without established regular cycles may be anovulatory or amenorrheic after discontinuing. Thos with such problems should be so informed and other methods encouraged. Post-use anovulation, possibly prolonged, ma occur in women without previous irregularities. Higher incidence of galactorrhea and of pituitary tumors has been associate with postpill amenorrhea. One study reported 16-fold increased prevalence of pituitary prolactin-secreting tumors in patien with postpill amenorrhea when galactorrhea was present. **11.** *Ectopics:* In failures with combination OCs, the ratio of ectop to intrauterine pregnancies is no higher than in nonusers. **12.** *Breast feeding:* OCs may decrease quantity and quality of mil A small fraction of OC steroids appears in milk. Effects if any on child are unknown. If feasible defer OCs until after weanin **13.** *Infertility* may occur after discontinuing OCs. While impairment diminishes with time, there is still an appreciable differen in nulliparas aged 25-29 after 30 months; difference is negligible after 48 months. In nullips aged 30-34 impairment persis to 72 months and is more severe for 2-year users. In paras aged 25-34, difference is negligible after 30 months. **Precaution** Conduct complete history and physical prior to OC use and annually thereafter. Include breasts, abdomen, and pelvis, wi BP, Pap, and lab tests. Preexisting uterine leiomyomata may enlarge. Mental depression may occur; with positive histor observe carefully and discontinue if serious recurrence. Fluid retention may occur; prescribe cautiously and monitor careful in convulsive disorders, migraine, asthma, or cardiac, hepatic, or renal dysfunction. History of jaundice in pregnancy increas risk of recurrence on OCs; observe carefully and discontinue if it occurs. Cholestatic jaundice occurred after OC ar troleandomycin use. OC/cyclosporine combination may be hepatotoxic. Steroids may be poorly metabolized in liver dysfunctio and should be given cautiously. Tryptophan metabolism may be disturbed and result in pyridoxine deficiency; megaloblast anemia has been reported. Serum folate may be depressed and may be exacerbated in post-OC pregnancy. Advise patholog of OC use when submitting specimens. Endocrine and liver function tests may be altered; repeat abnormal tests after stoppi for 2 months. These have been observed: increased BSP retention and other abnormalities in liver function tests; increas prothrombin and coagulation factors VII, VIII, IX, X; decreased antithrombin III, increased platelet aggregability; increas thyroid-binding globulin leading to increased circulating total thyroid hormone (PBI, T^4); decreased T^3 uptake, unaltered fr T^4, decreased pregnanediol excretion; reduced metyrapone response; increased blood transcortin, corticosteroid, triglyceri phospholipid, reduced serum folate; impaired glucose tolerance, altered plasma trace minerals. Influence of prolonged OC u on pituitary, ovarian, adrenal, hepatic, or uterine function, or on immune response not established. OCs may mask onset climacteric. Cervical chlamydial and gonorrheal prevalence is increased; do not assume OC protects against chlamydial PI HIV seropositivity was associated with OC use. *Information for patients.* See patient labeling. *Drug interactions.* OC effectivene may be decreased and more BTB occur with rifampin, isoniazid, ampicillin, neomycin, penicillin V, tetracycline, chloramphenic sulfonamides, nitrofurantoin, griseofulvin, barbiturates, phenytoin, carbamazepine, primidone, phenylbutazone, analgesi tranquilizers, antimigraines. OCs may alter effectiveness of oral anticoagulants, anticonvulsants, tranquilizers, tricyc antidepressants, antihypertensives, theophylline, caffeine, vitamins, hypoglycemics, clofibrate, glucocorticoids, acetaminophe **Adverse reactions:** Increased risk of the following serious adverse reactions has been associated with OCs: thrombophlebi and thrombosis; pulmonary embolism; arterial thromboembolism; Raynaud's disease, myocardial infarction; corona thrombosis; cerebral thrombosis; cerebral hemorrhage; hypertension; gallbladder disease; Budd-Chiari syndrome; beni adenomas and other hepatic lesions, with or without intra-abdominal bleeding, liver cancer, congenital abnormalities. There evidence of association between the following and OCs, though confirmatory studies have not been done: mesente thrombosis; neuro-ocular lesions, eg, retinal thrombosis and optic neuritis. The following are believed drug related: nause vomiting, gastrointestinal symptoms. BTB, spotting, change in menstrual flow, dysmenorrhea, amenorrhea during and aft use, infertility post-OC, edema, chloasma or melasma, which may persist post-OC, breast changes (tenderness, enlargemer secretion), weight changes, change in cervical erosion and secretion, endocervical hyperplasia, lactation decrease, cholesta jaundice, migraine, enlarged uterine leiomyomata, allergic rash, mental depression, reduced carbohydrate tolerance, vagir candidiasis, change in corneal curvature (steepening), intolerance to contact lenses. Association not confirmed or refuted f premenstrual-like syndrome, cataracts, libido changes, chorea, appetite changes, cystitis-like syndrome, headache, paresthes nervousness, dizziness, auditory disturbances, rhinitis, fatigue, backache, hirsutism, scalp hair loss, erythema multiforme nodosum, hemorrhagic eruption, herpes gestationis, hidradenitis suppurativa, hemolytic uremia, malignant hypertensio impaired renal function, acute renal failure, sometimes irreversible, itching, vaginitis, porphyria. PVCs, abnormal EK pulmonary hypertension, TTP, anemia, pancreatitis, hepatitis, colitis, Crohn's disease, gingivitis, dry socket, lupus erythematosu rheumatoid arthritis, pituitary tumors (eg, adenoma) with amenorrhea and/or galactorrhea after use, malignant melanom endometrial, cervical, breast, and bile duct carcinoma. **Acute overdosage:** Serious ill effects have not been reported aft large acute doses of OCs in young children. Nausea and withdrawal bleeding might occur. **Important note: Comple prescribing information should be consulted prior to use and is available on request.**

Organon enjoys a worldwide reputation with the medical profession with its major oral contraceptives. In this area they continue to strive for perfection. Recently the innovative efforts of Organon research have lead to a historical landmark in oral contraception with the introduction of the world's lowest estrogen dose pill. Again this demonstrates Organon's ability to lead the way in matching innovation with reliability.

ORGANON IN GYNAECOLOGY

striving for completeness

Organon

down through the year

Organon's worldwide reputation in gynaecology is based not only on its innovative OCs and IUDs, but the broad product portfolio includes forms of obstetric therapy together with gonadotrophins and hormone replacement therapy.
This range of products has over many years been a source of confidence to several generations of women.

Use of urinary luteinizing hormone immunoassays in the assessment of luteal function in infertile women

Gregory H. Corsan, MD,[a] Ekkehard Kemmann, MD,[a] Michael Bohrer, MD,[a] Michael Blotner, MD,[a] Paul Smilow, MD,[b] and Robert Shelden, PhD[a]

New Brunswick, New Jersey

It has been suggested that the chronologic date of an endometrial biopsy performed to evaluate luteal adequacy should be based on the date of the luteinizing hormone surge rather than the date of the next menstrual period. Sixty-four infertile women used a urinary luteinizing hormone immunoassay to identify the luteinizing hormone surge; timed serum progesterone level tests and an endometrial biopsy were then performed. An out-of-phase endometrium was identified in 26.6% of cycles dated traditionally and 28.1% of cycles dated from the luteinizing hormone surge. No relationship was identified between progesterone levels and endometrial biopsy results when the next menstrual period was used. When the luteinizing hormone surge was used no progesterone cutoff value could be identified that would reliably distinguish between in-phase and out-of-phase cycles. Use of a urinary luteinizing hormone immunoassay offers no advantage over the next menstrual period and does not lead to better agreement between histologic and chronologic dating. (Am J Obstet Gynecol 1992;166:41-6.)

Key words: Luteal phase defect, progesterone, luteinizing hormone immunoassays, diagnostic test

It is commonly stated that inadequate hormonal preparation of the endometrium for implantation of the blastocyst may be a cause of repetitive spontaneous abortion and infertility.[1-3] This clinical disorder, referred to as luteal phase deficiency, is thought to be caused by a recurrent postovulatory deficiency in the production of progesterone from the corpus luteum.[4] The most widely accepted and clinically applicable method of evaluating corpus luteal function has been a timed luteal phase endometrial biopsy.

Traditionally the chronologic date of the endometrial biopsy has been based on the date of onset of the next menstrual period after the endometrial biopsy and assumes a 14-day luteal phase in all women. It has recently been suggested that midcycle events correlate more accurately with endometrial biopsy results than does the next menstrual period.[5-8] Urinary luteinizing hormone (LH) immunoassays may be useful in evaluating luteal function by allowing a more accurate assignment of the chronologic day of the endometrial biopsy because they use the midcycle LH surge rather than the next menstrual period. This may reduce the number of false positive out-of-phase endometrial biopsy results and possibly avoid further unnecessary evaluation and therapy for luteal phase deficiency. In addition, urinary LH immunoassays may allow more accurate timing of serum progesterone levels in the luteal phase and may provide a more reliable means of identifying the short luteal phase than basal body temperature graphs.

The purposes of this investigation were as follows: (1) to determine whether a urinary LH immunoassay offers any advantage over the next menstrual period in assigning the chronologic date to the endometrial biopsy; (2) to determine whether serial (three) urinary LH-timed serum progesterone levels correlate with results of an endometrial biopsy specimen obtained in the same cycle and whether timed serum progesterone values can be used to discriminate reliably between normal and abnormal cycles as defined by the timed late-luteal phase endometrial biopsy; and (3) to evaluate the relationship between the short luteal phase and LH-timed endometrial biopsy results obtained in the same cycle.

Material and methods

Patient characteristics. Otherwise healthy infertile women seen for evaluation at the Reproductive Endocrine/Infertility Clinic at The University of Medicine and Dentistry of New Jersey–Robert Wood Johnson University Hospital were recruited for this study. Participating subjects had had at least 1 year of unprotected coitus without conception. Each subject had a history of spontaneous, regular ovulatory menses at an interval of 25 to 35 days. Women receiving clomiphene

citrate, bromocriptine, progesterone vaginal suppositories, or other medications potentially having an effect on the ovarian cycle were excluded. Patients with histories of short luteal phase, luteal phase deficiency, or repetitive spontaneous abortion were also excluded.

Clinical protocol. The study protocol was approved by the Institutional Review Board. After written informed consent was obtained from the subjects, they were asked to use an ovulation prediction kit (QTest, Becton Dickinson, Franklin Lakes, N.J.) each day at home beginning 2 to 3 days before the expected day of ovulation as determined by prior basal body temperature charts or menstrual history. A urine LH test was performed daily (late afternoon or early evening). The day that the urinary LH surge was detected was referred to as LH + 0. Serum progesterone levels were obtained by venipuncture between 7:30 and 10 AM 4 (LH + 4), 7 (LH + 7), and 10 (LH + 10) days after identification of the midcycle urinary LH surge. Occasionally blood was drawn 1 day before or after the recommended day(s) because of scheduling problems. On the same morning as the third progesterone determination (LH + 10) and endometrial biopsy was performed with an endometrial suction curette (Pipelle, Unimar, Inc., Wilton, Conn.) with a tenaculum if needed. Subjects recorded the date of onset of menses (full flow) after the endometrial biopsy.

Tissue obtained from the endometrial biopsy was fixed in 10% buffered formalin, processed in routine fashion, embedded in paraffin, and evaluated by two experienced pathologists in a blinded fashion. Efforts were directed to give as precise an evaluation of postovulatory dating as possible. The two pathologists independently reviewed and dated all slides at the end of the study according to standard criteria and a single-day assignment. The mean of the two histologic cycle days assigned the endometrial biopsy specimen by the two observers was used in the statistical analysis. An out-of-phase biopsy was defined as a ≥3 day lag between endometrial development as determined by the criteria of Noyes and the chronologic date of the biopsy as determined by either the next menstrual period or the LH surge. The date of onset of menses after the endometrial biopsy was assigned as day 28, and the chronologic date of the biopsy was calculated by counting backward. Luteal length was defined as the number of days after the detection of the urinary LH surge up to and including the day before onset of the next menses.[9] Short luteal phase was defined as a luteal phase duration of 11 or fewer days.[10]

Hormone assays. Urinary LH was detected with a widely available ovulation prediction kit (QTest), with all subjects following the instructions provided with the kit. All serum progesterone specimens were centrifuged within 2 hours of collection and stored at −20° C until assayed. Specimens were assayed in the same batch with a commercially available kit (Coat-A-Count, Diagnostics Products Corp., Los Angeles). The intraassay variation for progesterone was 8.3%.

Statistical analysis. Two sample independent Student's t tests were used to compare subsets of subjects. Relationships between continuous variables are summarized by the Pearson product-moment correlation coefficient. To determine whether a linear combination of variables predicts outcome, multiple regression analysis was performed on the data. p Values were considered significant if they were <0.05 two-tailed. All values reported are mean ± SD unless otherwise noted.

Results

Of the 86 subjects who entered the study, 64 completed it by identifying the urinary LH surge and having three serum progesterone level tests and an endometrial biopsy performed in the same cycle. Twenty-two other subjects could not be included in the data analysis for a variety of reasons, including inability to detect an LH surge ($n = 2$), pregnancy during the study cycle ($n = 5$), noncompliance ($n = 3$), endometritis on biopsy ($n = 2$), cervical stenosis ($n = 2$), or incomplete sampling ($n = 8$). Data from five subjects who conceived in the study cycle were excluded from the general data analysis and were analyzed separately.

Mean subject age was 32.1 ± 4.6 years (range 22 to 44 years). The urinary LH surge was detected on mean cycle day 14.75 ± 2.70 (range 10 to 24). The mean luteal days for measurement of serum progesterone were LH + 4.20, LH + 7.11, and LH + 10.04. Mean cycle length was 29.03 ± 3.30 days (range 23 to 38 days), and mean luteal length was 13.27 ± 2.20 days (range 8 to 21 days). Mean serum progesterone values on LH + 4, LH + 7, and LH + 10 were 8.53 ± 3.80, 13.19 ± 6.38, and 11.59 ± 6.50 ng/ml, respectively. The mean sum of the three progesterone levels was 33.41 ± 13.50 ng/ml for all cycles.

The mean histologic day assigned the endometrial biopsy specimen by observer 1 was 23.13 ± 2.74 days and 22.38 ± 2.81 days by observer 2. The mean difference between the two raters was ±0.75 days ($p < 0.05$). The histologic day assigned the endometrial biopsy taken as an average of the two raters was 22.75 ± 2.67 days. Correlation between the observers was high ($r = 0.860$, $p < 0.05$). The observers agreed exactly in 18.8% of specimens and agreed within ±2 days in 89.9% of specimens. The mean chronologic day of the cycle on which the endometrial biopsy occurred was cycle day 23.74 ± 2.10 with the next menstrual period method and cycle day 24.02 ± 0.67 with the urinary LH surge method, or a mean of 0.28 days later with the LH method (not significant). A secretory en-

dometrium was associated with a midluteal (LH + 7) progesterone value >3 ng/ml in 98% of cycles.

When standard criteria (next menstrual period) were used to evaluate each cycle, 26.6% of cycles were out of phase. When the urinary LH surge was used to assign the chronologic day to the endometrial biopsy, 28.1% were out of phase (not significant). There was no difference between mean progesterone values obtained on LH + 4, LH + 7, or LH + 10 in in-phase or out-of-phase cycles as defined by standard criteria (Table I). No significant difference existed between the sum of the three progesterone values obtained in in-phase (34.35 ± 15.23 ng/ml) and out-of-phase (33.04 ± 13.4 ng/ml) cycles as defined by standard criteria.

A significant difference existed between mean progesterone values on LH + 4 when comparing in-phase (9.07 ng/ml) and out-of-phase (6.76 ng/ml) cycles when the urinary LH surge was used to assess the cycle ($p < 0.02$). There was no significant difference between progesterone values on LH + 7 and LH + 10 and the sum of the three progesterone values between in-phase and out-of-phase cycles with the LH surge to evaluate luteal adequacy (Table I).

To explore the possibility that some linear combination of progesterone values may explain the variance in the data, multiple regression-discriminant analysis was used. No distinction between in-phase and out-of-phase cycles based on progesterone determinations obtained on LH + 4, LH + 7, or LH + 10, and the sum of progesterone values for cycles assessed by traditional criteria was identified. When the urinary LH surge was used to assign the chronologic date to the biopsy, only in the case of serum progesterone on LH + 4 was there any correlation ($p < 0.05$) between any linear function of serum progesterone values and luteal adequacy as determined by endometrial biopsy. However, a progesterone cutoff value on LH + 4 with acceptable diagnostic test properties could not be identified. The best serum progesterone cutoff value determined on LH + 4 was 7.0 ng/ml; however, this level showed a sensitivity of 50%, specificity of 79%, positive predictive value of 44%, negative predictive value of 79%, and accuracy of 69%. Using the serum cutoff progesterone value of 7.0 ng/ml as suggested by Daya and Ward[11] on LH + 4 did not allow us to predict in-phase or out-of-phase biopsies with sufficient sensitivity and specificity to permit use of this single luteal progesterone determination to assess luteal function.

A total of five endometrial biopsies were performed during conception cycles. One of these pregnancies spontaneously aborted in the first trimester, a spontaneous abortion rate (20%) similar to that expected in a normal population. Progesterone values on LH + 4, LH + 7, and LH + 10, and the sum of progesterone values were not significantly different in pregnancy versus nonpregnancy cycles. In two conception cycles the endometrial histologic date was >2 days behind the chronologic date of the endometrial biopsy based on the urinary LH surge, suggesting luteal inadequacy.

When luteal phase length was determined with the urinary LH surge, 12 (18.8%) of 64 cycles had short luteal phases (≤11 days) (Table II). Of the 12 women with short luteal phases, 2 (16.7%) of the cycles were out of phase by the LH method and 4 (33%) were out of phase by standard criteria. Of those women with normal luteal length, 30.2% had an out-of-phase endometrial biopsy by LH surge criteria. Mean progesterone values on LH + 4 and LH + 7 did not differ in women with or without short luteal phases. Mean serum progesterone on LH + 10 was significantly lower ($p < 0.05$) for women with short luteal phases (6.46 ± 3.1 ng/ml) when compared with women with luteal length of >11 days (12.37 ± 6.5 ng/ml). Luteal length was positively correlated ($p < 0.001$) with progesterone on LH + 4 and negatively correlated with progesterone on LH + 10 ($p < 0.001$).

Comment

Evaluation of luteal adequacy by endometrial biopsy continues to be a commonly performed investigation in the evaluation of both repetitive spontaneous abortion and infertility. It has been suggested that the chronologic day assigned the endometrium should be correlated to the midcycle LH surge rather than the date of onset of the next menstrual period.[5-8] The conventional approach to determining the chronologic date of the endometrial biopsy by counting backward from the date of the next menstrual period may be flawed because it is clear that only a minority of cycles appear to have a luteal phase length of exactly 14 days,[10] and confusion often exists between postbiopsy spotting and true menses. There may be better agreement between histologic and chronologic dating of endometrial biopsy specimens (and thus a lower rate of false-positive results) when the LH surge is used to assign a chronologic date to the specimen.[8] Urinary LH immunoassays correlate well with serum radioimmunoassays for LH[12] and provide us with a simple, relatively inexpensive, and practical means of identifying the preovulatory LH surge.[13]

Shoupe et al.[7] showed an 84.6% accuracy rate in dating the endometrial biopsy from the serum LH surge and suggested that use of urine LH kits may allow more accurate dating of the endometrial biopsy specimen. Similarly, Li et al.[8] found that use of the prospective method of dating the endometrial biopsy from the LH surge (detected in serum and/or urine) rather than the next menstrual period could reduce the incidence of out-of-phase biopsies from 42% to 10%. These studies suggested that use of the next menstrual period to as-

sign the chronologic date of the endometrial biopsy leads to overestimation of the incidence of out-of-phase cycles and may lead to unnecessary further evaluation and therapy.

Single or multiple serum progesterone level tests continue to be recommended as means of assessing luteal function.[14-19] These tests continue in clinical practice in spite of knowledge that progesterone is secreted from the corpus luteum in an episodic manner such that peripheral serum progesterone values can vary greatly from minute to minute.[20-23] The pulsatility of progesterone release and resultant highly variable serum progesterone concentrations likely explain the difficulty many authors have had in correlating endometrial biopsy findings with serum progesterone levels.[15, 24] These facts led Syrop and Hammond[25] to suggest that the intrinsic variability of progesterone levels in the midluteal phase can be minimized by using timed morning blood for progesterone determinations.

In spite of the potential theoretic advantages that urinary LH immunoassays offer in assessing luteal function, we found no significant difference in the incidence of out-of-phase endometrial biopsies whether traditional criteria (the next menstrual period) or the urinary LH surge was used to assign the chronologic day to the endometrial biopsy. Why daily serum LH determinations by radioimmunoassay[7, 8] and not the identification of the urinary LH surge by QTest decreased false-positive endometrial biopsy results is not readily apparent. Additional variables may have been introduced by allowing subjects to test urine at home and outside the controlled environment of a laboratory. In addition, once daily urine testing may not have permitted accurate identification of the day of the LH surge. It is also possible that the correlation between urinary LH determinations by enzyme immunoassay and serum LH determinations by radioimmunoassay may not be as high as previously reported.[12] The subjectivity and imprecision introduced by dating the endometrium with the standard dating criteria of Noyes may also have contributed to our findings.[26]

We have also attempted to correlate the results of the endometrial biopsy with urinary LH-timed serial morning luteal phase progesterone values in the same cycle. Although serum progesterone levels on LH + 4 did differ between in-phase and out-of-phase cycles when the urinary LH surge was used, no progesterone cutoff value on LH + 4 that could distinguish in-phase and out-of-phase cycles with acceptable sensitivity and specificity could be identified. This finding is consistent with the report of Li et al.,[27] which found that retarded endometrial development was more likely to be associated with a subnormal salivary progesterone profile in the early luteal phase than the late luteal phase. In addition, another recent study found that total pregnanediol excretion was significantly less for luteal phase deficiency cycles during the first 5 days of the luteal phase.[28]

We can only speculate as to why progesterone levels in the early luteal phase and not the midluteal and late luteal phases identified a greater mean progesterone value for in-phase cycles when LH timing was used. That mean progesterone values on LH + 4 did not differ between in-phase and out-of-phase cycles as determined by the next menstrual period may be related to our ability to identify better the early luteal phase with urinary LH assays. Total progesterone production from the corpus luteum as determined by daily serum or salivary progesterone assays is lower in cycles with an out-of-phase endometrial biopsy.[29] It has been demonstrated that progesterone secretion in the early luteal phase is stable and does not demonstrate rapid fluctuations over 24 hours as in the midluteal and late luteal phases.[20, 21] It may be that decreased pulsatility of progesterone secretion in the early luteal phase permitted us to detect the higher levels of progesterone in in-phase cycles more readily. It is possible that the higher serum progesterone levels in the early luteal phase led to a direct improved effect on endometrial development and maturation.

The role that the short luteal phase plays in infertility, if any, is uncertain. It is not known whether a short luteal phase cycle is by necessity abnormal in terms of luteal function. Short luteal phases are not uncommon and may represent a variant in the spectrum of normal luteal function.[10] Short luteal phases occur with the same frequency in normal and infertile populations.[9, 10] Our finding of an in-phase endometrial biopsy (by both criteria) in the majority of patients with a short luteal phase supports the concept that identifying a cycle with a short luteal phase does not necessarily signify that luteal function, as determined by endometrial biopsy, is adversely affected.

We have demonstrated in this study that, with the exception of serum progesterone on LH + 4, both single and serial luteal progesterone levels timed by urinary LH immunoassay correlate poorly with the assessment of luteal function as determined by the endometrial biopsy. Our data suggest that the practice of using luteal phase serum progesterone values and even well-timed serial morning specimens to evaluate luteal adequacy provides little meaningful information and correlates poorly with histologic findings on endometrial biopsy. In addition, identification of the urinary LH surge by QTest did not result in better agreement between chronologic and histologic dating of the endometrial biopsy and did not appear to offer any advantages over traditional dating techniques.

We gratefully acknowledge the expertise of Simcha Pollack, PhD, Department of Quantitative Analysis, St. John's University, Queens, New York in the statistical analysis of our data. We are also grateful to Elliot Krauss, MD for his help in interpreting the endometrial biopsies.

Intracerebral, aortic, and umbilical artery flow velocity waveforms in the late-first-trimester fetus

Juriy W. Wladimiroff MD, PhD, Tjeerd W.A. Huisman, MD, and Patricia A. Stewart, PhD

Rotterdam, The Netherlands

OBJECTIVES: Our objectives were to determine the success rate in obtaining flow velocity waveforms in the first-trimester fetal circulation and to establish possible preferential flow to the fetal cerebrum at this early stage of gestation.

STUDY DESIGN: Flow velocity waveform recordings were made in the umbilical artery, fetal descending aorta, and fetal intracerebral arteries in 30 normal pregnancies between 11 and 13 weeks of gestation.

RESULTS: Technically acceptable waveforms were obtained from the descending aorta in 15 fetuses, from the intracerebral circulation in 17 fetuses, and from the umbilical artery in all 30 fetuses. Absent end-diastolic velocities in the descending aorta and umbilical artery were associated with forward flow throughout the cardiac cycle in intracerebral arteries.

CONCLUSION: A relatively low cerebral vascular resistance in the late-first-trimester normal fetus is suggested. (Am J Obstet Gynecol 1992;166:46-9.)

Key words: Transvaginal ultrasonography, pulsed Doppler, fetal circulation

Third-trimester pregnancies are characterized by forward end-diastolic flow velocities in umbilical and fetal arterial vessels that reflect a low-resistance feto-placental unit.[1] After the introduction of a Doppler method for recording flow velocity waveforms in the human fetal internal carotid artery in third-trimester pregnancies,[2] evidence was provided of reduced cerebral vascular resistance in cases of intrauterine growth retardation that is due to placental insufficiency.[2-4]

Transvaginal ultrasonography allows more detailed visualization of fetal structural development in early pregnancy[5] and as a result is a potential tool for the Doppler recording of blood flow in first-trimester fetal vessels such as the common and internal carotid artery, the descending aorta, the cardiac outflow tract, and the umbilical artery. A preliminary study on umbilical artery flow velocity waveforms with transabdominal continuous-wave Doppler ultrasonography has demonstrated high pulsatility as a result of absent end-diastolic flow velocities that reflect high umbilical-placental vascular resistance.[6] Because early pregnancy is particularly characterized by rapid growth of the fetal

head, it is unknown whether a relatively low vascular resistance is present at the cerebral level.

The objective of this study was twofold: (1) to determine the success rate in obtaining technically acceptable flow velocity waveforms in the fetal intracerebral circulation, the descending aorta, and the umbilical artery in late-first-trimester pregnancies and (2) to relate intracerebral artery flow velocity waveforms to those obtained from the descending aorta and the umbilical artery to establish possible preferential blood flow to the fetal cerebrum at this early stage of gestation.

Material and methods

Thirty normal singleton pregnancies were included in the study. Maternal age varied between 23 and 38 years (median 27 years). Gestational age ranged between 11 and 13 weeks (median 12 weeks). All pregnant women consented to participate in the study. The study protocol was approved by the hospital's ethics committee. A combined transvaginal real-time and pulsed Doppler system (Hitachi E.U.B. 450, Medical Cooperation, Tokyo) with a carrier frequency of 3.5 and 6.5 MHz was used. The system operates at power outputs of <100 mW/cm^2 spatial peak–temporal average in both imaging and Doppler modes by the manufacturer's specifications. Each woman was included in the study once. Doppler studies were performed by one examiner (J.W.W.). Maximum flow velocity waveforms were collected from the fetal intracerebral circulation, the descending aorta, and the umbilical artery. Intracerebral artery flow velocity waveforms were documented on a transverse cross section through the lower part of the fetal cerebrum; this showed a heart-shaped cross section of the brain stem with the anterior lobes representing the cerebral peduncles.[2] No distinction could be made between internal carotid, middle, or anterior cerebral artery waveforms. Flow velocity waveforms from the lower thoracic part of the fetal descending aorta were recorded from a sagittal cross section through the fetal trunk that displayed a major section of the fetal spine.[7] The flow velocity waveform in the umbilical artery was obtained from a free-floating loop of the umbilical cord.[8] Sample volume length was 0.1 to 0.3 cm. The pulsatility of the waveform was expressed by the pulsatility index, which is derived by dividing the difference between peak systolic and end-diastolic velocity by the mean flow velocity over the entire cardiac cycle.[9] Heart rate (beats per minute) was calculated from peak velocity time intervals in the descending aorta. All Doppler studies were performed with the woman in the semirecumbent position and during fetal apnea, because fetal breathing movements modulate blood flow velocity waveforms.[10] The total examination time was limited to 10 minutes in each instance.

All flow velocity waveforms were recorded on hard copies. A microcomputer (Olivetti M 24, Olivetti BV, Leiden) linked to a graphics tablet was used for analysis of Doppler recordings. An average of three consecutive flow velocity waveforms of similar appearance and with the highest velocity was used to establish each value. Data are presented as mean ± 1 SD.

Results

Technically acceptable flow velocity waveforms were obtained from intracerebral arteries in 21 fetuses (70%), from the descending aorta in 15 (50%), and from the umbilical artery in all of the 30 fetuses studied. Although flow velocity waveforms in the descending aorta (Fig. 1) and umbilical artery (Fig. 2) display ab-

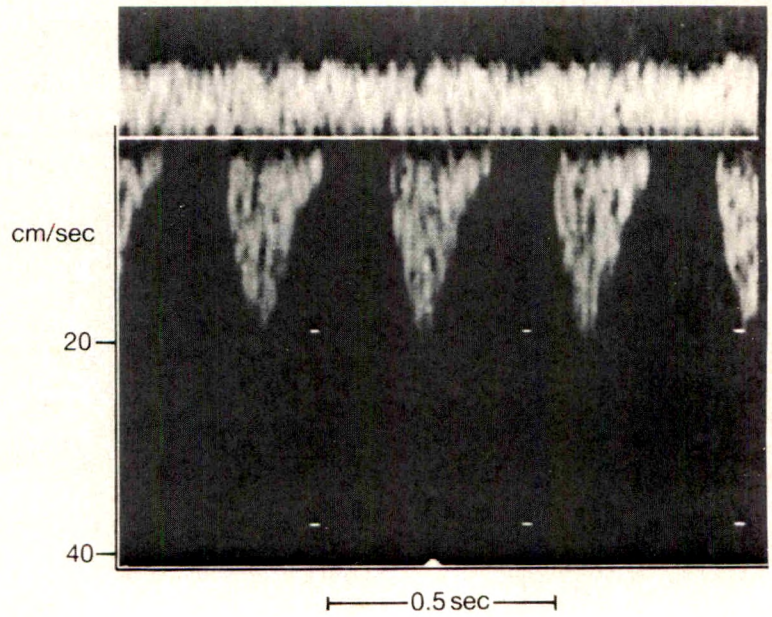

Fig. 2. Flow velocity waveform from umbilical artery in late-first-trimester normal fetus.

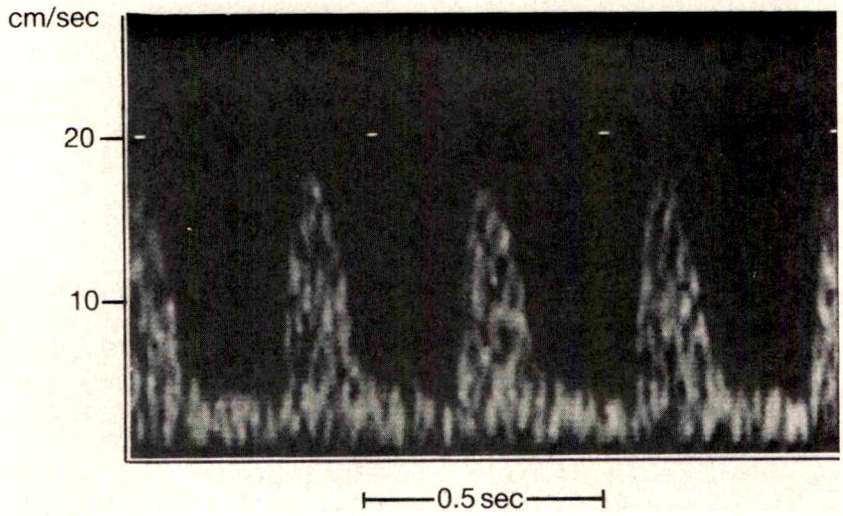

Fig. 3. Flow velocity waveform from intracerebral arterial circulation in late-first-trimester normal fetus.

sent end-diastolic flow, flow velocity waveforms in the intracerebral arteries are characterized by forward flow throughout the cardiac cycle (Fig. 3). The pulsatility index was 2.5 ± 0.2 in the fetal descending aorta, 2.6 ± 0.3 in the umbilical artery, and 2.0 ± 0.2 in the intracerebral artery. Fetal heart rate ranged between 146 and 188 beats/min with a mean value of 170 ± 6 beats/min. No statistically significant correlation existed between flow velocity in all three vessels and the heart rate.

Comment

The objective of this study was to establish the nature of intracerebral, aortic, and umbilical flow velocity waveforms in late-first-trimester pregnancies. Flow velocity waveform recording was successful in more than half of the women examined. Fetal motor activity, particularly of the trunk, was the main cause of failure to obtain acceptable waveforms. Exact identification of the intracerebral vessels under investigation was not possible, although positioning of the sample volume anterior to the cerebral peduncles should limit the origin of the waveforms to the internal carotid and the middle and anterior cerebral arteries. Intracerebral forward end-diastolic flow, as opposed to absence of end-diastolic flow in the descending aorta and umbilical artery, reflects comparatively lower vascular resistances in the fetal cerebrum. This is supported by the observation

that the mean intracerebral pulsatility index value in this study is only marginally higher than that established in late-second-trimester pregnancies.[11] In contrast, a similar comparison for the mean pulsatility index in the descending aorta and umbilical artery revealed that late-first-trimester pregnancies are associated with considerably higher values, i.e., by factor 1.4 for the descending aorta and by factor 2.0 for the umbilical artery.

Our late-first-trimester fetal heart rates are higher than those observed in second- and third-trimester pregnancies; this is due to parasympathetic immaturity.[12] Heart rate dependency was established in normal third-trimester pregnancies for all three fetal vessels.[13] The rather narrow heart rate distribution may explain the absence of heart rate dependency of fetal flow velocity waveforms in this study.

It can be concluded that the transvaginal Doppler technique can be used to study the early human fetal circulation. The intracerebral velocity waveforms suggest a relatively low vascular resistance at fetal cerebral level in early gestation.

Editors' note

The American Journal of Obstetrics and Gynecology introduces a new format for abstracts accompanying regular articles, society articles, and Current Investigation articles. Authors submitting these manuscripts to the Journal should provide an abstract of no more than 150 words structured according to the following headings: Objective(s), Study Design, Results, and Conclusion(s). Exceptions to this requirement include Clinical Opinion, Current Development, case report, and brief communication articles. Abstracts for these articles will continue to follow the standard abstract format. Please consult the Information for Authors for details.

Ovarian metastases in stage IB carcinoma of the cervix: A Gynecologic Oncology Group study

Gregory P. Sutton, MD,[a] Brian N. Bundy, PhD,[b] Gregorio Delgado, MD,[c] Bernd-Uwe Sevin, MD, PhD,[d] William T. Creasman, MD,[e] Francis J. Major, MD,[f] and Richard Zaino, MD[g]

Indianapolis, Indiana, Buffalo, New York, Washington, D.C., Miami, Florida, Charleston, South Carolina, Denver, Colorado, and Hershey, Pennsylvania

Surgical and pathologic findings at laparotomy for radical hysterectomy in 990 patients with clinical stage IB carcinoma of the cervix were analyzed to determine the frequency of metastases to the ovary. Ovarian spread was identified in 4 of 770 (0.5%) patients with squamous carcinoma and 2 of 121 (1.7%) with adenocarcinoma. No patients with adenosquamous carcinoma (n = 82) or other histologic types (n = 17) had ovarian metastases. Although the frequency of metastases was greater among patients with adenocarcinoma, this was not statistically significant (p = 0.19, Fisher's exact test). All 6 patients with ovarian metastases had other evidence of extracervical disease. Three underwent radical hysterectomy and bilateral salpingo-oophorectomy. Of these, one patient received extended field radiotherapy and died of disease 18 months after diagnosis. Two patients, one treated with combination chemotherapy and one with no adjunctive therapy, are alive without evidence of disease at 59 and 62 months, respectively. Three patients underwent exploratory laparotomy with salpingo-oophorectomy and lymphadenectomy without hysterectomy. All three patients died of disease at 2, 3, and 30 months; the first and last patient received adjunctive radiotherapy. Not all patients underwent oophorectomy. Of 347 patients with at least unilateral ovarian preservation, no postoperative pelvic radiotherapy, and no gross extracervical disease or metastasis to the paraaortic nodes, pelvic recurrence developed in 16. There was no excess of pelvic recurrences in patients with adenocarcinoma (0/41) or adenosquamous carcinoma (1/29, 3.4%) when compared with those with squamous carcinoma (15/270, 5.6%). This suggests no excess of occult ovarian metastases in nonsquamous tumors of the cervix. There is no evidence in these data of an increased risk of ovarian preservation in patients with stage IB carcinoma of the cervix with no gross extracervical disease. (AM J OBSTET GYNECOL 1992;166:50-3.)

Key words: Ovarian metastases, carcinoma of the cervix

Early stage squamous carcinoma of the cervix rarely metastasizes to the ovary. Preservation of the ovaries in premenopausal women undergoing surgical therapy for early invasive cervical cancer has been one of the foundations of practice in gynecologic oncology since McCall et al.[1] published the results of their 9-year retrospective study in 1958.

6/1/31439

Mann et al.[2] recently reported two cases of ovarian metastases in stage IB adenocarcinoma of the cervix. They cited evidence[3] suggesting that the practice of ovarian preservation during surgery for early adenocarcinoma of the cervix was not as safe as had been established in squamous lesions. The purpose of the current study was to determine whether there is an increased risk of ovarian metastases in clinical stage IB adenocarcinoma and adenosquamous carcinoma of the cervix when compared with squamous carcinoma.

Material and methods

Women with previously untreated histologically confirmed International Federation of Gynecology and Obstetrics stage IB cervical cancer were eligible for a prospective surgical-pathologic study conducted by the Gynecologic Oncology Group.[4] Eligibility requirements included a signed informed consent and surgical procedure as noted here. Patients were ineligible if they had received chemotherapy or radiotherapy, had other noncutaneous malignancies (melanoma excepted), had greater than International Federation of Gynecology

and Obstetrics stage IB lesions, or were poor operative risks. At surgery, patients underwent a thorough examination while they were under anesthesia, peritoneal fluid was obtained for cytologic evaluation on entering the abdomen, and radical hysterectomy and bilateral pelvic and paraaortic lymphadenectomy as described by Meigs[5] were performed. For patients with evidence of tumor confirmed by frozen section in tissues other than the uterus, cervix, or pelvic lymph nodes, only exploration and appropriate biopsies were required. In most of these cases radical surgery was not completed and radiotherapy was given. Similarly, patients with fixed, histologically positive, nonresectable pelvic nodes were required to have only paraaortic lymph node biopsy and exploration of the abdomen and pelvis before definitive radiotherapy. Removal or nonremoval of the ovaries was determined by the primary surgeon. There was no prospective attempt to establish guidelines for the conservation or removal of ovarian tissue. Although menopausal status was not coded in the primary study, 209 patients (21%) were >52 years of age.

Representative slides of the primary lesion and additional positive sites were reviewed by the Gynecologic Oncology Group Pathology Committee and note was made of the depth of invasion and the presence or absence of capillary space involvement.

For our study, data from Gynecologic Oncology Group statistical files were reviewed for those cases in which spread to the ovaries at the primary operation was identified. Fisher's exact test[6] was used to measure the association between cell type and ovarian metastasis.

Results

Between May 1981 and April 1984, 1125 patients were entered into this surgical-pathologic study. Of these, 121 were excluded preoperatively for reasons including wrong stage, minimal tumor invasion, inadequate pathologic material to confirm eligibility, and late registration. There were 14 postoperative exclusions; 12 had incorrect or double primaries and the remaining two were excluded because their institution failed to provide the necessary documentation. The remaining 990 patients were evaluable for this study and include 49 patients who underwent exploration but did not have all the required surgical procedures performed.

Of the evaluable patients, 770 (77.9%) had squamous lesions, 121 (12.2%) had adenocarcinoma, 82 (8.2%) had adenosquamous carcinoma, and 17 (1.7%) had other histologic types of tumor.

One hundred eleven patients (11.2%) did not undergo radical hysterectomy because of the finding at laparotomy of gross extracervical disease or metastases to the paraaortic nodes. Eighty-nine of these patients had squamous cancer and 22 had nonsquamous lesions. There were 94 (84.7%) patients who received definitive radiotherapy. Four of these patients (3.6%) had ovarian and other metastases at the time of laparotomy. Three had squamous carcinoma and one had adenocarcinoma. Details of these four cases are found in Table I. All had extensive extracervical spread and all but one received postoperative radiotherapy. All four patients died of cancer at intervals of 2, 3, 18, and 30 months after exploratory surgery.

A total of 833 patients with no gross extracervical disease or metastasis to the paraaortic nodes underwent radical hysterectomy and lymphadenectomy. Two of these patients were found to have ovarian metastases at laparotomy (0.2%), one with squamous carcinoma and one with adenocarcinoma. These metastases were 3 and 6 cm in diameter and were unilateral in both cases. One patient with squamous carcinoma did not receive adjunctive radiotherapy and was alive without disease 62 months after surgery. The patient with adenocarcinoma received chemotherapy with cisplatin, doxorubicin, and cyclophosphamide and was alive and well 59 months postoperatively.

Of the 833 patients who underwent radical hysterectomy, 439 (52.7%) also had bilateral salpingo-oophorectomy. Unilateral adnexectomy with preservation of the contralateral ovary was performed in 91 patients, and three had a solitary residual ovary removed at the time of radical hysterectomy. Thus 391 patients undergoing radical hysterectomy had at least one gonad preserved. Of this group 47 received postoperative pelvic radiotherapy, leaving 344 patients at theoretic risk for recurrence from undetected micrometastases in the residual ovary. In 16 of these 344 patients (4.7%) recurrence with a pelvic component did develop. However, there was no excess of pelvic recurrence in patients with adenocarcinoma (0/41) or adenosquamous carcinoma (1/29, 3.4%) when compared with those with squamous carcinoma (15/267, 5.6%). A few patients in this series underwent ovarian transposition and would therefore be at risk for abdominal recurrence if ovarian metastases were present. However, there was no observed difference in the rate of abdominal recurrence by histologic type.

Overall, ovarian metastases were observed in 6 of 990 patients in this study, for a prevalence rate of 0.6%. The distribution of ovarian metastases varied according to the histologic type of tumor. Among 770 patients with squamous cell carcinomaa, four, or 0.5%, had ovarian spread. This contrasts with two of 121 (1.7%) patients with adenocarcinoma and none of 99 with adenosquamous carcinoma or other histologic types. Although metastases are more common in adenocarcinoma and adenosquamous carcinoma in this series, no statistical significance was associated with this difference ($p = 0.19$, Fisher's exact test).

Characteristics of the six patients with clinical stage

Table I. Ovarian metastases in stage IB carcinoma of the cervix

Age (yr)	*Histologic type*	*Surgery*	*Recurrence (mo)*	*Status*	*Survival*	*Other metastases*
35	Squamous	Lap, RT	3.0	DOD	44.9	Pelvic and paraaortic nodes, peritoneal wash
44	Squamous	Lap, RT	3.1	DOD	4.2	Pelvic and paraaortic nodes, fallopian tube
62	Squamous	Radical RT	18.0	DOD	30.1	Pelvic and paraaortic nodes peritoneal wash
24	Adenocarcinoma	Lap, RT	2.2	DOD	2.2	Fallopian tube, appendix, parametrium
44	Squamous	Radical	61.8*	NED	61.8*	Parametrium
34	Adenocarcinoma	Radical, Chemorx	58.6*	NED	58.6*	Fallopian tube

Lap, Laparotomy and bilateral oophorectomy only; *RT*, postoperative radiotherapy; *DOD*, dead of disease; *Radical*, radical hysterectomy, bilateral salpingo-oophorectomy, and lymphadenectomy; *Chemorx*, combination chemotherapy; *NED*, alive with no disease.

*Patient is alive with no evidence of disease as of time indicated.

IB carcinoma of the cervix and ovarian metastases are outlined in Table I.

Nonmetastatic ovarian neoplasms identified in this group of patients included one patient with a Sertoli cell tumor and contralateral serous cystadenoma, four patients with papillary cystadenofibromas, and one each with a Brenner tumor, adrenal rest, and mucinous cystadenoma of low malignant potential. These patients represented 0.9% of the total in this series.

Comment

International Federation of Gynecology and Obstetrics stage IB carcinoma of the cervix may be treated by radical hysterectomy or pelvic radiotherapy with similar rates of disease control.[7] In young women radical hysterectomy is often the preferred method of therapy because normal vaginal function can be maintained. The salvage of ovarian function is a second advantage of surgical therapy. McCall et al.[1] demonstrated that the risk of ovarian involvement in early squamous lesions of the cervix is low and that gonadectomy is not required in the absence of visible metastases. This principle of ovarian preservation has been applied in the case of early adenocarcinoma of the cervix by many clinicians. Mann et al.[2] challenged this practice, suggesting that its safety had not been established in nonsquamous lesions of the cervix.

The true incidence of ovarian metastases in stage IB adenocarcinoma of the cervix is unknown and would require microscopic examination of all ovarian tissues at the time of radical hysterectomy. However, some information is available regarding the finding of visible metastases. Kjorstad and Bond[8] described two patients in a series of 150 (1.3%) with ovarian spread in the absence of lymph node metastases. Both underwent oophorectomy, radical hysterectomy, and postoperative pelvic radiotherapy and are free of recurrence. Tabata et al.[3] reported two cases (7.7%) of ovarian metastases among 26 patients undergoing radical hysterectomy and pelvic lymphadenectomy for stage IB adenocarcinoma of the cervix. This incidence was greater than that for squamous lesions (none in 122 cases). Survival information was not presented. In a series of autopsies[3] on patients with advanced disease who had received radiotherapy, chemotherapy, or no treatment, there was a significantly greater finding of ovarian spread among subjects with adenocarcinoma (22 of 77, 28.6%) when compared with those with squamous tumors (104 of 597, 17.4%, $p < 0.02$).

Mann et al.[2] cited two cases of stage IB adenocarcinoma of the cervix with ovarian metastases. The first patient underwent bilateral oophorectomy for the incidental finding of endometriosis and was found to have microscopic metastases in both ovaries without other extracervical disease. She received postoperative radiotherapy and was free of disease at 36 months. The second patient had bilateral pelvic node involvement and microscopic extension into the anterior vaginal fornix. She was alive and well 42 months after surgery and radiotherapy. On the basis of these two cases and a review of the literature, these authors ". . . adopted a policy of recommending oophorectomy at the time of radical hysterectomy and pelvic node dissection for adenocarcinoma of the cervix."[2]

Kaminsky and Norris[9] identified neoplasms in ovaries of 25 of 161 women with endocervical adenocarcinoma either at the time of or subsequent to surgery for this condition. Ten patients had metastases from the cervical primary and, although stage was not discussed, there was generalized pelvic and peritoneal involvement in seven of these cases.

In this report the incidence of ovarian metastases among subjects with squamous carcinomas of the cervix was 0.5%. This finding is nearly identical to that of Baltzer et al.[10] (4/749, 0.5%) and Shingleton and Orr[11] (1/258, 0.4%) and confirms the safety of ovarian pres-

ervation in squamous cancers. All patients with ovarian metastases had evidence of other extracervical disease. Although ovarian metastases were observed more frequently among patients with adenocarcinomas, the absolute incidence of ovarian spread remained very low. Additionally, those patients with isolated ovarian metastases did well when radical hysterectomy was completed in this series of patients. There is no conclusive evidence from these data suggesting an increased risk associated with ovarian preservation in patients who have no gross extracervical disease.

No increased rate of pelvic recurrence could be demonstrated in this series of nonovariectomized patients with adenocarcinoma when compared with those with squamous tumors. Therefore it would seem reasonable to conserve normal-appearing ovaries in young women undergoing radical hysterectomy for treatment of cervical adenocarcinoma and adenosquamous carcinoma, providing that no other extracervical spread is present and that the patient understands the small risk of undetected ovarian spread.

Describing and interpreting 24-hour blood pressure patterns in physiologic pregnancy

Pietro Cugini, MD,[a] Loredana Di Palma, MD,[a] Paola Battisti, MD,[a] Giuseppe Leone, MD,[a] Antonio Pachí, MD,[b] Rosalba Paesano, MD,[b] Cristiana Masella, MD,[b] Giovanni Stirati, MD,[c] Alessandro Pierucci, MD,[c] Anna Rachele Rocca, MD,[c] and Santo Morabito, MD[c]

Rome, Italy

The time course of blood pressure in clinically healthy (pregnant and nonpregnant) women was followed by automatic ambulatory monitoring. Chronobiologic methods revealed the time course of dynamic rhythm characteristics as a function of gestational age. Differences were found between nonpregnant and pregnant women with an overall lowering during pregnancy of the rhythm-adjusted midline estimating statistic of rhythm (mesor). (Am J Obstet Gynecol 1992;166:54-60.)

Key words: Blood pressure, chronobiology, hypertension, pregnancy

The physiologic pattern of blood pressure consists of 80,000 to 140,000 tensions that take place beat to beat during the day-night cycle. Thus, so-called casual measurements[1] should be replaced by noninvasive automated monitoring to improve clinical assessment of the constitutive sequence of the 24-hour blood pressure pattern. However, the automated monitoring has to be biometrically interpreted, considering that blood pressure is a rhythmic variable showing a circadian-dependent periodicity.[2-8] Interpretation criteria are particularly crucial for pregnancy because blood pressure shows changes peculiar to each stage of gestation.[9-16] On the other hand, the designation of normotensive or hypertensive pregnancies may be important for mothers and babies, whose 24-hour blood pressure pattern shows a chronobiologic separation according to the positive or negative family history.[17]

Our study was designed to approach the 24-hour blood pressure pattern in physiologic pregnancy by describing and interpreting time-qualified variability with particular reference to the periodic pattern.

Material and methods

Subjects and protocol. Thirty pregnant women and thirty nonpregnant women were investigated (Table I). These subjects were stratified from a large sample of randomly investigated individuals. Their participation was allowed because they were classified *a posteriori* to be clinically healthy subjects in accordance with extensive clinical checkups. Furthermore, the pregnant women were all primiparous women not at risk of hypertension and with no history of familial and personal high blood pressure. The pregnant women had uneventful gestations and were vaginally delivered of term infants with Apgar scores >7.

Table I. Clinical data in nonpregnant and pregnant women

Characteristics	*Nonpregnant women*	*Pregnant women*
No. observations	30	30
Age (yr)	20-25	20-26
Height (cm)	176 ± 4	166 ± 5
Weight (kg)	58 ± 4	57 ± 5*
Casual blood pressure		
Systolic (mm Hg)	110-170	105-115
Diastolic (mm Hg)	70-80	65-75

Blood pressure values given as range.
*Before pregnancy.

The 24-hour blood pressure monitoring in pregnant women was repeated in each trimester of pregnancy at 8 to 10, 18 to 20, and 32 to 34 gestational weeks, respectively. Both the nonpregnant women and pregnant women were hospitalized to be synchronized to light-dark alternation (lights on 7 AM; lights off 11 PM) and meal-timing schedule (breakfast 8:30 AM; lunch noon; dinner 6:30 PM) by using a noninvasive ambulatory automated recorder (Space Labs, ICR, Redmont, Washington) that took measurements (oscillometric technique) for systolic and diastolic blood pressure at programmable intervals.

Biometric analysis. Individual time data series were analyzed with methods of noninferential and inferential biometry.

Noninferential biometry refers to the analysis of the distribution for blood pressure values estimated independently of their temporal qualification (macroscopic cumulative biometry) or qualified by their daily temporality (macroscopic temporal biometry). Inferential biometry (microscopic temporal biometry) refers to the analysis of the circadian rhythmicity with the Single Cosinor method[18] and the Single Cosint (combination of cosine and integration) procedure.[19]

The single cosinor method is a periodic regression analysis fitting a 24-hour cosine curve to raw data and defining the optimal waveform by means of the least squares method. The cosinor procedure uses this equation:

$$Yt = M + A \cdot \cos(\omega \cdot t + \phi) \qquad (1)$$

where M (mesor, acronym of midline estimating statistic of rhythm) is the rhythm-adjusted mean; A (am-

SBP, Systolic blood pressure; *DBP*, diastolic blood pressure; *TI*, tolerance interval.

plitude) represents the extent of oscillatory wave from mesor; ϕ (acrophase) is the timing of the wave with reference to local midnight; t is a fraction of the time period (τ); ω is the angular frequency given by $2\pi/\tau$. The dispersion limits for mesor, amplitude, and acrophase are computed with the population-mean cosinor.[20] The confidence limits are estimated as SEM for mesor and 95% confidence limits for amplitude and acrophase. The Single Cosint method is an integral periodic analysis that estimates the parameter aesor (acronym of area estimating statistic of rhythm), that is, the surface covered by the sinusoidal wave of a given biologic rhythm. The cosint method uses this formula:

$$\text{Aesor} = \int_{t0}^{t24} [M + A \cdot \cos(\omega \cdot t + \phi)]\, dt \qquad (2)$$

where the coefficients have the same meaning as in equation 1. The overall aesor estimates the baric impact as the total number of millimeters of mercury that relate to the systolic and diastolic blood pressure circadian cycle.[21] The aesor may be estimated in a fraction of the circadian time such as diurnal and nocturnal hours (partial aesor). The diurnal and nocturnal aesors differ in relation to the acrophase location. The dispersion limits for the aesor were estimated as SEM.

The sample-related estimates in both the noninferential and inferential procedures were further analyzed to derive the reference limits as 90% tolerance limits (90% TL), herein intended as the reference intervals that include 90% of distribution with 90% of probability. The 90% TL were computed with this formula:

$$90\%\ \text{TL} = M + SD \cdot t_{(0.1)\,(df)} \qquad (3)$$

where M and SD are respectively the mean and standard deviation of the sample distribution, and t is the integral of Student's distribution for a probability $(1 - \alpha)$ of 0.1. *df* is the symbol of the degrees of freedom given by $n - 1$ observations.[22-24]

Comparative statistics. The statistical differences between nonpregnant women and pregnant women were analyzed by different procedures such as the Student *t* test, median test, discriminant analysis, and parameter test, respectively, for the equality of the means, medians, gaussian distribution, and rhythmometric parameters.

Results

Macroscopic cumulative biometry. The analysis of cumulative means and their reference limits for both the 24-hour systolic and diastolic blood pressure patterns is displayed in Table II. The biometric estimates document that the overall mean for systolic and dia-

stolic blood pressure is reduced in pregnant women as compared with nonpregnant women. A *t* test found the gestational reduction of cumulative blood pressure mean level to be statistically significant, even though the values tend to increase during the second and third trimester of pregnancy.

The frequency distribution analysis is illustrated in Table III. The frequency densities document the overall distribution of both the systolic and diastolic blood pressure values as being consistently different in pregnant women as compared with nonpregnant women. The dissimilarity applies to the entire set of descriptive parameters, that is, the median, mode, extremes, range, variation coefficient, 97th percentile, and numerous-

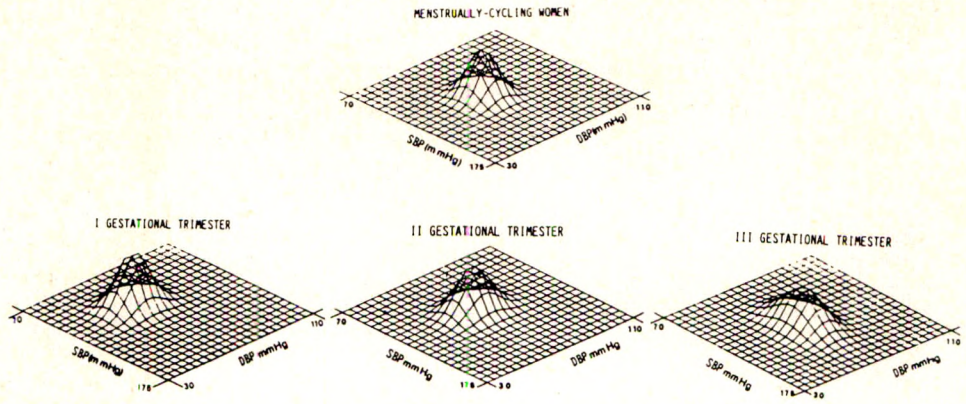

Fig. 1. Bivariate representation of the gaussian distribution found in cumulated values that constitute 24-hour systolic *(SBP)* and diastolic *(DBP)* blood pressure pattern in nonpregnant and pregnant women.

ness of constitutive frequencies. The class repartition documents that the population of blood pressure values is differently composed in pregnant women as compared with nonpregnant women. A median test found the differences in distribution to be statistically significant, even though the medians tend to change during the various trimesters of pregnancy.

The gaussian analysis of the systolic and diastolic blood pressure cumulative distributions is depicted in Fig. 1. The bivariate plots document that a gaussian curve is detectable in both populations of cumulative blood pressure values in pregnant women and nonpregnant women. The gestational systolic and diastolic blood pressure values, however, cover a narrower dispersion in their variability around the mean. A bivariate discriminant analysis found these differences to be statistically significant ($p < 0.001$) within their distributive normality.

Macroscopic temporal biometry. The analysis of time-qualified mean levels and their reference limits is displayed in Table IV. The estimates document that the time-qualified means for both the 24-hour systolic and diastolic blood pressure patterns are consistently different in pregnant women as compared with nonpregnant women. The gestational time-qualified dispersion of values is also peculiar. A t test found the time-qualified decrease of gestational blood pressure values to be statistically significant at each time point (significance ranging from $p < 0.01$ to $p < 0.001$).

More details on the intertime variability of the 24-hour blood pressure patterns are given in Table V. The estimates indicate that the 24-hour mean level of both the 24-hour systolic and diastolic blood pressure patterns is noticeably reduced in pregnant women as compared with nonpregnant women. The differences in time-qualified variability are also well demonstrated by the variation coefficient. A t test found the gestational decrease of 24-hour systolic and diastolic blood pressure mean level to be statistically significant ($p < 0.001$ in each trimester).

Microscopic temporal biometry

Cosinor analysis. The analysis of rhythm properties and their reference limits is reported in Table VI. The p values indicate that the sinusoidality testing validated the occurrence of a circadian rhythm for the 24-hour systolic blood pressure and diastolic blood pressure patterns in both pregnant women and nonpregnant women. However, the gestational systolic and diastolic blood pressure circadian rhythms exhibit a less pronounced mesor and a greater amplitude of oscillation. The first trimester of pregnancy is, additionally, characterized by a consistent shift of the acrophase. The parameter test found the mesor decrease in the gestational blood pressure circadian rhythm to be statistically significant, even though the parameter tends to increase during the second and third trimester of pregnancy.

Cosint analysis. The analysis of baric impact and its reference limits is summarized in Table VII. The estimates indicate that the baric impact of both the systolic and diastolic blood pressure circadian rhythms is reduced in pregnant women as compared with nonpregnant women. A t test found the gestational decrease of baric impact to be statistically significant.

Comment

An unanswered question relates to the reason(s) why blood pressure changes so deeply during pregnancy. To answer this question it is mandatory to explore blood pressure in its naturally occurring changes, taking into consideration that the physiologic arrangement is characterized by a within-day variability.[5-7]

We are aware that an approach to the 24-hour blood pressure patterns may be informative if the time series are analyzed by appropriate descriptive statistics. Thus, the statistical approach to the gestational 24-hour blood pressure patterns was made in this study in the most extensive way possible.

The first approach was the macroscopic cumulative biometry, which was performed with the scope of es-

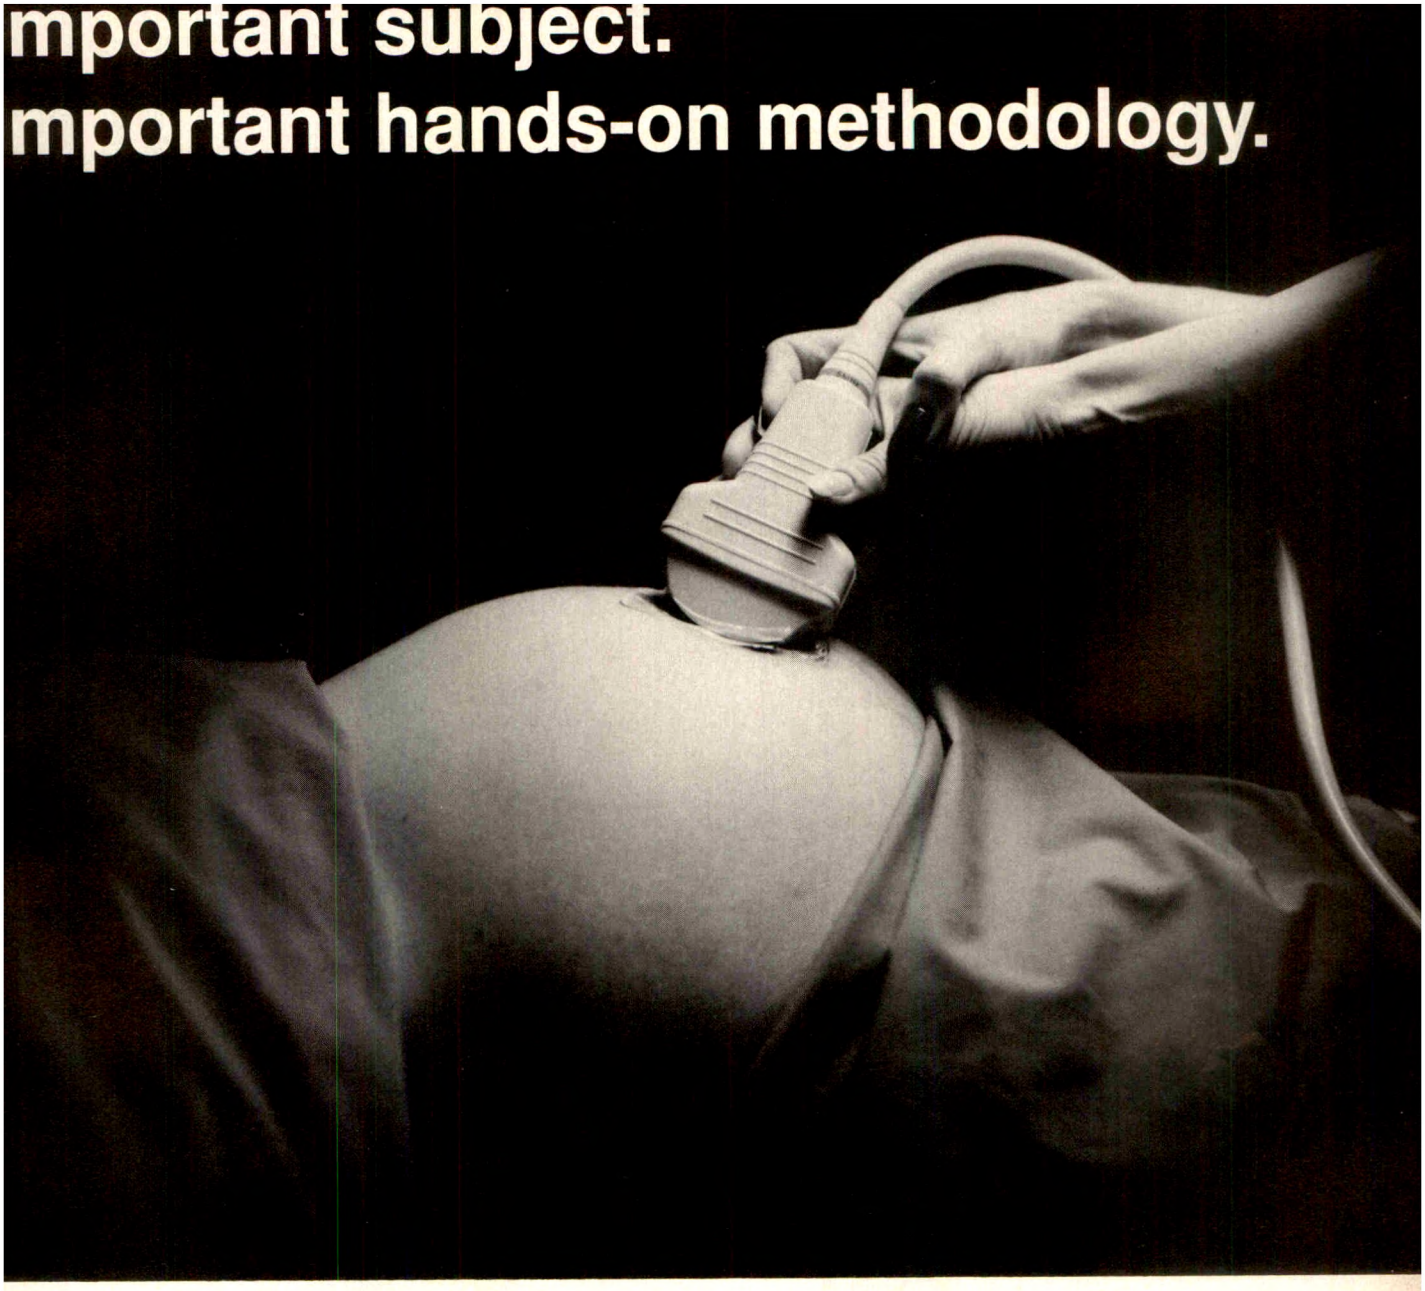
‡$p < 0.05$

timating the overall distribution of both the 24-hour systolic and diastolic blood pressure patterns. The analysis invariably documented a less pronounced mean level in gestational blood pressure. The frequency analysis, in turn, revealed that blood pressure values in pregnancy are consistently shifted toward the left side of the distribution. The discriminant analysis clarified that such a shift is statistically significant. The shift notwithstanding, the gestational blood pressure values appear to be normally distributed, authorizing the approach to their reference limits via the parametric statistics. Accordingly the reference limits computed in our study by the statistical correction of *t* distribution appear to be appropriate for deciphering the normality in the gestational 24-hour blood pressure pattern.

The second approach was the macroscopic temporal biometry performed to quantify the distribution of the gestational 24-hour blood pressure pattern around the clock. The time-qualified measures of central distribution documented that gestational blood pressure values show a homogeneous decrease in mean levels causing the temporal profile to reach a less pronounced height. The lower level of the within-day curve suggests that pregnancy acts to modify the physiologic properties of blood pressure in their global structure. This is the reason why the time-qualified standard limits reported in our study may be regarded as appropriate references for the gestational blood pressure monitoring.

The third approach was the microscopic temporal biometry that provided an unambiguous interpretation

of the bioperiodicity of the gestational 24-hour blood pressure pattern. Basically, the cosinor method documented that the blood pressure circadian rhythm shows peculiar properties in pregnant women. The rhythmometric changes manifested themselves during the first trimester; the blood pressure fluctuation took place late in the evening with a delay of about 6 hours. However, the acrophase tends to advance timing, the orthodox phase being adjusted since the second trimester of pregnancy. It is important that the blood pressure circadian rhythm in pregnancy was invariably seen to show a consistent reduction in mesor, unequivocable expression of a structural interaction with the entire pattern. The reference limits of this adjustment are clearly computed in our study.



The last approach in the microscopic temporal biometry was the cosint analysis, which documented the gestational 24-hour blood pressure pattern to change in one of the most important physiologic attributes. Because the baric impact is frankly reduced, it can be concluded that pregnancy globally reduces the blood pressure load during the 24-hour span. The standard limits of this reduction are clearly visible in our study.

It must be stressed that the physiologic properties of biologic rhythms have a meaning from a functional point of view. With respect to this, it is important to remember that the mesor is the measurable expression of the tonic level for a given periodic function. The amplitude and acrophase, in turn, are the quantitative and temporal estimates of the phasic activity for a given rhythm. When the mesor varies in magnitude, its change may be seen as a quantitative modulation of the tonic property. When the amplitude changes in extent, its variation can be regarded as a quantitative modulation of the phasic activity. Last, when the acrophase rotates in timing its shift may be considered a temporal readjustment of the phasic periodicity. Translating this into the present findings means that the gestational 24-hour blood pressure pattern changes prominently in its tonic regulation. The readjustment of the blood pressure circadian tone is the mechanism for which pregnancy is able to reduce the baric impact, providing concrete protection to arterial vasculature.

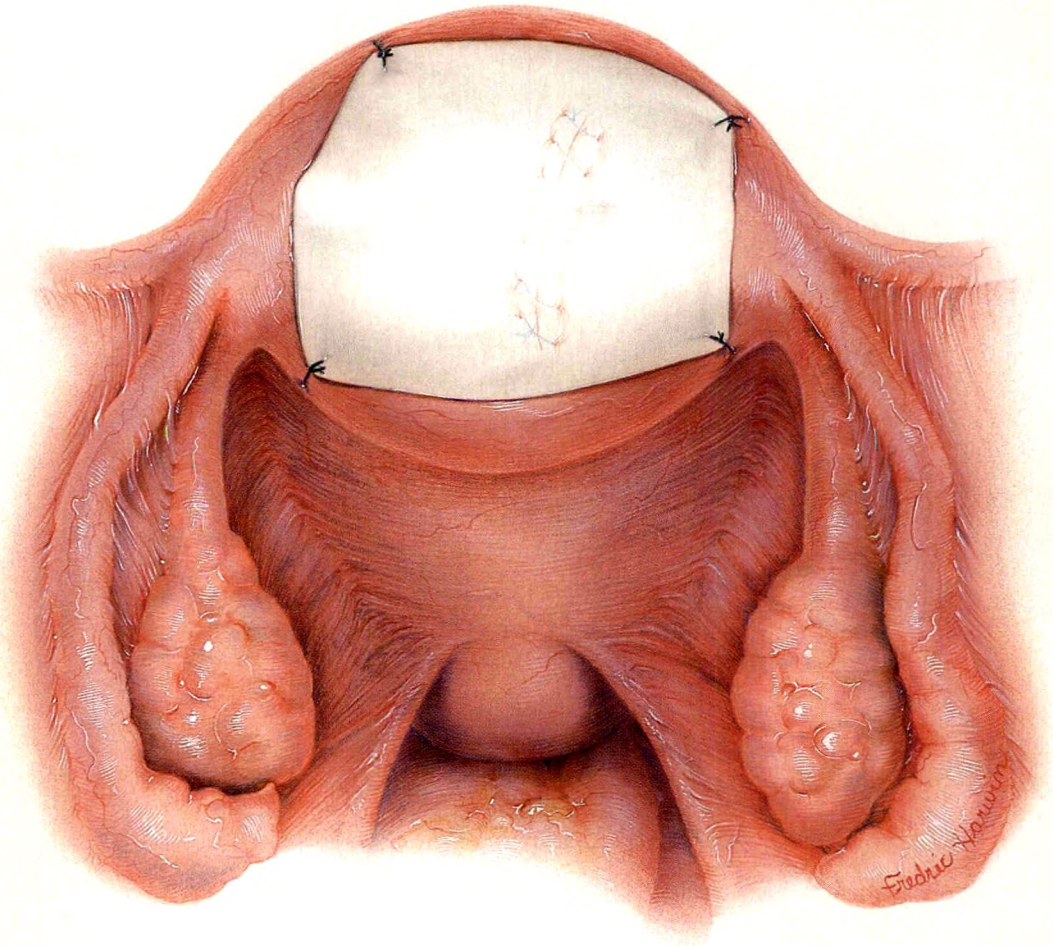
mportant subject.
mportant hands-on methodology.



xceptional skills are born of exceptional training. And there e none better than skills gained on a live, pregnant patient. or the last decade we've emphasized not only the how of the ience of ultrasound, but also the why behind each technique. /e offer comprehensive training seminars in abdominal, ascular, obstetric/pelvic, and cardiac ultrasound. And, for our convenience, our seminars are held in major cities across e United States as well as at our modern new facility in the Dallas area. We offer a variety of two-, three-, and five-day programs at reasonable fees. Classes are roughly half thoery and half intensive hands-on training. Class size is strictly limited, and postconference support is free to our guests—forever. All of our seminars are SDMS-approved for CEUs. Call KMA 24 hours a day for a free information kit that tells you about us and any of the twenty different seminars we conduct regularly.

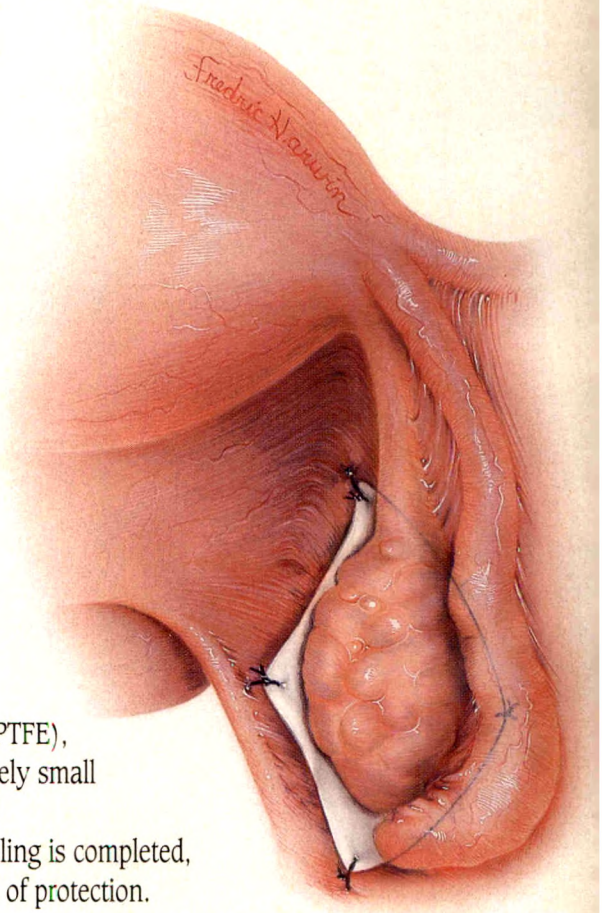
Invariant Performanc

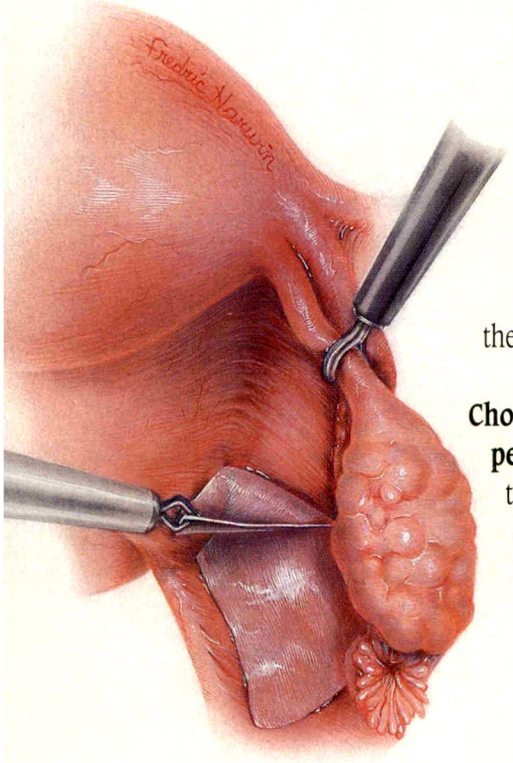
Reconstruction..



The GORE-TEX Surgical Membrane — Configured for Peritoneal Reconstruction — protects denuded areas while healing progresses beneath the material.

®GORE-TEX is a registered trademark of W.L. Gore & Associates, Inc. ©1990 W.L. Gore & Associates, Inc.

n Peritoneal



..The GORE-TEX® Surgical Membrane
'he Choice in Peritoneal Reconstruction

Successful peritoneal reconstruction following pelvic surgery in ıe female requires dependable measures to establish the continuity of the peritoneum and the normal anatomy of the pelvic area. Medical literature reports the use of an inert, nonabsorbable barrier as an attractive means of approaching this goal.

Performance by Design

Composed of the inert biomaterial expanded polytetrafluoroethylene (e-PTFE), he GORE-TEX Surgical Membrane limits tissue attachment with an extremely small pore size (<1μ). The nonabsorbable GORE-TEX Surgical Membrane is a physical barrier that remains in place to protect denuded areas as healing is completed, unlike absorbable materials, which provide a limited time of protection.

Proven and Established

The GORE-TEX Surgical Membrane has a long record of safety and effectiveness It has demonstrated reliability among cardiac surgeons for more than 14 years. I addition, use in multicenter clinical studies continues to substantiate safety and the invariant performance of the GORE-TEX Surgical Membrane.

Convenient

Available in specific configurations tailored for peritoneal reconstruction; the GORE-TEX Surgical Membrane — *Configured for Peritoneal Reconstruction* — is packaged sterile and **can be resterilized**.

Choose the GORE-TEX Surgical Membrane for invariant performance in peritoneal reconstruction. To receive further information or to consult with an application specialist, call **800-437-8181**. For orders and overnight delivery 24 hours a day, call **800-528-8763**.

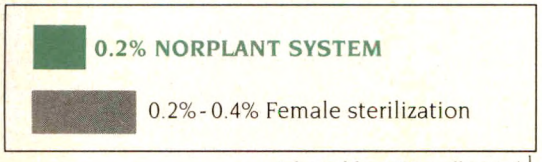
NORPLANT® SYSTEM

levonorgestrel implants



Six reasons why you can feel comfortable recommending it to your patients

Effectiveness comparable to tubal ligation

Although no contraceptive is 100% effective, the NORPLANT SYSTEM is one of the most effective forms of birth control ever developed. The average annual gross pregnancy rate over a five-year period is less than 1%.

Lowest expected and typical failure rates with NORPLANT SYSTEM vs. sterilization during first-year use[1]

Adapted from Trussell J, et al.[1]

Long-term convenience... estrogen-free

NORPLANT SYSTEM, a progestin-only contraceptive, is an excellent option for women desiring a long-term method. Its effectiveness lasts for five years and is not dependent on compliance.

Reversible, with prompt return to previous level of fertility

NORPLANT SYSTEM is reversible at any time; the contraceptive effect ceases when the capsules are removed. In one study, 40% of women wanting to conceive did so within 3 months of removal, 63% by 6 months, 76% by 12 months, and 90% by 24 months.[2]

High patient acceptance despite menstrual pattern changes

NORPLANT SYSTEM causes menstrual irregularities (the most common complaint),* which occur in many women during first-year use and diminish over time. Only 9.1% of patients discontinued during first-year use due to these changes.[3†]

Women who are thoroughly informed of potential menstrual changes and side effects are more tolerant of them when they occur.[4]

Well-received, well-liked by American women

One study of 140 users revealed that 94% were satisfied with NORPLANT SYSTEM, 91% recommended it to their friends, and 74% wanted to use it again.[5]

A 10- to 15-minute office procedure

A local anesthetic and a small 2 mm incision...little or no discomfort during insertion...proper placement should not leave a noticeable scar...in most cases sutures are not needed.

*Serious as well as minor side effects may occur (see prescribing information).

†Based on multicenter trials of 2,470 women.

Please see brief summary of prescribing information on adjacent page.

NORPLANT® SYSTEM

levonorgestrel implants

Lasts 5 years...yet is reversible

NORPLANT® SYSTEM

levonorgestrel implants

Lasts five years…yet is reversible

BRIEF SUMMARY OF PRESCRIBING INFORMATION. CONSULT THE PACKAGE LITERATURE FOR FULL PRESCRIBING INFORMATION.

Indications and Usage

The NORPLANT SYSTEM is indicated for the prevention of pregnancy and is a long-term (up to 5 years) reversible contraceptive system. The capsules should be removed by the end of the 5th year. New capsules may be inserted at that time if continuing contraceptive protection is desired.

Contraindications

1. Active thrombophlebitis or thromboembolic disorders. 2. Undiagnosed abnormal genital bleeding. 3. Known or suspected pregnancy. 4. Acute liver disease; benign or malignant liver tumors. 5. Known or suspected carcinoma of the breast.

Warnings

A. WARNINGS BASED ON EXPERIENCE WITH THE NORPLANT SYSTEM

1. *Bleeding Irregularities* — Most women can expect some variation in menstrual bleeding patterns. Irregular menstrual bleeding, intermenstrual spotting, prolonged episodes of bleeding and spotting, and amenorrhea may occur, and could mask symptoms of cervical or endometrial cancer. Overall, these irregularities diminish with continued use. Because amenorrhea may occur, missed menstrual periods cannot serve as the only identifier of early pregnancy. Perform pregnancy tests whenever pregnancy is suspected. If pregnancy occurs, the capsules must be removed. Hemoglobin concentrations found in clinical trials generally indicated that reduced menstrual blood loss is associated with NORPLANT SYSTEM use. Blood loss resulting in hemoglobin values consistent with anemia occurred rarely.

2. *Delayed Follicular Atresia* — Atresia of the follicle is sometimes delayed, resulting in enlarged follicles that are clinically indistinguishable from ovarian cysts. In the majority of women, enlarged follicles disappear spontaneously. Rarely, they twist or rupture and surgical intervention may be required.

3. *Ectopic Pregnancies* — Ectopic pregnancies have occurred among NORPLANT SYSTEM users, although clinical studies have shown no increase in the rate of ectopic pregnancies per year among NORPLANT SYSTEM users as compared with users of no method or of IUDs. The incidence among NORPLANT SYSTEM users (1.3 per 1000 woman-years) was significantly below the rate estimated for noncontraceptive users in the U.S. (2.7 to 3.0 per 1000 woman-years). Ectopic pregnancy risk may increase with duration of NORPLANT SYSTEM use and increased weight of the user. Rule out ectopic pregnancy in any patient presenting with lower-abdominal pain.

4. *Breast-feeding* — Steroids are not the contraceptives of first choice for lactating women. Levonorgestrel has been identified in breast milk. Limited data suggests no significant effects on infant growth or health when mothers used the NORPLANT SYSTEM beginning 6 weeks after parturition.

5. *Foreign-body Carcinogenesis* — Rarely, cancers occur at foreign-body intrusion sites or old scars. None has been reported in NORPLANT SYSTEM clinical trials and risk to users is judged to be minimal.

6. *Thromboembolic Disorders* — Remove capsules if active thrombophlebitis or thromboembolic disease develops. With prolonged immobilization removal should be considered.

B. WARNINGS BASED ON EXPERIENCE WITH COMBINATION (PROGESTIN PLUS ESTROGEN) ORAL CONTRACEPTIVES (OCs)

Note: Many of the side effects or risks listed below are thought to be estrogen-related; the association of the NORPLANT SYSTEM progestin-only method to these risks is unknown.

1. *Cigarette Smoking* — Cigarette smoking increases the risk of serious cardiovascular side effects from combined OC use. Risk increases with age and heavy smoking (≥15 cigarettes/day) and is quite marked in women over 35 years old.

2. *Elevated Blood Pressure* — Increase in blood pressure has been reported in combination OC users; prevalence increases with long exposure.

3. *Thromboembolic Disorders and Other Vascular Problems* — An increased risk of thromboembolic and thrombotic disease is associated with combination OC use. Estimate of relative risk is 4- to 11-fold higher for users vs. nonusers.

Cerebrovascular Disorders: Combination OCs increase the relative and attributable risk of cerebrovascular events (thrombotic and hemorrhagic strokes). Generally, risk is greatest among hypertensive women > 35 years of age who smoke.

Myocardial Infarction (MI): An increased risk of MI has been attributed to combined OC use. This is thought to be primarily thrombotic in origin and related to the estrogen component. Increased risk occurs primarily in smokers or women with other underlying risk factors for coronary-artery disease. Relative risk of heart attack for combined OC users is estimated as 2 to 6 times that for nonusers. Absolute risk is very low for women under 30 years old.

Studies indicate a significant trend toward higher MI and stroke rates with increased progestin doses in combination OCs. However, recent data indicated no increased MI risk with past use of levonorgestrel-containing OCs.

4. *Carcinoma* — Recent evidence in the literature suggests no association between OC use and increased risk of breast cancer in the overall population of users. The Cancer and Steroid Hormone (CASH) study also showed no latent effect on breast cancer risk for at least a decade following long-term use. Some of these same studies have shown an increased relative risk of breast cancer in certain subgroups; no consistent pattern has been identified. Some studies suggest an association between combination OCs and an increase in the risk of cervical intra-epithelial neoplasia in some populations of women. The extent to which such findings may be due to differences in sexual behavior and other factors remains controversial. A cause-and-effect relationship between combined OC use and breast or cervical cancer has not been established. Combination OCs may decrease ovarian and endometrial cancer risk. Irregular bleeding patterns associated with NORPLANT SYSTEM use could mask cervical or endometrial cancer symptoms.

5. *Hepatic Tumors* — Hepatic adenomas are associated with combination OC use; estimated incidence is 3 events per 100,000 users per year. Risk increases after 4 or more years of use. Hepatic adenomas are benign but may rupture and cause death through intra-abdominal hemorrhage.

6. *Ocular Lesions* — Retinal thrombosis is associated with OC use and is believed to be related to the estrogen component. However, NORPLANT SYSTEM capsules should be removed if there is unexplained partial or complete vision loss; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Undertake appropriate diagnostic and therapeutic measures immediately.

7. *Use Before or During Early Pregnancy* — Extensive epidemiological studies reveal no increased risk of birth defects when OCs are used prior to pregnancy. Studies also do not suggest a teratogenic effect when taken inadvertently during early pregnancy. No evidence suggests that risk with NORPLANT SYSTEM use is different.

8. *Gallbladder Disease* — Early studies reported an increased lifetime relative risk of gallbladder surgery in OC or estrogen users. More recent studies, however, indicate that the relative risk of gallbladder disease with OC use may be minimal; this may be related to use of OCs with less estrogen and progestin content.

Precautions

GENERAL

1. *Physical Examination and Follow-up* — A complete medical history and physical examination should be taken prior to implantation or reimplantation of NORPLANT SYSTEM capsules and at least annually during its use. Exams should include special reference to the implant site, blood pressure, breasts, abdomen and pelvic organs, including cervical cytology and relevant laboratory tests. Rule out malignancy in cases of undiagnosed, persistent or recurrent abnormal vaginal bleeding. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care.

2. *Carbohydrate Metabolism* — Altered glucose tolerance is found in some combination and progestin-only OC users. Effects of NORPLANT SYSTEM on carbohydrate metabolism appear minimal. Observe diabetic and prediabetic patients carefully while using the NORPLANT SYSTEM. Follow women being treated for hyperlipidemias closely if using the NORPLANT SYSTEM. Some progestins may elevate LDL and may render control of hyperlipidemias more difficult. (See **Warnings**.)

3. *Liver Function* — Consider removing capsules if jaundice develops. Steroid hormones may be poorly metabolized in patients with impaired liver function.

4. *Fluid Retention* — Steroid contraceptives may cause some degree of fluid retention. Prescribe with caution, and careful monitoring, in patients with conditions possibly aggravated by fluid retention.

5. *Emotional Disorders* — Consider removing capsules if significant depression occurs since the symptom may be drug-related. Observe carefully those with history of depression and consider removal if depression recurs to a serious degree.

6. *Contact Lenses* — Contact-lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist.

7. *Insertion and Removal* — Insertion is advised during the first 7 days of the cycle or immediately following abortion to insure that the woman is not pregnant and to assure contraceptive effectiveness during first cycle of use. Capsules may be inserted at any time during the cycle provided pregnancy has been excluded and a nonhormonal contraceptive method is used for the remainder of the cycle. Insertion is not recommended before 6 weeks postpartum in breast-feeding women. Follow insertion and removal instructions closely. Healthcare professionals are strongly advised to be instructed in the procedures before they attempt them. Proper insertion just under the skin facilitates removals; proper insertion and removal should result in minimal scarring. If all capsules cannot be removed at first attempt, attempt removal later when the site has healed. Bruising may occur at implant site during insertion or removal. Hyperpigmentation may occur over implant site but is usually reversible following removal. **See Full Prescribing Information for Detailed Insertion/Removal Instructions.**

8. *Infections* — Implant site infection has been uncommon (0.7%); aseptic technique and proper insertion/removal reduces possibility of infection. Institute treatment if infection occurs; remove capsules if infection persists.

9. *Expulsion* — Expulsion of capsules was uncommon; frequency increased when capsule placement was extremely shallow, was too close to incision, or when infection was present. Replace expelled capsule with new sterile capsule. Treat and cure any infection before replacement. Contraceptive efficacy may be inadequate with fewer than 6 capsules.

10. *Provisions for Removal* — Advise women that capsules may be removed at any time for any reason. Personnel instructed in removal technique should perform removal on request or at the end of 5 years of usage. Upon removal, dispose of capsules in accordance with Centers for Disease Control Guidelines for biohazardous waste.

DRUG INTERACTIONS: Reduced efficacy (pregnancy) in NORPLANT SYSTEM users has been reported when phenytoin or carbamazepine were used concomitantly. Warn NORPLANT SYSTEM users of possible decreased efficacy with use of related drugs.

DRUG/LABORATORY TEST INTERACTIONS: 1. Sex-hormone-binding globulin concentrations are decreased. 2. Thyroxine concentrations may be slightly decreased and triiodothyronine uptake increased.

CARCINOGENESIS: See **Warnings** section and Full Prescribing Information.

PREGNANCY: Pregnancy Category X. See **Warnings** section and Full Prescribing Information.

NURSING MOTHERS: See **Warnings** section and Full Prescribing Information.

INFORMATION FOR THE PATIENT: See Patient Labeling. Provide copy of patient labeling to the patient. Advise patients that Prescribing Information is available upon request. Inform prospective users of risks and benefits associated with NORPLANT SYSTEM use, with other forms of contraception, with no contraception, and about insertion/removal procedures. Informed consent from all patients may be desired in light of techniques involved with insertion and removal.

Adverse Reactions

The following have been associated with the NORPLANT SYSTEM during first year of use: many bleeding days or prolonged bleeding (27.6%); spotting (17.1%); amenorrhea (9.4%); irregular (onsets of) bleeding (7.6%); frequent bleeding onsets (7.0%); scanty bleeding (5.2%); pain or itching near implant site - usually transient - (3.7%); infection at implant site (0.7%); removal difficulties affecting subjects - based on 849 removals - (6.2%).

Controlled clinical studies suggest that the following, occurring during the first year, are probably associated with NORPLANT SYSTEM use: headache; nervousness; nausea; dizziness; adnexal enlargement; dermatitis; acne; change of appetite; mastalgia; weight gain; hirsutism, hypertrichosis, and scalp-hair loss. The following were reported with a frequency of 5% or greater during the first year and possibly may be related to NORPLANT SYSTEM use: breast discharge; cervicitis; musculoskeletal pain; abdominal discomfort; leukorrhea; vaginitis.

Overdosage

Overdosage may cause fluid retention with its associated effects and uterine bleeding irregularities.

Dosage and Administration

The NORPLANT SYSTEM consists of six Silastic® capsules, each containing 36 mg of the progestin, levonorgestrel. The total administered (implanted) dose is 216 mg. Implantation of all six capsules should be performed during the first 7 days of the onset of menses by a healthcare professional instructed in the NORPLANT SYSTEM insertion technique. Insertion is subdermal in the midportion of the upper arm about 8 to 10 cm above the elbow crease. Distribution should be in a fanlike pattern, about 15 degrees apart, for a total of 75 degrees. Proper insertion will facilitate later removal. **(See Full Prescribing Information for Detailed Insertion/Removal Instructions.)**

Derivation of new mathematic formulas for determining whether a D-positive father is heterozygous or homozygous for the D antigen

Michael H. Kanter, MD
Los Angeles, California

OBJECTIVES: This article derives new mathematic formulas to calculate the probability that the husband of a D-negative woman is heterozygous for the D antigen.
STUDY DESIGN: Current published formulas and tables that estimate this probability are biased in that they incorrectly assume that the father is randomly selected from the general population. With Bayes' theorem, new formulas were derived to eliminate this bias.
RESULTS: The probability of the husband being homozygous or heterozygous for the D antigen can be expressed as a function of the number of previous D-positive children. If he has any D-negative children, he is an obligate heterozygote.
CONCLUSION: Previously published formulas and tables that estimate the likelihood of the father being heterozygous or homozygous at the D locus should no longer be used in the obstetric setting. (Am J Obstet Gynecol 1992;166:61-3.)

Key words: Erythroblastosis fetalis, Rh-Hr blood group system, Rh isoimmunization, hemolytic disease of the newborn

In spite of the success of Rh immune globulin in reducing the incidence of sensitization to the D antigen, anti-D still develops in D-negative women of childbearing age.[1] This sensitization may result from failure to receive Rh immune globulin during a previous pregnancy, failure of Rh immune globulin to prevent sensitization when it is given, or from previous transfusion of D-positive blood.

Numerous textbooks[1-9] state that when anti-D develops it is important to know whether the woman's mate is homozygous or heterozygous at the D locus. The reason for determining this is that a homozygous D-positive father will produce only D-positive offspring, whereas a heterozygous father has a 50% chance of producing a D-negative offspring in whom hemolytic disease of the newborn cannot develop as a result of anti-D. The main use of this knowledge is in advising a couple as to the risk that a future baby will have severe hemolytic disease of the newborn and in deciding about permanent sterilization or artificial insemination from a D-negative donor.[6] Others[5] state that knowledge of whether the father is heterozygous or homozygous for the D antigen has prognostic value in the patient who is already pregnant.

Unfortunately, the D antigen cannot be detected directly. Therefore determining the zygosity of the D-positive father is done indirectly by phenotyping the father for the C, c, E, and e antigens, which are closely linked to the D locus. Published formulas or tables from several standard textbooks,[1, 4-7] are then used to determine the zygosity of the D antigen. During a previous study of hemolytic disease of the newborn,[10] however, it became obvious that these formulas give biased results (subsequent text).

Specifically, the widely used formulas and tables incorrectly assume that the person being tested is selected randomly from the population. In reality, testing is performed only on husbands of D-negative women who have been sensitized to the D antigen. As noted, this situation usually occurs as a result of the couple's previously having had D-positive children. As a result, the prospective father being tested is more likely to be homozygous at the D locus than one randomly selected from the population. Similarly, if the prospective father has had even a single D-negative child, he is an obligate heterozygote. Any further testing of the father is not only unnecessary but potentially misleading.

Only a minority of authors[8, 9] recognize this bias, and they fail to give any estimate as to how large it is or what can be done mathematically to eliminate it. As noted, however, the vast majority of authors[1, 4-7] fail even to recognize any bias with currently used methods.

It is the purpose of this article to derive simple mathematic formulas and tables that will provide an unbiased estimate of the likelihood of a prospective father being homozygous or heterozygous at the D locus, on the basis of the number and Rh(D) type of previous

children and the presence of C, c, E, and e antigens in the prospective father.

Derivation of formulas

Only minimal assumptions will be made. For convenience, "father" shall refer to the man for whom it is desired to know whether he is homozygous or heterozygous for the D antigen. The term "mother" shall refer to his mate, who is D-negative and has anti-D in the serum. Only previous offspring by the father and a D-negative mate (she may or may not be the father's current mate) are considered in the formulas. The father will be assumed to be D positive (the formulas do not apply to D^u fathers, and if the father is D negative, there is no concern of hemolytic disease of the newborn as a result of anti-D because there can be no D-positive children). Crossover in the Rh system will be ignored.

Let i = the phenotype of the father at the C, c, E, and e loci, (P(DD | *i*) = the probability that a person randomly selected from the population is homozygous for D, given that he is D positive and has phenotype *i*, and P(Dd | *i*) = the probability that a person randomly selected from the population is heterozygous for D, given he is D positive and has phenotype *i*. Obviously (Dd | *i*) = 1 − P(DD | *i*)

The above quantities are those currently in use, and as noted above, give a bias when the father is known to have had previous D-positive offspring.

We will now use Bayes' theorem[11] to eliminate the bias in the estimates. Let *n* = the number of D-positive children that the father has had by mating with a D-negative woman. If he has had any D-negative children, he is an obligate heterozygote regardless of his tested phenotype *i*, and the formulas derived herein are not necessary. With Bayes' theorem:

$$P(DD \mid i \text{ and } n) = \frac{P(DD|i)P(n|DD)}{P(DD|i)P(n|DD) + P(Dd|i)P(n|Dd)}$$

and P(Dd | *i* and *n*) = 1 − P(DD | *i* and *n*). With Mendel's first law, P (*n* | Dd) = $(1/2)^n$ and P(*n* | DD) = 1. Thus

$$P(DD \mid i \text{ and } n) = \frac{P(DD|i)}{P(DD|i) + P(Dd|i)(1/2)^n}$$

and P(Dd | *i* and *n*) = 1 − P(DD | *i* and *n*).

Values for P(DD | *i*) and P(Dd | *i*) have already been calculated from the gene frequencies of the Rh system and are readily available.[7]

Results

Values for the probability of the father being heterozygous at the D locus [P(Dd | *i* and *n*)] are listed in Tables I and II for whites and blacks, respectively. Note that if *n* = 0 (i.e., if the father has had no previous children), the formulas derived herein reduce to those published elsewhere,[1, 4-7] as expected. One can immediately see that for the father who has had several D-positive children, the probability of his being heterozygous decreases. For some phenotypes this is quite dramatic. For example, if a white D-positive father has the phenotype CcDe, the standard tables in use would indicate that he has a 90% chance of being heterozygous for the D antigen. According to Table I, however, if

he has had three previous D-postive children, the probability of his being heterozygous drops to 0.53. A similarly large potential error exists for whites whose phenotypes are either cDEe or cDe. For the other Rh phenotypes in whites, the presence of previous D-positive offspring still decreases the likelihood of the father being heterozygous; however, the absolute decrease is less. This result occurs because even when previous offspring are ignored or none exist ($n = 0$), the father is already probably homozygous (see Table I).

For blacks, in general, there is less likelihood that the father is heterozygous than for whites. For the phenotypes CcDe, cDEe, and cDe, the father has about a 50% chance of being homozygous for the D antigen if one uses either standard published tables or if he has had no previous children. One can see, however, that if he has had several D-positive children, the odds are more likely that he is homozygous (see Table II).

Comment

The above formulas were derived with very few assumptions (i.e., Mendel's first law, Bayes' theorem). Identical results to the formulas derived herein, however, were obtained by use of more cumbersome but well-accepted methods of genetic analysis.[12]

When using these formulas, one should keep in mind that the race of the father is the one considered in these formulas and tables. Additionally, one is assuming that the father is the true biologic father of any previous children.

At first glance, one might believe that most people do not have very many children and thus any bias introduced by ignoring them is small. This may be the case in the general population, but one must remember that this analysis applies to couples in which the mother has been immunized to the D antigen. In most cases this is the result of having had two or more previous children.[9] Thus one would expect that women immunized to the D antigen, as a rule, have had significantly more children than those among the general population.

The formulas derived in this article have the advantage that all the data should be readily available. Currently, for the immunized mother, most obstetricians should obtain a detailed history, including the blood type of previous offspring and the presence and severity of hemolytic disease of the newborn in previous pregnancies. In addition, most blood banks routinely determine the Rh type of every newborn if the mother is D negative,[7] so that in many cases there may already be a record of the Rh type of any previous offspring. (Repeat testing of the previous offspring may be necessary if previous results are not available.) If a previous fetus died in utero of hemolytic disease of the newborn, for purposes of these formulas, one can assume that the fetus was D positive.

Some authors[5,8,9] have stated that family studies may be of use in determining the zygosity of the father for the D antigen. These studies, however, may still be inconclusive and family members may not be available for testing. Therefore one should use Tables I and II as a preliminary screening device. If the probability of homozygosity is sufficiently close to 0 or 1, family studies would be unnecessary. What value is sufficiently close to 0 or 1 is a completely arbitrary decision. One should keep in mind, however, that if one is 90% certain that a father is homozygous, the probability of the next offspring being D positive is 0.95. In the unusual situation in which family members are available for testing and the formulas yield results that are not sufficiently close to 0 or 1, family studies may be justifiable.

In summary, this article has described new formulas to determine whether a D-positive father is heterozygous or homozygous for the D antigen. These formulas have eliminated the errors of the currently used formulas.[1,4-7] These previously published formulas and tables should not be used for the couple with previous offspring.

I thank Sue E. Hodge, DSc, for her comments and critical review of this manuscript.

Insulin-like growth factor I and II binding in human myometrium and leiomyomas

Yallampalli Chandrasekhar, PhD, James Heiner, MD, Collin Osuamkpe, MS, and Manubai Nagamani, MD

Galveston, Texas

OBJECTIVES: The purpose of this study is to determine if the human myometrium has receptors for insulin-like growth factors I and II and whether the concentration of these receptors is increased in leiomyomas.

STUDY DESIGN: Specific binding of iodine 125–labeled insulin-like growth factors I and II was examined in the membrane preparations of myometrium and leiomyomas obtained from 10 women with uterine leiomyomas.

RESULTS: Binding studies indicate presence of specific binding sites for both insulin-like growth factors I and II in the myometrium and leiomyoma. The concentration of binding sites for insulin-like growth factor I, but not for insulin-like growth factor II, was significantly ($p < 0.01$) higher in leiomyomas than in the myometrium. The dissociation constants for insulin-like growth factors I and II receptors in both myometrium and leiomyoma were similar.

CONCLUSION: insulin-like growth factor I, but not insulin-like growth factor II, receptors are increased in leiomyomas compared with those in myometrium, indicating that insulin-like growth factor I may play a role in the generation and/or growth of this tumor. (Am J Obstet Gynecol 1992;166:64-9.)

Key words: Insulin-like growth factors, IGF-I, IGF-II, myoma

Insulin-like growth factors (IGF) I and II are single-chain peptide hormones that have a high degree of amino acid homology with each other and with proinsulin. Originally named somatomedins because of their potent growth-promoting activity in cartilage and skeletal tissues, the IGFs are now known to act on a variety of other cells and nonskeletal tissues.[1] Although traditionally the liver has been regarded as the origin of IGFs, several nonhepatic tissues have been shown to contain immunoreactive IGFs and messenger ribonucleic acid (mRNA) for IGFs.[2, 3] Recent studies indicate the presence of mRNA for both IGF-I and IGF-II in the uterine tissue, and estrogens increase this mRNA.[4-7] In the human uterus, both IGF-I and IGF-II are expressed in myometrium and leiomyomas,[6, 7] and immunoreactive IGF-I and IGF-II have been detected in explant cultures of myometrium and leiomyomas.[8]

Estrogens have been shown to stimulate the production of several growth factors in estrogen-responsive cells.[9] There is increasing evidence that the growth factors may function as autocrine, paracrine, and endocrine mediators of estrogen-induced cell growth and differentiation.[8-11] Uterine leiomyomas occur in 25% of women of reproductive age, and growth of these tumors appears to be estrogen dependent.[12, 13] It is possible that this estrogen-induced effect may be mediated through the growth factors.

The actions of IGFs and other growth factors are initiated by their interaction with specific receptors on the target cells. This study was undertaken to evaluate the possible role of IGF-I and IGF-II in the generation or growth of leiomyomas of the uterus. Experiments were designed to determine (1) if human myometrium has receptors for IGF-I and IGF-II and (2) whether the concentration of these receptors is increased in leiomyomas.

Table I. Clinical characteristics of women with and without myomas

	With myomas	*Without myomas*
Age (yr)	38.8 ± 6.3*	38.0 ± 7.0
Parity	3.0 ± 1.8	3.7 ± 1.5
Weight (lb)	210 ± 34	163 ± 80
Percent ideal body weight	172 ± 18	130 ± 53

*Mean ± SD.

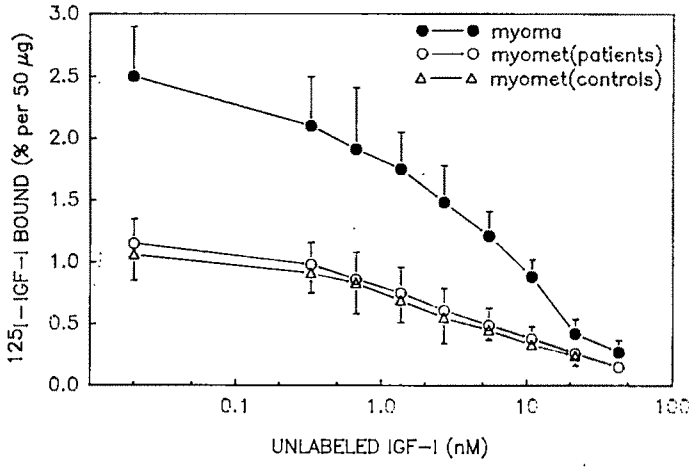

Fig. 1. Inhibition, by increasing concentrations of unlabeled IGF-I, of specific binding of [^{125}I]IGF-I to membrane preparations obtained from myoma or myometrium of women with or without myoma. Binding is expressed as specific binding in percent of total tracer added. Each *data point* is mean ± SEM for 7 to 10 individuals.

Material and methods

Tissue collection and membrane preparation. Samples of myomas and myometrium were obtained from 10 patients with uterine myomas at the time of myomectomy or hysterectomy. The ages of the women ranged from 29 to 48 years (mean 38.8 years). They were not on any hormonal treatment. All of them were multiparous and had a history of irregular menstrual cycles of 1 to 2 years' duration. Endometrial histologic studies revealed focal adenomatous hyperplasia in one patient; all the other women had proliferative endometrium. Samples of leiomyomas were obtained from the center of the tumors, to avoid contamination of myometrium. In each patient the sample was obtained from the largest of all the myomas that were present. The size of the myomas sampled ranged from 4 cm to 10 cm in diameter. For comparison, samples of myometrium were also obtained from seven women without uterine myomas who were undergoing hysterectomy during the proliferative phase of the cycle for nonendocrine problems (cervical dysplasia or uterine prolapse). Endometrial histology in all seven control women indicated proliferative endometrium. Clinical characteristics of women with and without myomas are shown in Table I. Both groups were comparable for age and parity. Body weights of patients with myoma were heavier than weights of those without myomas. Tissue samples were washed with buffer to remove any blood, immediately frozen with liquid nitrogen, and stored at −70° C until the time of preparation of membrane fractions.

Immediately before binding experiments tissue samples were chopped into small pieces with a single-edged razor blade and homogenized at 4° C in 10 mmol/L Tris hydrochloride, pH 7.8, containing 250 mmol/L sucrose and 1 mmol/L calcium chloride (Tris hydrochloride buffer).[14] Homogenization was done at a setting of 70 in a Tekmar Tissumizer (Tekmar Co., Cincinnati) with three 15-second bursts and a 1-minute cooling interval. The homogenates were centrifuged at 800 *g* for 10 minutes to remove tissue fragments and nuclei. The supernatants were recentrifuged at 35,000 *g* for 30 minutes, and the membrane pellets were washed twice and resuspended in Tris hydrochloride buffer with 0.1% gelatin. Protein concentration in the membrane preparations were determined by the method of Lowry et al.[15] with bovine serum albumin used as standard.

specimen were incubated in triplicate with 0.01 nmol/L [^{125}I]IGF (Amersham, Arlington Heights, Ill.) in the absence or presence of seven or eight concentrations (0.33 to 43.0 nmol/L) of unlabeled IGF (Amgen Biologicals, Thousand Oaks, Calif.) in a volume of 0.2 ml Tris hydrochloride buffer with 0.1% gelatin. The incubations were carried out for 3 hours at 22° C or for 16 hours at 4° C for IGF-II and IGF-I binding, respectively. After the separation of the bound from free [^{125}I]IGF by centrifugation or filtration, specific binding data were analyzed according to the method of Scatchard with a Ligand software program to determine apparent dissociation constants and specific binding capacities. A correlation coefficient of >0.95 was obtained for all the Scatchard plots, indicating that the points form a straight line. The student *t* test was used to compare the differences in IGF binding capacities.

Specificity studies. To evaluate the specificity of IGF binding, membrane fractions of myometrium were incubated in the presence of constant amounts (1×10^5 counts/min) of [^{125}I]IGF with or without increasing concentration (0.33 to 400 nmol/L) of unlabeled IGF-I, IGF-II, or insulin.

Results

IGF-I. Specific binding of [^{125}I]IGF-I to membrane fractions obtained from myoma tissues (mean ± SE 2.5% ± 0.4% per 50 μg protein) was significantly ($p < 0.01$) higher than that to myometrial membranes obtained from the same uterus (1.15 ± 0.20). Specific binding of IGF-I to membrane fractions from myometrium of women with myomas was not significantly different from that of women without myomas (1.06 ± 0.21) (Fig. 1).

Displacement of the specific binding of [^{125}I]IGF-I to the membranes by unlabeled IGF-I was dose dependent and was similar for both myometrial and myoma tissues. Both myometrial and myoma membranes bound IGF-I with high affinity (Fig. 2). The apparent dissociation constants of IGF-I binding were similar in membranes prepared from myomas (4.9 ± 0.6 nmol/L) and myometrial tissues obtained from women with (3.9 ± 0.7 nmol/L) or without myoma (3.6 ± 0.9 nmol/L). On the contrary, the number of specific binding sites for IGF-I in myomas (299.3 ± 70.5 fmol/mg protein) were significantly ($p < 0.01$) higher than that in myometrium obtained from women with (81.8 ± 24.5 fmol/mg protein) or without (75.0 ±

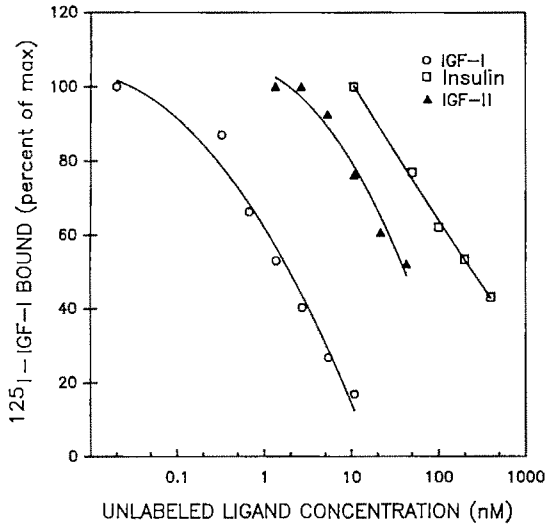

Fig. 5. Competition of increasing concentrations of cold IGF-I, IGF-II, and insulin for [^{125}I]IGF-I binding to myometrial membranes. Binding is expressed as percentage of maximum binding in absence of cold ligand. Total binding of [^{125}I]IGF-I to myometrial membranes in absence of cold ligand was 2.8%/50 μg protein. Each *point* represents mean of triplicates.

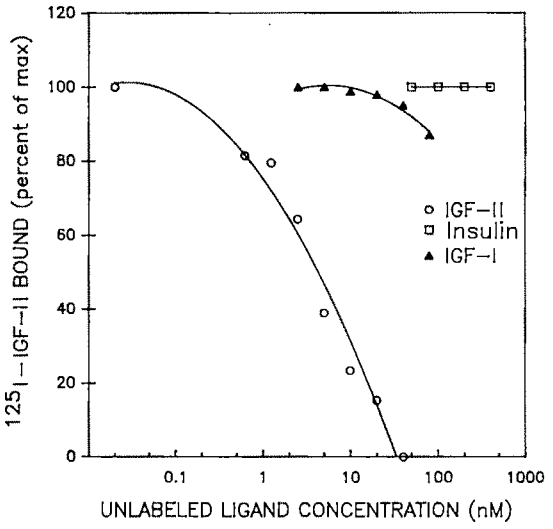

Fig. 6. Competition of unlabeled IGF-II, IGF-I, and insulin for specific [^{125}I]IGF-II binding to myometrial membranes. Binding is expressed as percentage of maximum binding in absence of cold ligand. Total binding of [^{125}I]IGF-II to myometrial membranes in absence of cold ligand was 8.9%/50 μg protein. Each *point* represents mean of triplicates.

27.5 fmol/mg protein) myoma. There was no correlation between IGF-I binding and the size of the myomas.

IGF-II. Specific binding of [^{125}I]IGF-II to membrane fractions was similar in myoma (6.58% ± 0.91% (±SE)/50 μg protein) and myometrial membranes obtained from women with (6.31 ± 0.84) or without (6.43 ± 1.11) myoma (Fig. 3). Displacement of the specific binding of [^{125}I]IGF-II to the membranes by unlabeled IGF-II was dose dependent and was similar for myometrial and myoma tissues. Scatchard analysis of the binding indicated a single class of high-affinity binding site in both myoma and myometrium (Fig. 4). The apparent dissociation constants of IGF-II binding were similar in membranes prepared from myomas (4.26 ± 0.41 nmol/L) and myometrial tissue obtained from women with (3.95 ± 0.68 nmol/L) or without (4.15 ± 0.90 nmol/L) myomas. In contrast to IGF-I, specific IGF-II binding sites are not significantly different between myoma (528.1 ± 68.7 fmol/mg protein) and myometrium with (562.3 ± 71.4 fmol/mg protein) or without (588.4 ± 94.5 fmol/mg protein) myoma.

Specificity studies. IGF-I was more potent than IGF-II in displacing [^{125}]IGF-I binding to myometrial membranes, whereas insulin demonstrated considerably lower inhibitory potency (Fig. 5). IGF-II was able to displace [^{125}I]IGF-II binding to these membranes in a dose-dependent manner. There was only slight displacement of [^{125}I]IGF-II observed with very high concentrations of IGF-I and no displacement by insulin (Fig. 6). These observations are in accordance with the general properties of IGF-I aand IGF-II receptors.

Comment

Even though uterine leiomyomas are one of the most common gynecologic tumors, little is known about their origin or what stimulates their growth. Townsend et al.[16] observed that myomas are derived from growth and proliferation of a single smooth muscle cell. In the current study we have demonstrated the presence of specific binding sites for both IGF-I and IGF-II in the human myometrium and leiomyomas. Presence of increased numbers of binding sites for IGF-I, but not IGF-II, in leiomyomas compared with myometrium indicates that IGF-I may play a role in the generation or growth of this tumor.

This is the first demonstration of IGF-II binding in leiomyomas and myometrium. There has been only one previous report on IGF-I binding in leiomyomas. Our observation of an increased number of binding sites for IGF-I in myomas is in agreement with this report.[17] We have made an additional observation that there is no significant difference in IGF-I binding sites in myometrial tissues obtained from women with or without myoma. The other growth factor that has been studied in myomas is epidermal growth factor.[17,18] EGF was not increased in myomas in these previous studies.

Insulin-like growth factors are known to bind with high affinity to two types of cell-surface receptors: type I, which generally binds IGF-I preferentially over IGF-II and shows a low affinity for insulin, and type II,

which binds IGF-II with high affinity, has negligible binding affinity for IGF-I, and has no affinity for insulin.[19, 20] In the current study we examined the specificity of IGF-I and IGF-II binding to the myometrial membranes. Binding of both IGF-I and IGF-II was specific to their receptors, as revealed from competitive inhibition of specific [^{125}I]IGF by various unlabeled ligands.

Many cell types have been demonstrated to produce IGF-binding proteins, and these binding proteins may modulate IGF action locally in various tissues.[21, 22] At least three IGF binding proteins have been sequenced and their complementary deoxyribonucleic acid cloned, and human endometrial cells have been found to secrete IGF binding proteins.[10, 21] To eliminate possible interference by these soluble IGF binding proteins in our IGF receptor assay, the membrane preparations used in these assays were washed several times before they were resuspended in the assay buffer. Using Western ligand blotting methods,[23] we were unable to detect the presence of IGF binding proteins in these membrane preparations (data not shown). Therefore the IGF binding in our assay system indeed represents IGF binding sites in these tissues.

The tendency of uterine myomas to arise and grow during reproductive years and regress after menopause indicates that estrogen could be one of the factors involved in its pathogenesis and growth. This is further supported by the fact that the size of the leiomyomas regress when estradiol levels are suppressed with long-acting gonadotropin-releasing hormone treatment.[24] A significantly higher concentration of estrogen receptors has been observed in the leiomyomas than in the adjacent normal myometrium.[25] Previous studies indicate that both IGF-I and IGF-II are expressed in uterine tissues and are regulated by estrogen.[5] Murphy et al.[5] observed that administration of estradiol significantly increased the expression of mRNA for both IGF-I and IGF-II in rat myometrial and stromal cells. In addition, IGF-I and IGF-II ribonucleic acid has been demonstrated in human leiomyomas.[7] It is possible that estrogen stimulation may enhance expression of both IGF-I and IGF-II in the myometrial tissue. The demonstration of binding sites for both IGF-I and IGF-II indicates an autocrine or paracrine role for these growth factors in uterus. Because there was an increase in myoma binding for IGF-I but not for IGF-II compared with myometrium, it is possible that IGF-I, but not IGF-II, may be mediating the estrogen-induced cell proliferation in uterine myomas and play a role in the generation and growth of leiomyomas of the uterus.

Impairment of counterregulatory hormone responses to hypoglycemia in pregnant women with insulin-dependent diabetes mellitus

Michael P. Diamond, MD,[a] E. Albert Reece, MD,[b] Sonia Caprio, MD,[c] Timothy W. Jones, MD, Stephanie Amiel, MD, Nancy DeGennaro, RN,[b] Andrea Laudano, RN,[a] Mario Addabbo, Robert S. Sherwin, MD,[c] and William V. Tamborlane, MD[d]

New Haven, Connecticut

Intensive insulin therapy directed at elimination of hyperglycemia is advocated during pregnancy in women with insulin-dependent diabetes mellitus. Because such treatment is complicated by frequent hypoglycemic episodes, we evaluated maternal and fetal responses in nine intensively treated pregnant women with insulin-dependent diabetes mellitus during an insulin-induced, gradual, controlled fall in plasma glucose levels. In contrast to values in nonpregnant control women, reductions in glucose to 44 ± 2 mg/dl in pregnant diabetic patients failed to elicit an increase in glucagon levels. Epinephrine release during hypoglycemia was also markedly suppressed in the pregnant diabetic subjects (106 ± 32 vs 327 ± 52 pg/ml in controls, $p < 0.001$). Furthermore, the plasma glucose level at which epinephrine and growth hormone were released was 5 to 10 mg/dl lower in the pregnant women with insulin-dependent diabetes mellitus ($p < 0.05$). The basal feta heart rate remained unchanged and continued to manifest accelerations during the hypoglycemic state. We conclude that the high frequency of hypoglycemia in intensively treated pregnant women with insulin-dependent diabetes mellitus may be due in part to impaired counterregulatory hormonal responses. (Am J Obstet Gynecol 1992;166:70-7.)

Key words: Hypoglycemia, pregnancy, diabetes mellitus, counterregulation, insulin

Infants of mothers with insulin-dependent diabetes mellitus are at increased risk for fetal and neonatal complications, including congenital malformations, stillbirths, macrosomia, and birth injuries.[1] Initiation of intensive insulin therapy aimed at achieving strict glycemic control after conception has resulted in a decreased incidence of all these complications, with the notable exception of congenital malformations.[2, 3] Unfortunately, the methods used to achieve tight regulation of glucose levels have been accompanied by frequent episodes of maternal hypoglycemia.[4] In one report from our center,[4] more than one sixth of blood glucose measurements were <50 mg/dl, all women had hypoglycemic symptoms, and eight of 22 experienced severe hypoglycemia. This frequency of severe hypoglycemic episodes is higher than that reported in nonpregnant patients with insulin-dependent diabetes mellitus receiving either intensive or conventional insulin treatment.[5] Although the mechanisms responsible for the high frequency of hypoglycemia in intensively treated mothers are unknown, this phenomenon may reflect more stringent target glucose goals during pregnancy.

Previous studies in nonpregnant patients receiving intensive insulin therapy suggest that such therapy is associated with the development of suppressed counterregulatory responses to hypoglycemia[6, 7] that appear to be due to a lowering of the plasma glucose level triggering counterregulatory hormone responses.[6] Whether similar adaptations occur in pregnant women with tightly controlled insulin-dependent diabetes mellitus has not been determined. The current study was consequently undertaken to examine maternal homeostatic responses and fetal well-being during a controlled hypoglycemic stimulus with the hypoglycemic clamp technique in pregnant women with tightly controlled insulin-dependent diabetes mellitus.

Material and methods

Nine pregnant patients with insulin-dependent diabetes mellitus (27 ± 2 years old) were recruited from the Yale Diabetes Faculty Practice in the Division of

From the Divisions of Reproductive Endocrinology[a] and Maternal-Fetal Medicine,[b] Department of Obstetrics and Gynecology, the Department of Medicine,[c] and the Department of Pediatrics,[d] Yale University School of Medicine.

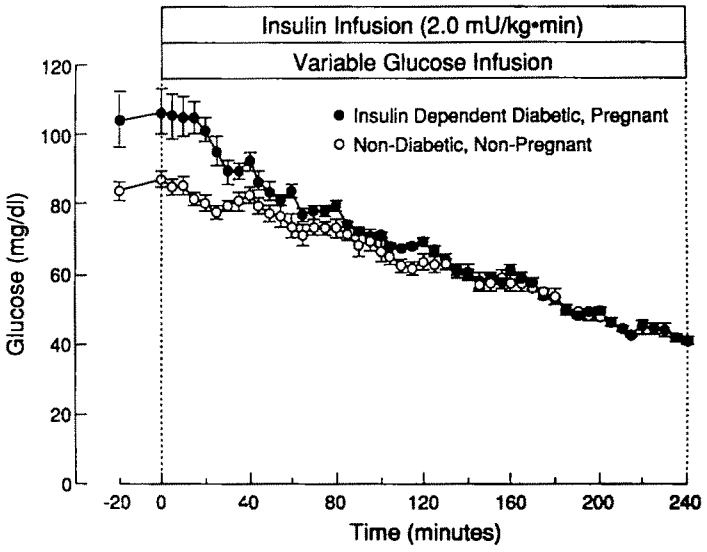

Fig. 1. Plasma glucose levels during hypoglycemic clamp studies in pregnant, intensively treated insulin-dependent diabetic women, and nonpregnant, nondiabetic control women.

Maternal-Fetal Medicine, Department of Obstetrics and Gynecology. To be eligible for study, they had to have had insulin-dependent diabetes mellitus for >1 year before pregnancy, have been treated intensively in the Diabetes in Pregnancy Program for ≥8 weeks, and have been able to achieve glycosylated hemoglobin levels <8.5% (mean ± 3 SD of nondiabetic controls). Patients were excluded if they had other hormone deficiencies or clinical evidence of autonomic neuropathy that might predispose to problems with hypoglycemia. Clinical characteristics of these women, including White's classification, are summarized in Table I. Estimated gestational age at the time of study ranged from 21 to 37 weeks (by last menstrual period and ultrasonographic assessment). The duration of diabetes mellitus in these women ranged from 3 to 22 years (average 16 ± 2 years, median 17 years).

Clinical management of diabetes during pregnancy has been previously described.[4] Briefly, pregnant diabetic women measured blood glucose levels at home approximately seven times per day (before and after each meal and at bedtime) with a reflectance meter. Accuracy of these home measurements was confirmed by weekly laboratory measurements. Insulin doses were continuously adjusted on the basis of the home glucose profiles, with the goal of fasting and preprandial levels <100 mg/dl and 2-hour postprandial levels <120 mg/dl. Rapid-or intermediate-acting insulin was administered as three or more daily injections (n = 8) or by a continuous subcutaneous insulin infusion with a portable pump (n = 1). Hypoglycemic episodes were recorded and subjectively graded as mild (responded to self-administered snack), moderate (required another person's assistance), or severe (required glucagon or intravenous glucose, usually in an emergency room setting). Obstetric management has also been previously described[4] and included antepartum biophysical and biochemical monitoring, serial ultrasonographic examinations, assessment of fetal lung maturity before elective intervention, and a policy of vaginal delivery unless intervening events necessitated cesarean section.

Seven healthy, age-matched, nonobese, nonpregnant, nondiabetic women served as controls. The mean age of these women was 27 ± 2 (range 20 to 35) and their glycosylated hemoglobin value averaged 6.5 ± 0.4. These nondiabetic women received the same hypoglycemic clamp study as the pregnant diabetics, except that the last step lowering the plasma glucose level to 45 mg/dl was omitted (because of symptoms in the nondiabetic subjects).

Written informed consent was obtained from all subjects before the study. The study protocol was approved by the Human Investigation Committee of Yale University School of Medicine.

Procedures. Studies were performed after a 10-hour overnight fast. Diabetic subjects were admitted to the Yale General Clinical Research Center on the evening before the study. Their evening dose of intermediate-acting insulin was omitted. An indwelling intravenous catheter was placed in an antecubital vein for monitoring plasma glucose, and basal insulin replacement was provided by a low-dose intravenous infusion of insulin that was adjusted every 30 to 60 minutes to achieve plasma glucose levels of ~100 mg/dl, without nocturnal hypoglycemia, as previously described.[6]

On the morning of study a second catheter was inserted into a dorsal hand vein, and that hand was then placed in a heated box (65° to 70° C) to arterialize ve-

nous blood.[8] This line was used for blood sampling during the clamp study. After a 30-minute rest period, two blood samples were obtained at 20 minute intervals for measurement of baseline glucose and hormone levels. A primed continuous infusion of rapid-acting human insulin (Novolin R, Squibb-Novo, Princeton, N.J.) was then begun; the continuous rate was 2 mU/kg/min, preceded by priming of 8 mU/kg/min for 5 minutes and 4 mU/kg/min for 5 minutes. Plasma glucose levels were determined every 5 minutes during the insulin infusion with a Beckman Glucose Analyzer II (Beckman, Fullerton, Calif.), and a variable infusion of 20% dextrose was adjusted to maintain the desired glycemic plateau. The plasma glucose level was brought to ~90 mg/dl by the end of the first 40 minutes of the study. Thereafter, plasma glucose was reduced by 10 mg/dl every 40 minutes until a plateau of 50 mg/dl was achieved. In the pregnant diabetic women the study was extended for an additional 40 minutes to allow plasma glucose to fall to 45 mg/dl.

In all pregnancies in which the estimated gestational age of the fetus was ≥30 weeks, a reactive nonstress test was obtained before the study was begun. In those fetuses <30 weeks estimated gestational age or with a nonreactive nonstress test, fetal well-being was established by a biophysical profile score of at least 8 out of 10. Fetal heart rate (FHR) monitoring was performed to assess fetal well-being during each 40-minute plateau. At the completion of the study, the FHR was monitored during reestablishment of a normal glucose level and again after lunch.

Determinations. Plasma glucose was measured in duplicate at the patient's bedside with a glucose analyzer (Beckman). The calibration of the analyzer was checked at 30-minute intervals; the coefficient of variation for the assay was <2%. Catecholamines were measured

with a radioenzymatic assay (Amersham, Arlington Heights, Ill.). Growth hormone (Kallestad Diagnostics, Austin, Tex.), cortisol (Clinical Assays, Cambridge, Mass.), and glucagon (ICN Biomedicals, Inc., Carson, Calif.) were determined by radioimmunoassay. Human chorionic gonadotropin and prolactin were measured by immunoradiometric techniques (Serono Diagnostics, Woking, Surrey, England). Human placental lactogen (hPL) levels were determined by Smith Kline Clinical Laboratories, King of Prussia, Pa. Glycosylated hemoglobin was measured chromatographically after saline solution washing to remove the labile fraction with a microcolumn kit (Isolab, Akron, Ohio).

Analyses. The weekly mean glucose value (see Table I) represents the average of every preprandial and postprandial glucose measurement for a 1-week period before the study and comprises at least four measurements each day of the week. The plasma glucose threshold for hormone release determined during the clamp procedure was defined as the glucose level at which an unequivocal sustained increment in circulating hormone concentrations above basal levels was first observed: 75 pg/ml for epinephrine, 50 pg/ml for norepinephrine, 7 ng/ml for growth hormone, and 7 μg/dl for cortisol.[6] In each subject the mean of all control hormone values was used as the basal hormone level from which significant change was measured. To avoid the confounding effects of spontaneous growth hormone peaks, we used the mean of the four nadir values during the euglycemic phase as the baseline for defining growth hormone thresholds. The incremental value for epinephrine was chosen as one likely to be of clinical relevance,[9] and the values for growth hormone and cortisol were chosen from published definitions of normal responses to the insulin tolerance test of pituitary-adrenal axis function as previously described.[10] These definitions were used to avoid errors caused by small spontaneous fluctuations in hormone levels during the study. Because of differences in basal values during pregnancy for growth hormone and cortisol, these data are presented as the increment above basal values.

Data are presented as mean ± SEM. Comparisons between the diabetic and nondiabetic groups were made by analysis of variance with a repeated-measures design and by the Student t test. Comparisons within each group were performed by analysis of variance and paired t test. A p value <0.05 is reported as significant.

Results

Diabetes control. As shown in Table I, there was a modest variation in weekly mean glucose levels (range 85 to 139 mg/dl) in the patients during intensive treatment. At the time of the clamp study, all but one of the subjects had glycosylated hemoglobin levels in the normal range (i.e., 4% to 8.5%). As expected,[4] achievement of stringent treatment goals was associated with the common occurrence of moderate and severe hypoglycemic episodes (Table I).

Counterregulatory hormone responses. As shown in Fig. 1, basal glucose levels after the overnight fast were higher in the pregnant women with insulin-dependent diabetes mellitus than in control women (105 ± 8 vs 85 ± 2 mg/dl, $p < 0.05$). However, plasma glucose levels were virtually identical in the two groups after the initial 40 minutes of the study (Fig. 1).

As shown in Fig. 2, basal glucagon, epinephrine, and norepinephrine levels were similar in the pregnant diabetics and healthy nonpregnant control subjects. After induction of hypoglycemia, glucagon levels (109 ± 11 pg/ml, basal) in the pregnant subjects with insulin-dependent diabetes mellitus declined slightly to 91 ± 12 pg/ml (p = not significant) by the end of the study (plasma glucose 44 ± 2 mg/dl). In contrast, in the nonpregnant, nondiabetic control group glucagon initially declined but then rose from a plateau level of 75 ± 12 pg/ml to 115 ± 21 pg/ml ($p < 0.01$) when plasma glucose fell to 48 mg/dl.

In the nondiabetic women, plasma epinephrine rose from 41 ± 11 to 327 ± 52 pg/ml ($p < 0.001$) at the

†$p < 0.01$ versus controls.

end of the study when the plasma glucose level was 50 mg/dl. In contrast, in spite of equivalent hypoglycemia, the rise in the plasma epinephrine level in the pregnant diabetic women was blunted and delayed. When the plasma glucose level was lowered to 50 mg/dl in the pregnant women with insulin-dependent diabetes mellitus the rise in plasma epinephrine level was only one third (106 ± 32 pg/ml) of that seen in control women ($p < 0.001$). Even when the glucose level was lowered to 44 ± 2 mg/dl, the epinephrine level was still lower than that observed in controls (Fig. 2). Furthermore, the plasma glucose threshold triggering release of epinephrine was 46 ± 2 mg/dl, a value significantly less than that in control subjects (55 ± 3, $p < 0.05$) (Table II). There was no significant difference in the rise of norepinephrine in the two groups during hypoglycemia.

Basal immunoreactive growth hormone levels were elevated in the pregnant diabetic women (11.0 ± 0.7

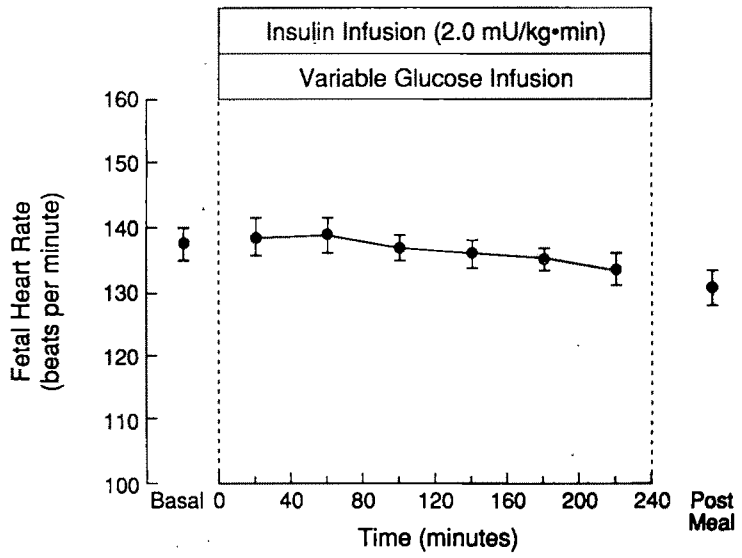

Fig. 5. FHRs from pregnant, intensively treated insulin-dependent diabetic pregnancies during hypoglycemic clamp studies.

Table IV. Glucose and hormone levels during hypoglycemic clamps in previously described nonpregnant subjects and pregnant subjects in current study with insulin-dependent diabetes mellitus

	Nonpregnant diabetic subjects		*Pregnant diabetic subjects (this study): Intensive treatment*
	Conventional treatment	*Intensive treatment*	
Glucose (mg/dl)			
Basal	92 ± 1	90 ± 1	105 ± 8
180-200 min	53 ± 1	50 ± 1	50 ± 1
220-240 min	48 ± 2	42 ± 1	44 ± 2
Epinephrine (pg/ml)			
Basal	55 ± 10	41 ± 9	26 ± 4
180-200 min	477 ± 75	138 ± 27	96 ± 29
220-240 min	690 ± 123	320 ± 64	194 ± 46
Growth hormone (ng/ml)			
Basal	13.2 ± 2.1	9.7 ± 1.4	1.0 ± 0.7
180-200 min	19.9 ± 2.3	17.4 ± 4.6	15.8 ± 1.5
220-240 min	21.2 ± 3.5	30.3 ± 6.3	19.6 ± 2.5

ng/ml) as compared with controls (2.7 ± 0.4 ng/ml; $p < 0.001$, Fig. 3). Nevertheless, the increase in growth hormone in the final 80 minutes in the nonpregnant, nondiabetic controls was greater than that in the pregnant diabetics. Additionally, the plasma glucose threshold for release of growth hormone was significantly suppressed in the pregnant diabetics (44 ± 2 vs 50 ± 1 in controls, $p < 0.01$) (Table II). Basal cortisol levels were also significantly higher in the pregnant diabetic individuals than the control women (26.3 ± 31 vs 12.9 ± 2.5 μg/dl $p < 0.01$, Fig. 3). Cortisol levels rose slightly, but insignificantly above baseline, in both groups during the study. There was no significant change in plasma human chorionic gonadotropin, hPL (Fig. 4), or prolactin during hypoglycemia.

Fetus. The baseline FHR of the eight fetuses ≥27 weeks' estimated gestational age during the control period ranged from 128 to 150 beats/min, with a mean of 138 ± 3 beats/min. Reduction in the glucose level to 45 ng/dl was associated with no significant change in the mean FHR (Fig. 5) and continued identification of FHR accelerations.

Neonatal outcome. As shown in Table III, delivery of infants occurred at an average of 38.2 ± 0.6 weeks' gestation (range 34 to 40 weeks) and followed the conclusion of the study by 63.2 ± 11.5 days (range 12 to 114 days). Five of the infants were delivered vaginally and four by cesarean section; indications for cesarean section were cephalopelvic disproportion in all four women. Average Apgar scores at 1 minute and 5 minutes were 8.7 ± 0.2 and 8.8 ± 0.2, respectively. The average fetal weight was 3385 ± 151 gm. The only neonatal complication was hyperbilirubinemia in one infant (Table III).

Comment

The detrimental effects of poor maternal glycemic control on the fetus throughout gestation[11, 12] have led to the common use of intensive insulin therapy in women with insulin-dependent diabetes mellitus in an attempt to maintain normal glucose profiles. Although improvements in metabolic control clearly diminish the incidence of fetal complications,[2, 3] it is uncertain whether the more stringent goals of achieving normal blood glucose profiles in pregnancy offers additional benefits outweighing the risk of increased fetal and maternal hypoglycemia. Cousan et al.[4] have previously reported a very high frequency of hypoglycemic events with strict glycemic control. In part, this may be due to the large doses of insulin that are required to meet target plasma glucose goals, especially in the later stages of pregnancy. Alterations in counterregulatory mechanisms may contribute as well. Nonpregnant[6, 7] patients with long-standing insulin-dependent diabetes mellitus lose the ability to secrete glucagon in response to hypoglycemia.[13, 14] Although adrenomedullary and other counterregulatory responses are sufficient to compensate for the loss of glucagon in many patients, recent studies in nonpregnant subjects with insulin-dependent diabetes mellitus[6, 7] suggest that intensive insulin therapy itself may adversely effect the magnitude and timing of the release of other counterregulatory hormones (e.g., epinephrine, growth hormone, and cortisol). Such acquired deficits in counterregulation might be an additional factor contributing to the frequent occurrence of severe hypoglycemia during diabetic pregnancies where vigorous attempts at restoring normoglycemia have been commonplace.

In this study we evaluated pregnant patients with insulin-dependent diabetes mellitus receiving intensive insulin therapy and experiencing frequent hypoglycemic episodes and demonstrated deficient secretion of glucagon and retarded and reduced release of epinephrine and growth hormone in response to a standardized hypoglycemic stimulus compared with nonpregnant, nondiabetic women. Furthermore, there was no increase in secretion of hPL during hypoglycemia in our patients. It is noteworthy that hPL levels have been shown to rise in nondiabetic pregnant subjects during hypoglycemia in some[15, 16] but not all reports.[17] Thus deficient hPL response to hypoglycemia in insulin-dependent diabetics may reflect an additional impairment attributable to diabetes or its control, a defect that represents a derangement in the fetal-placental unit rather than being solely of maternal origin.

The mechanism underlying the impaired response to hypoglycemia in pregnant women with insulin-dependent diabetes mellitus is unclear. The defect might be a result of pregnancy, the diabetic state, or the institution of strict metabolic control. An effect of pregnancy per se cannot be excluded because of our inability to perform hypoglycemic clamp studies in nondiabetic pregnancies for ethical reasons. Of the counterregulatory hormones examined, prior reports using insulin tolerance testing suggest that the growth hormone response to hypoglycemia in pregnancy may be impaired.[18-20]

Additionally, as already described, long-standing diabetes is associated with loss of the ability to secrete glucagon in response to hypoglycemia, and in some cases a reduction in the magnitude of epinephrine responses as well.[13, 14] With regard to glycemic control, institution of intensive insulin therapy is associated with impairment in counterregulatory hormone response in individuals with insulin-dependent diabetes mellitus,[6, 7] an effect associated with a reduction in the plasma glucose threshold for initiating counterregulatory responses. If we compare the epinephrine and growth hormone rise in pregnant women with insulin-dependent diabetes mellitus reported here with intensively managed nonpregnant patients with insulin-dependent diabetes mellitus reported previously,[6] a trend to greater impairment in counterregulatory hormone secretion is seen during pregnancy (Table IV). It is noteworthy that these pregnant women with insulin-dependent diabetes mellitus had lower glycosylated hemoglobin levels than in the nonpregnant subjects in the previous report, perhaps indicating better metabolic control. Alternatively, the lower glycosylated hemoglobin may be due to younger red blood cell age.

As assessed by electronic FHR monitoring, the fetuses tolerated hypoglycemia without significant changes in FHR. These findings allow some degree of reassurance for the pregnant diabetic experiencing hypoglycemic episodes, particularly in view of the clinical report of persistent severe fetal bradycardia attributed to a similar degree of maternal hypoglycemia in two patients.[21] However, the rise in maternal epinephrine levels associated with hypoglycemia (and perhaps fetal elevations of epineprhine in association with fetal hypoglycemia) did not elicit a rise in the basal FHR. It is possible insufficient amounts of maternal epinephrine crossed the placenta, that the fetus (at the estimated gestational age studied) does not respond to hypoglycemia by increasing catecholamine secretion, or that the fetus is not able to respond to epinephrine by acceleration of the FHR. More in-depth assessment of fetal well-being is required before definitive conclusions can be drawn about the impact of hypoglycemia on the fetus.

In summary, while the relative contributions of intensive insulin therapy, diabetes mellitus, and pregnancy per se is not fully delineated, this report clearly demonstrates that counterregulatory hormone response to hypoglycemia is impaired in pregnant insu-

lin-dependent diabetic women. Thus intensive metabolic regulation of such subjects is associated with frequent hypoglycemic episodes, not only because of the effect of insulin per se but also because of derangement of compensatory hormonal secretion. Importantly, the fetus tolerated this temporary hypoglycemic challenge without alteration of the FHR.

Intrapartum amniotic fluid index and its relationship to fetal distress

Stephen C. Robson, MD, Robin A. Crawford, MD, John A.D. Spencer, MD, and Angela Lee, PhD

London, England

Amniotic fluid index was measured in 50 consecutive laboring women after membrane rupture. The 10th percentile of the normal range was 6.2 cm. Thirty-three women had a repeat measurement by a second observer. Although there was no systematic bias between the two observers, the limits of agreement were wide: 95% of the measurements by one observer were between 0.59 and 2.07 times those of the second. Closer agreement was observed when amniotic fluid index was low (<6.2 cm). The relationship between intrapartum amniotic fluid index and fetal distress was then investigated in a further 60 laboring women. When compared with women with a normal intrapartum amniotic fluid index, women with a low amniotic fluid index had higher incidences of fetal heart rate abnormalities during the first stage of labor (64% vs 20%, $p < 0.01$), meconium (grade II or III) at delivery (64% vs 35%, $p < 0.05$), and operative delivery for fetal distress (57% vs 17%, $p < 0.01$). Umbilical artery pH and Apgar scores were, however, similar for the two groups. Measurement of intrapartum amniotic fluid index may be an appropiate method for selecting women suitable for intrapartum amnioinfusion. (Am J Obstet Gynecol 1992;166:78-82.)

Key words: Labor, amniotic fluid infex, fetal distress

Antepartum oligohydramnios increases the risk of meconium staining, intrapartum cardiotocographic abnormalities, and operative delivery for fetal distress.[1,2] Recently measurement of amniotic fluid volume has been extended into the intrapartum period. Sarno et al.[3] reported that a low amniotic fluid index in the latent phase of labor was associated with an increased risk of cesarean section for fetal distress and 1-minute Apgar score <7. They defined a low amniotic fluid index as ≤5 cm. This figure was derived from the original studies of amniotic fluid index during pregnancy by Phelan et al.[4] A recent large study has shown this value corresponds to an amniotic fluid index <1st percentile at 37 to 43 weeks' gestation.[5] No data exist regarding the normal range of amniotic fluid index in labor.

The present study was designed to (1) define the normal range of amniotic fluid index in established labor after membrane rupture, (2) determine the reproducibility of amniotic fluid index measurements in the context of their clinical use in labor, and (3) investigate the association between a low amniotic fluid index and fetal distress.

Material and methods

The study was conducted on the labor ward at Queen Charlotte's and Chelsea Hospital, London. The protocol was approved by the hospital Ethical Committee, and the procedure was explained to each subject before verbal consent was obtained. All the women recruited to the study were between 36 and 41 completed weeks' gestation, (confirmed by an early ultrasonographic scan) and were in established labor (cervical dilation ≥ 5 cm) with ruptured membranes and a cephalic presentation. Two groups of subjects were investigated. Fifty consecutive women, seven of whom were at ≥41 weeks' gestation, constituted the population group. Amniotomy had been performed in 23 subjects, and the membranes had ruptured spontaneously in 27. These subjects were studied by either R.A.C. or S.C.R. to determine the normal range of amniotic fluid index in labor. Sixty women, 16 of whom were ≥41 weeks' gestation, made up the study group. These subjects were selected and studied by one observer (R.A.C.) when he was resident on the labor ward. Amniotomy had been performed in 28 subjects, and membranes had ruptured spontaneously in 32. All amniotomies were performed for augmentation of spontaneous labor or for induction of labor. Women with meconium staining or fetal heart rate abnormalities were preferentially recruited into the study group in the hope of selecting subjects with oligohydramnios. A repeat ultrasonographic examination was performed by a second observer (S.C.R.) in 33 of this group to determine

the reproducibility of intrapartum amniotic fluid index measurements. This second measurement was performed within 10 minutes of the first, and the second observer was unaware of the original results. The details of the population and study groups are shown in Table I.

Ultrasonographic examinations were performed with a portable real-time ultrasonography system (Aloka SSD 210DX) with a 3.5 MHz linear array transducer. Amniotic fluid index was measured by the four-quadrant technique described by Phelan et al.[4] Ultrasonographic measurements were not reported to the labor ward staff. All women in the study group had continuous cardiotocographic monitoring throughout labor. The time of amniotic fluid index measurement was marked on the cardiotocographic recording. The cervical dilatation and the presence and grade of meconium at the time of measurement were recorded. Meconium was graded as I to III.[7] A diagnosis of fetal distress was made by the attending medical staff on the basis of fetal heart rate abnormalities with or without scalp blood sampling.

Umbilical arterial blood gas determinations were performed within 15 minutes of delivery after double clamping of the cord. The presence of a nuchal cord together with the cord length, the presence and grade of meconium at delivery, and the 1- and 5-minute Apgar scores were recorded by the attending midwife or pediatrician. Cardiotocographs were retrospectively reviewed by one of the authors (J.A.D.S.) who was unaware of the ultrasonographic measurements. The cardiotocograph during the 30 minutes before measurement of amniotic fluid index was scored according to the criteria of Krebs et al.[8] In addition, the first- and second-stage cardiotocographic tracings were recorded as normal or abnormal (suspicious or pathologic) according to the International Federation of Gynecologists and Obstetricians classification[9] (1987), and the presence of variable decelerations was noted.

Statistical analysis. The 10th percentile for the amniotic fluid index was determined with a frequency

table from the population study data. Interobserver reproducibility was assessed by the limits of agreement method.[10] Differences between the subjects with low and normal amniotic fluid index values in the study group were compared with the Student t test and χ^2 analysis.

Results

The data for amniotic fluid index from the population group were normally distributed with a mean ± SD of 9.7 ± 2.8 cm. The 5th and 10th percentiles were 3.4 and 6.2 cm, respectively.

A statistically significant correlation was found between the absolute difference and the mean of paired measurements (Fig. 1). No significant correlation was evident after log transformation, and therefore the limits of agreement were calculated on the transformed data. The mean difference was not significantly different from zero ($\log_e$ = 0.101, 95% confidence interval − 0.007 to 0.210), indicating no systematic bias between the observers. However, the limits of agreement were wide; in 95% of cases amniotic fluid index measurements by R.A.C. were 0.59 to 2.07 times those by S.C.R. Although agreement over the range of amniotic fluid index was poor, the diagnosis of a low amniotic fluid index appeared to be more reproducible: Of the nine women in which S.C.R. recorded an amniotic fluid index <6.2 cm, R.A.C. agreed in eight cases.

Of the 60 women in the study group, 14 had a low amniotic fluid index (defined as <10th percentile, i.e., <6.2 cm) at the time of measurement. The labor and birth weight details were similar in the two groups (Table II). The incidence of intrapartum complications

*Grade II or III.

and the immediate neonatal outcome in the two groups are shown in Table III. The Krebs score before amniotic fluid index measurement was similar, although significantly more women in the low amniotic fluid index group had grade II or III meconium at the time of measurement. Women in the low amniotic fluid index group were more likely to have the following: an abnormal first-stage cardiotocogram, reflecting a higher incidence of variable decelerations; fetal blood sampling during labor; an operative delivery for fetal distress; and grade II or III meconium at delivery. Although there was a trend toward an increased incidence of abnormal cardiotocograms during the second stage in the low amniotic fluid index group, this difference was not statistically significant. In spite of the higher incidence of fetal distress in the low amniotic fluid index group, the mean umbilical artery pH and base excess together with the mean Apgar scores and percentage with Apgar scores ≤7 were similar in the two groups. No infant required admission to the Special Care Baby Unit.

Comment

This is the first study to report the normal range of amniotic fluid index in established labor after membrane rupture. We chose to confine the study to women in the active phase of labor after ruptured membranes. The rationale for this was that we felt oligohydramnios and cord compression were most likely to occur at this time. The 10th percentile for intrapartum, on the basis of this consecutive series of women at term, was 6.2 cm. This is equivalent to the 2.5th percentile at 37 to

Table IV. Predictive ability of low amniotic fluid index for subsequent fetal distress

	Prevalence (%)	*Sensitivity (%)*	*Specificity (%)*	*Positive predictive value (%)*	*Negative predictive value (%)*
Meconium (grade II or III)	42	36	86	64	65

Umbilical artery pH <7.12	20	25	77	21	80
Apgar score <7 at 1 min	20	33	79	29	83

43 weeks' gestation,[5] suggesting that the definition of intrapartum oligohydramnios should be lower than that used antenatally.

Interobserver variability of amniotic fluid index measurements was assessed by the limits of agreement method of Bland and Altman.[10] This method has been shown to be the most appropriate method of studying interobserver variation.[11] The results suggest that, over the range of amniotic fluid indexes studied, the variability of measurements was large. Rutherford et al.[12] reported the mean percentage errors for intraobserver and interoberver comparisons to be between 10% and 16%. Lower figures were reported by Moore and Cayle,[5] although these authors noted that for low volumes of amniotic fluid the percentage error was ≥20%. The mean percentage error for paired measurements in our study was 22%. This greater variability may be due in part to the lower amniotic fluid index values, but it may also reflect the true variability of measurements when applied in clinical practice. Although the overall variability was large, there was reasonable agreement between the observers in the diagnosis of a low amniotic fluid index.

The results of the current study confirm that women with oligohydramnios are at increased risk of intrapartum fetal distress (as evidenced by the presence of moderate or thick meconium staining and fetal heart rate abnormalities) and that they are more likely to require operative delivery because of this.[1, 3] The incidence of variable decelerations during the first stage of labor was particularly high (64%). Retrospective analysis showed that this was by far the commonest cardiotocographic abnormality and was the main indication for fetal blood sampling and operative delivery in this group. A comparable incidence of variable decelerations was reported by Strong et al.[13] in women with an amniotic fluid index ≤5 cm. The association between reduced amniotic fluid volume and variable decelerations is well documented.[14, 15] The pathophysiologic basis for these periodic changes in fetal heart rate appears to be umbilical cord compression.[16] Previous studies have shown that variable decelerations during labor increase the umbilical arteriovenous pH difference[17] and that the severity and frequency of variable decelerations correlate with fetal capillary pH.[18] It was perhaps surprising therefore that, in spite of the higher incidence of variable decelerations in the low amniotic fluid index group, we were unable to demonstrate any difference in umbilical artery pH or Apgar score between the two groups. This may reflect the relatively small numbers of women studied; 53 women would have been required in each group to demonstrate a difference in pH of 0.05 as being significant at the 5% level with 80% power.

The predictive value of low intrapartum amniotic fluid index for subsequent fetal distress, umbilical artery acidemia, and low Apgar score is shown in Table IV. The high prevalence of these abnormalities in the study group reflects the undoubted selection bias within the group. Amniotic fluid index appeared to be a better predictor of subsequent fetal distress than acidemia or low Apgar score. The figures for sensitivity and specificity of amniotic fluid index for the prediction of operative delivery for fetal distress are almost identical to those reported by Sarno et al.[3]

The association between oligohydramnios and fetal distress has led some workers to investigate the role of intrapartum saline amnioinfusion. Results from randomized controlled trials have shown that the procedure reduces the incidence of variable decelerations and meconium staining below the cords.[13, 19, 20] Some workers have also shown a reduction in the rate of operative delivery for fetal distress and an increase in umbilical arterial pH,[13, 19] but this was not confirmed by Owen et al.[21] Although oligohydramnios was suggested as the underlying abnormality in these studies, only Strong et al.[13] used this as the sole criterion to select women for amnioinfusion. The discrepant results reported by Owen et al.[21] may be due to the rather heterogeneous group of women studied and the apparently normal preinfusion amniotic fluid index in the treatment group (mean ± SD = 9.2 ± 3.7 cm). It would seem logical that future randomized trials of amnioinfusion should be limited to women with ultrasonographically proved oligohydramnios. Use of an amniotic fluid index <6.2 cm appears to predict, with

reasonable consistency, women at increased risk of fetal distress, and it is suggested that this may be an appropriate selection criterion for future studies of amnioinfusion.

Colposcopy to establish physical findings in rape victims

Laura Slaughter, MD, and Carl R.V. Brown, PhD
San Luis Obispo, California

OBJECTIVE: Conventional rape examination protocols have been poor in yielding positive genital findings (10% to 30% typically). We report our experience with a revised protocol employing colposcopy to perform genital examinations of victims and to document findings.
STUDY DESIGN: Physical examinations were performed on rape victims seen by San Luis Obispo County's Suspected Abuse Response Team between 1985 and 1990, and the results were reviewed for this study.
RESULTS: Of 131 patients seen within 48 hours and who experienced penile penetration, 114 (87%) had positive findings. Colposcopic magnification allowed examiners to characterize these findings as acute mounting injuries, typically seen at 3, 6, and 9 o'clock on the posterior fourchette and consisting chiefly of lacerations, ecchymosis, and swelling.
CONCLUSIONS: An examination protocol that includes colposcopy may be the most reliable means to document and characterize genital findings in rape victims and to evaluate whether findings may be linked to a reported sexual assault. (AM J OBSTET GYNECOL 1992;166:83-6.)

Key words: Physical findings, rape, genital trauma, sexual assault

The difficulty of establishing physical findings in rape victims has been an accepted limitation in the medical and legal process that addresses sexual assault. While it is clear that a physical examination is an important element in patient management and that the findings of that examination can be a crucial factor in the corroboration of rape, conventional protocols have historically yielded positive genital findings in only 10% to 30% of cases.[1-3] This dearth of physical findings is compounded by the frequent absence of semen in laboratory specimens.[4, 5] Apart from circumstances surrounding the assault and the victim's subsequent behavior that might eliminate evidence, a significant incidence of sexual dysfunction in the offender has also been cited as a contributor to the lack of physical evidence.[4]

Over the last 13 years, many communities have formed multidisciplinary teams, adopting protocols to manage sexual assault victims in a more sensitive manner and to standardize the collection of evidence.[5-11] In spite of these efforts, the results of physical examinations have continued to yield low percentages of positive findings and have continued for the most part to depend on gross visualization. However, somewhat better results have been reported by authors using toluidine blue to evaluate patients experiencing penile penetration who are seen within 48 hours.[12, 13]

No published studies have evaluated the usefulness of the colposcope in the routine assessment of rape victims. Because we assumed, with others,[14] that colposcopic magnification might maximize visualization of genital findings, we established a protocol incorporating its use in 1984. We report here our experience using colposcopy to perform genital examinations in victims of sexual assault and compare our results to those using toluidine blue. We describe the findings afforded by colposcopic magnification and discuss the medical and forensic significance of this new technologic application.

Material and methods

This study was performed at the San Luis Obispo General Hospital, where for 6 years a medical team has used the colposcope in the assessment of genital trauma in rape victims. Since genital trauma in rape is typically associated with intromission[5] and generally assumed to resolve rapidly in most cases,[15] we were chiefly interested in what colposcopy could document in those victims who experienced penile penetration and were seen within 48 hours of the assault. Focusing on this population, we could also compare our results with those in published studies of protocols using toluidine blue (without colposcopy).

Examinations of 131 women who met these criteria were performed between January 1985 and December 1990, and their records were reviewed in preparing this report. All examinations were conducted by the Suspected Abuse Response Team (SART), which by interagency agreement evaluates all victims of sex crimes within the county. The physical examinations were performed by medical doctors and nurse examiners who are specifically trained in the forensic evaluation of sexual assault victims, usually with one doctor

48 hr	13/14 (93%)
Cumulative findings	114/131 (87%)

or nurse examiner conducting the examination. Examiners have been trained to identify any abnormal findings and to distinguish between acute traumatic changes and findings more likely to have resulted from previous vaginal or vulvar infections, vulvar dystrophies, or healed obstetric lacerations or episiotomies. Colposcopic photography was used both for documentation and for interevaluator corroboration.

Once a complaint of sexual assault had been received, the victim was brought to the SART examination facility for evaluation. After appropriate consents were obtained, a detailed interview was conducted jointly by law enforcement and medical personnel, immediately followed by physical examination and collection of evidence. Photographic documentation of genital findings with a Leisegang colposcope at ×15 magnification was routinely performed. The genital examination began with gross inspection of the perineum, introitus, hymen, and approximately the distal 2 cm of the vaginal mucosa. This was followed by colposcopic assessment of the same area at ×15 magnification. Both the white light and green filter of the colposcope were used. A speculum was then inserted into the vagina. Careful evaluation of the vaginal barrel and cervix was then performed with direct visualization followed by colposcopy. After all forensic specimens were obtained, toluidine blue dye was applied to the fourchette in the usual manner.[12] This area was then reinspected grossly and colposcopically. The data were recorded on forms provided by California's Office of Criminal Justice Planning. In addition, the medical examiner dictated a summary of the history, physical findings, and recommendations. Beginning in 1986, patients with positive findings were encouraged to schedule a follow-up examination. For those who did present for reassessment, the genital examination was repeated, including colposcopy and colposcopic photography.

Results

The study population of 131 patients consisted of 113 white, 5 black, 11 Hispanic, and 2 Asian women. The mean age of the study population was 25, with a range of 13 to 85 years. With colposcopic magnification, 114 (87%) had gynecologic trauma. In addition to gynecologic trauma, 72 victims (55%) also sustained nongynecologic trauma. Only 10 victims described sexual dysfunction (defined as erectile inadequacy, premature ejaculation, or retarded ejaculation) in their attackers. All 10 suffered both genital and nongenital trauma.

With the patient examined in the lithotomy position, the predominant injuries were seen between 3, 6, and 9 o'clock on the posterior fourchette, and were concentrated in the area between 5, 6, and 7 o'clock. These

*All values are for patients who were seen within 48 hours and who experienced penile penetration.

injuries included lacerations, abrasions, ecchymosis, and swelling. Lacerations usually occurred at the 6 o'clock position (Fig. 1). In nine instances, the injuries were extended, disrupting the fossa navicularis and producing hymenal tears. Abrasive injury to the medial aspect of the labia minora was a common accompaniment. Ecchymosis of the hymen and periurethral structures (Fig. 2) was also documented. Suturing was required for one woman suffering a perineal laceration. No patient required hospitalization because of these injuries.

Sixty-four patients returned for follow-up examination at an average of 25 days (range 4 to 54 days, excluding one patient seen at 134 days). Except in four cases where injuries were still in the process of resolution, all acute trauma had resolved by the second examination. Hymenal tears did not reunite and no scarring was observed, except in the patient who required suturing.

The results of this study are summarized in Table I. Presented are findings among subjects seen at 24 and 48 hours and the cumulative findings for the total population.

Comment

Two previous studies have used toluidine blue to document trauma in adult victims of sexual assault.[12, 13] In both, researchers showed that toluidine blue could significantly enhance visualization of genital trauma as compared with gross visualization alone. Neither study used colposcopy. We selected these for comparison, and 95% confidence intervals were constructed. As Table II shows, by this statistical method the percentages of positive findings by colposcopy are significantly greater than those in the toluidine blue studies.

Toluidine blue is a nuclear stain commonly used in gynecologic practice to detect vulvar cancer. Since normal vulvar skin contains no nuclei, it will not bind the dye. Lacerations that expose the deeper dermis will bind toluidine blue. Using this technique, some researchers have demonstrated that they could increase the number of vaginal lacerations seen grossly from one in 24 rape victims to 14 in 24 after application of toluidine blue.[13] However, this dye technique has applicability limited to the vulva and will not be taken up in areas of injury that are superficial or are beginning to reepithelialize. In our series toluidine blue did not define trauma not already seen with the colposcope. However, anticipating the need for a clear pictorial presentation of the findings in court, toluidine blue is useful to highlight injuries that a lay audience would find difficult to appreciate.

In addition to the history and initial findings, documentation of the healing process in our 64 subjects reporting for follow-up examination is important because it links the traumatic event to the injuries observed, establishing a time frame reliably associated with injury. Furthermore, documentation of the victim's anatomy at the follow-up examination effectively establishes her as her own control, against which we can evaluate the nature, extent, and cause of the injury. The performance of a follow-up examination is therefore strongly recommended; reassessment of the victim not only addresses the needs of the criminal justice system but provides more complete information about the resolution of genital injury seen in this group of patients.

The results of our study (including comparisons with the toluidine blue series) support the conclusion that colposcopy may be the best examination method yet reported for seeing genital findings associated with rape and for evaluating whether findings may be linked to a reported assault.

Only one study using the colposcope to evaluate genital changes after consentual sex exists in the medical literature.[14] Eighteen women were examined within 6 hours of intercourse. Microabrasions were seen in only two. Included in the authors' definition of trauma was increased vascularity, consisting of telangiectasia and broken capillaries; this was seen in nine subjects, and two of these women had this finding before intercourse. Of importance, none of the changes described were localized. This is in contrast to our group of rape victims, who typically have injury at the posterior fourchette. As noted in other studies, the posterior fourchette is the anatomic site of attachment to the perineal body and hence the point of greatest stress when force-

ful stretching is applied[12]; additionally, it represents the point of first contact of the penis with the vagina,[5] and the resulting trauma can be characterized as an acute mounting injury.

Now that the technology exists to assess and document the genital changes in rape victims, more work needs to be done to describe the nature, extent, and type of findings in this group. Comparison of the frequency, pattern, or severity of trauma in rape victims and in women experiencing voluntary sex may be useful, as well.

Rape is a forensic term characterizing sexual activity perpetrated against the will of the victim. The question of consent will ultimately remain with the court; nevertheless, obtaining corroborative physical data supporting the history in a time frame consistent with the alleged sexual activity is an important part of the medical assessment. The outcome of that assessment depends on an accurate examination. The rugal folds of the posterior fourchette make genital trauma difficult to see by gross visualization alone,[13] and frequently such trauma is not detected even when visualization is enhanced with toluidine blue. Our study shows that with an improved protocol, which includes use of a colposcope, examiners practiced in discriminating acute trauma from other vulvar lesions may be able to establish with greater frequency and reliability physical findings in rape victims who have had penile-vaginal contact and are examined within 48 hours.

Prompt assessment of the rape victim by a multidisciplinary team that incorporates medical examination with colposcopy may be the best way of collecting and documenting the forensic evidence in rape cases. The clarity afforded by colposcopic magnification will also allow us to further characterize genital changes associated with rape. The findings in this study support the opinion that rape victims often sustain mounting injuries. The ability to detect and document these injuries through colposcopic photography provides valuable medical and legal information.

We are indebted to the staff of San Luis Obispo County SART and San Luis Obispo General Hospital; to Sexual Assault Victim Education; to Dr. Roxy Peck (Cal Poly State University) for her statistical assistance; to Mrs. Sharon Arnold, who prepared the manuscript; and to Mary Kennedy Eggan, R.N., whose dedication to the treatment of assault victims inspired the establishment of the SART program.

Natural killer cell activity from pregnant subjects is modulated by RU 486

Keith A. Hansen, MD,[a,b,c] Michael S. Opsahl, MD,[b] Lynnette K. Nieman, MD,[c] James R. Baker, Jr., MD,[a] and Thomas A. Klein, MD[a]

Washington, D.C., and Bethesda, Maryland

Natural killer cells form an integral component of the body's innate immune system. Natural killer cell activity is reduced during pregnancy, especially in the latter half. To investigate the role progesterone may play in immunomodulating natural killer cell activity during pregnancy, we evaluated the effect of RU 486 on natural killer cells isolated from pregnant subjects. Natural killer cell activity was measured with an 18-hour, Chromium 51 release, microcytotoxicity assay with K-562 cells as target cells. We demonstrated that RU 486, in a concentration range from 5 to 40 μmol/L, augmented natural killer activity threefold to fivefold over baseline. This augmentation of activity was suppressed to baseline by the addition of excess progesterone. The addition of hydrocortisone resulted in an insignificant reduction in this augmented activity. This study suggests that progesterone may play a role as an immunomodulating factor in maternal acceptance of the fetal allograft. (Am J Obstet Gynecol 1992;166:87-90.)

Key words: Natural killer cells, pregnancy, RU 486

Allogeneic immune responses are responsible for the rejection of tissues transplanted between members of the same species.[1] In viviparous reproduction, the fetus represents an allograft that is not rejected by the maternal immune system. A number of hypotheses have been proposed to explain escape of the fetus from the basic principles of transplantation immunology. These hypotheses include considering the uterus as an immunologically privileged site, decidual T-suppressor cells down-regulating the maternal immune response, placental absorption of cytotoxic antibodies, maternal production of blocking antibodies, or placental production of circulating immune suppressants.[2]

The innate immune system plays a vital role as a nonspecific first line of defense against antigenic insults. Natural killer cells form an integral component of this defense and are capable of generating a non–major histocompatibility complex restricted immune response, without prior sensitization, to a number of different target cells, including virally infected cells, transformed cells,[3-7] and, when activated to lymphokine-activated killer cells, to trophoblast.[8, 9]

Natural killer cell activity is reduced during gestation, especially in the latter half.[10-13] The physiologic mechanism that results in reduction of natural killer cell activity during gestation is currently unknown, but a number of hypotheses have been advanced to explain this phenomenon.[14, 15] Szekeres et al.[16] showed that the immunosuppressive effect of pregnancy serum is dialyzable and can be removed by pretreatment with antiprogesterone antiserum. They were also able to demonstrate a dose-dependent decrease in natural killer cell activity with the addition of progesterone.[16-18] Sulke et al.[19] and Uksila[20] were unable to duplicate these results.

RU 486 is a steroid hormone synthesized by Roussel-UCLAF that has potent antiprogesterone and antiglucocorticoid effects. It functions as a competitive inhibitor at the progesterone and glucocorticoid receptors, with a higher affinity for the former than for the latter.[21-23] We sought to determine if blocking these receptors, specifically the progesterone receptor, on lymphocytes would alter natural killer cell activity in pregnant women.

Material and methods

Natural killer cells. Forty-nine subjects were recruited from the routine obstetric clinic at Walter Reed Army Medical Center. All subjects gave informed consent, with prior approval of the Committee for Protection of Human Subjects at Walter Reed Army Medical Center. The subjects ranged in age from 17 to 43, with a mean age of 26, and had a mean gravidity of 2 and a parity of 1. Gestational age ranged from 19 to 41

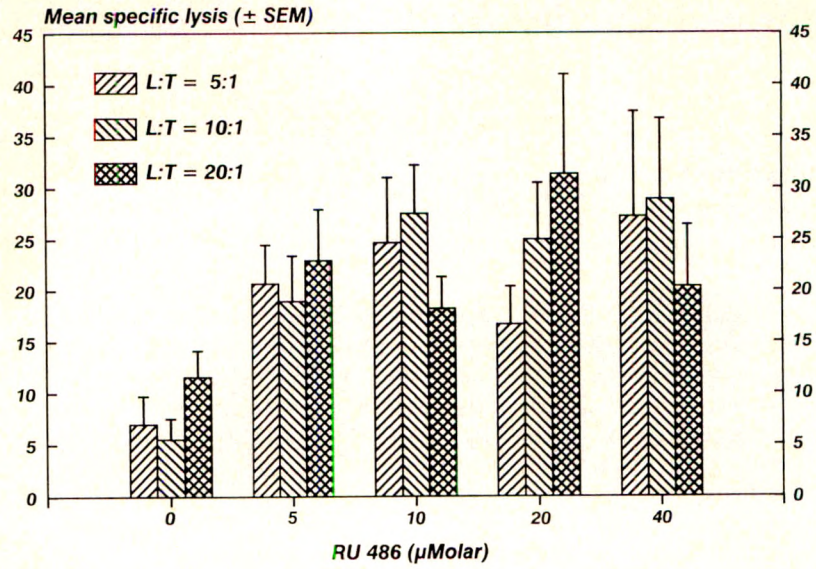

Fig. 1. Effect of RU 486 on natural killer cell activity at various lymphocyte-target cell ratios.

weeks, with a mean of 30 weeks. All subjects were healthy, were not receiving medications, and had no history of recent viral or bacterial infection.

Thirty milliliters of whole blood was obtained from each of the volunteers by standard venipuncture techniques into a heparinized test tube. This blood was diluted to 45 ml with sterile Hams F-10 medium. The mononuclear cells were separated by standard techniques with centrifugation through Ficoll-Hypaque.[24]

The mononuclear fraction was aspirated and washed two times with RPMI medium. These cells were suspended in RPMI with 10% fetal bovine serum and incubated for 1 hour at 37° C with 5% carbon dioxide in a sterile, plastic Petri dish. The nonadherent cells were collected and washed in a sterile RPMI medium. The cells were counted with a trypan blue exclusion technique to determine viability. The mononuclear cells were diluted with RPMI medium with 10% fetal bovine serum to achieve the appropriate concentration for lymphocyte/target cell ratios of 20:1, 10:1, and 5:1.

Target cells. K562 cells, a human erythroleukemic cell line, are a well-characterized natural killer cell target and were used in this series of experiments. This cell line was kept in a continuous culture in our laboratory in RPMI medium with 10% fetal bovine serum at 37° C in 5% carbon dioxide.

At the initiation of an experiment the K562 cells were harvested and washed twice. The K562 cells were labeled with 300 μCi of fresh chromium 51 for 2 hours. After two washes and counting done with a trypan blue exclusion technique to document viability, the cells were suspended in sterile RPMI medium with 10% fetal bovine serum to achieve a concentration of 10,000 viable cells per 100 μl.

Steroid hormones. The RU 486 was obtained in sterile, crystalline form from Roussel-UCLAF. It was brought into solution in 100% ethanol and titrated with RPMI medium to achieve the desired final concentration in a 30% ethanol solution. The range of concentrations of RU 486 include O (RPMI medium and 30% ethanol), 25, 50, 100, and 200 μmol/L.

Progesterone and hydrocortisone were obtained in sterile, crystalline form. These steroid hormones were brought into solution with a technique similar to the one used for RU 486.

Natural killer cell activity assay. Natural killer cell activity was determined in a ^{51}Cr release microcytotoxicity assay.[25] This assay was performed by initially pipetting 100 μl (10,000 cells) of labeled K562 cells into each well of a 96-well round-bottomed plate (Costar, Cambridge, Mass.). Then 100 μl of nonadherent mononuclear cells of varying concentrations was pipetted into each well to achieve lymphocyte/target cells ratios of 20:1, 10:1, 5:1, and 0:1 (spontaneous lysis) in triplicate. Fifty microliters of RU 486, at each of its concentrations, was pipetted into each well over the entire range of lymphocyte/target cell ratios for the initial dose-response experiments.

The same format was used to study the effect of the addition of progesterone or hydrocortisone on natural killer cells coincubated with RU 486. In this series of experiments 25 μl of 100 μmol/L RU 486 was added to each well over the entire range of lymphocyte/target cell ratios. Then 25 μl of 250 and 2500 μmol/L progesterone or 150 and 250 μmol/L hydrocortisone was added to each well over the entire range of ratios.

The 96-well plates were then incubated for 18 hours at 37° C in 5% carbon dioxide. At the conclusion of this incubation the supernatant was collected with a Titertek supernatant harvesting system (Skatron AS, Sterling, Va.), and the amount of ^{51}Cr released was de-

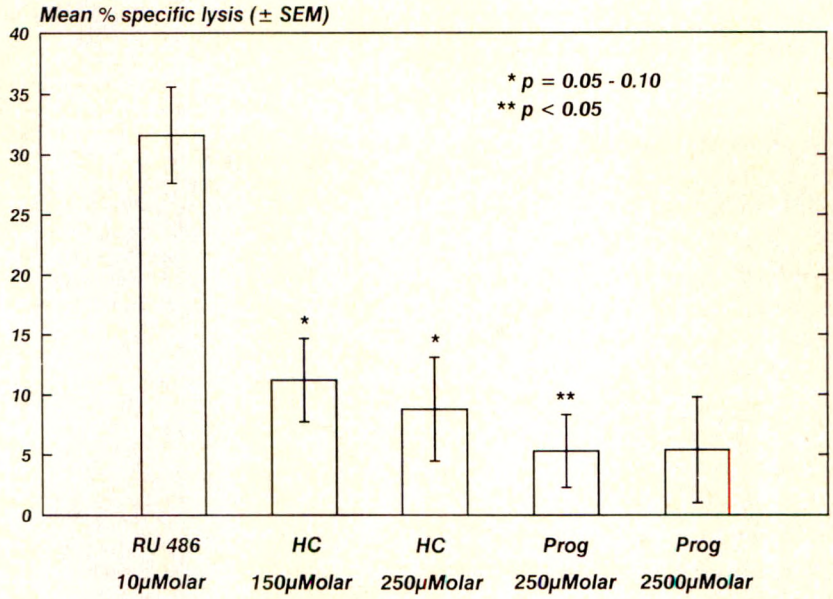

Fig. 2. Effect of hydrocortisone *(HC)* and progesterone *(Prog)* on RU 486–augmented activity. *Asterisk*, Hydrocortisone versus RU 486; *two asterisks*, progesterone versus RU 486.

termined in a γ-counter. The percent specific lysis was calculated with the following formula:

$$\% \text{ Specific lysis} = \frac{\text{Supernatant (counts/min)} - \text{Spontaneous (counts/min)}}{\text{Maximum (counts/min)} - \text{Spontaneous (counts/min)}} \times 100\%$$

Maximum counts per minute were equal to the total counts added to each well. Spontaneous lysis was equal to the counts in wells containing labeled target cells only, without nonadherent mononuclear cells, with and without the addition of hormones. Spontaneous lysis was always <30% of maximum counts per minute.

Statistics. A repeated-measures analysis of variance was used to detect any difference in natural killer cell activity created by adding RU 486. The effect of the addition of progesterone or hydrocortisone on RU 486 was analyzed with the Wilcoxon signed-rank test.

Results

RU 486 augmented natural killer cell activity threefold to fivefold above control levels at each lymphocyte/target cell ratio (Fig. 1). For each lymphocyte/target cell ratio the specific lysis at all the concentrations of RU 486 was statistically and significantly increased above control values. When the control group was excluded, there was no significant difference among the RU 486 groups.

Progesterone or hydrocortisone was added to the RU 486/lymphocyte reaction mixture from nine patients. Progesterone at a concentration of 25 μmol/L resulted in a statistically significant reduction in RU 486–augmented activity ($p = 0.008$). Hydrocortisone at a concentration of 15 and 25 μmol/L resulted in a reduction of activity ($p = 0.06$ and 0.09, respectively) (Fig. 2). Although the hydrocortisone-associated reduction did not reach statistical significance, there was insufficient power (0.55) in this series of experiments to exclude an effect.

Comment

Natural killer cells are a vital component of the innate immune system, where they primarily function in immune surveillance.[5-9] While natural killer cell activity is reduced in pregnancy, the exact mechanism producing this alteration is not known.[10-15] RU 486, a synthetic antiprogesterone, was used to further evaluate progesterone's role in immune modulation during pregnancy.

These studies revealed a statistically significant augmentation of natural killer cell activity by RU 486 over the entire range of concentrations when compared with control values. No statistical difference between the various concentrations of RU 486 were found when the control group was excluded. At the concentrations of RU 486 used in this series of experiments, we were unable to demonstrate a dose-response relationship. This suggests the need for further studies at lower concentrations to fully evaluate this effect before attributing it to an all-or-none phenomenon.

RU 486 is both an antiprogesterone and an antiglucocorticoid, with a lower affinity for the glucocorticoid receptor.[21-23] Progesterone or hydrocortisone was added to the culture wells to evaluate the specificity of the RU 486 effect. Progesterone at a concentration of 25 μmol/L significantly reduced RU 486–augmented natural killer cell activity. Hydrocortisone reduced RU 486–augmented natural killer cell activity; however, it did not reach statistical significance. These data suggest

that the primary effect of RU 486 on natural killer cell activity was through an antiprogesterone effect. Further studies with an increased number of hydrocortisone trials are necessary to clarify the role of glucocorticoids in RU 486–augmented natural killer cell cytotoxicity.

Progesterone could modulate natural killer cell activity in a direct or indirect fashion, or both. Direct modification of activity may occur by the binding of progesterone to specific natural killer cell nuclear receptors. Progesterone could alter activity indirectly by binding to receptors present in T-helper or T-suppressor cells and modifying the secretion of lymphokines by these cells. The lymphokines may then directly influence natural killer cell activity. Lymphokines having a stimulatory effect on natural killer cells include the interferons (especially inferferon gamma) and interleukin-2; prostaglandin E_2 has been shown to have an inhibitory effect.

Endometrial suppressor cells of the T-suppressor cell variety are recruited to the pregnant uterus in a hormone-dependent fashion.[26] Locally elevated levels of progesterone at the utero-placental interface may stimulate secretion of lymphokines by these T-suppressor cells. Szekeres-Bartho et al.[27, 28] demonstrated release of a suppressor factor by progesterone-stimulated lymphocytes isolated from both pregnant women and mice, which decreases natural killer cell activity in vitro. This reduction of natural killer cell activity may play a significant role in maternal acceptance of the fetal allograft.

We thank Louis Toro, SSG, for his technical assistance and Robin Howard for statistical analysis of the data.

Prenatal diagnosis of fetal cytomegalovirus infection

Monique E. Lamy, MD,[a] Kipanga N. Mulongo, MD,[a] Jean-François Gadisseux, MD,[b] Gilbert Lyon, MD,[b] Véronique Gaudy, MD,[c] and Michel Van Lierde, MD[c]

Brussels, Belgium

A prospective study (1988 to 1990) to evaluate the risk of fetal cytomegalovirus transmission was conducted with 1771 pregnant women; the test results of 861 were seronegative (48.6%). At each prenatal visit they were tested for serologic data and cytomegalovirus excretion in urine, saliva, and cervical secretions. If seroconversion occurred (with or without cytomegalovirus excretion), ultrasonography, amniocentesis, and cordocentesis were performed at 22 weeks' gestation; 7 cases of primary cytomegalovirus infection were investigated. In 5 cases the amniotic fluid cultures were positive; in 3 cases the fetal blood test results were positive for specific immunoglobulin M; and in 2 cases brain ultrasonography results were positive. Infection was confirmed with biopsies of fetal tissue. In two other cases, the cord blood and amniotic fluid test results were negative, and the neonates were free of infection. (Am J Obstet Gynecol 1992;166:91-4.)

Key words: Prenatal, cytomegalovirus, amniocentesis, cordocentesis, ultrasonography

Cytomegalovirus is considered to be the first cause of congenital infection.[1] Maternal infections are mostly asymptomatic; however, transplacental transmission occurs in about 50% of cases.[2] Furthermore, 90% of infected neonates show no clinical signs of infection at birth, although some will have late manifestations of congenital cytomegalovirus infection.[2] Prenatal diagnosis is therefore essential to detect those fetuses at risk of having symptoms and late sequelae. In a prospective survey seven cases of primary cytomegalovirus infection were investigated for fetal transmission. In addition to detecting specific immunoglobulin M (IgM) antibodies with cord blood tests and fetal brain echography, we emphasized virus isolation from amniotic fluid culture for antenatal diagnosis.

conversion occurred (with or without cytomegalovirus excretion), ultrasonography, amniocentesis, and cordocentesis were performed at 22 weeks' gestation with informed consent from these women to detect transplacental cytomegalovirus transmission.

Serologic methods. Sera or fetal blood was titrated for IgM and immunoglobulin G (IgG) by enzyme-linked immunosorbent assay (Behring, Marburg, Germany) and for complement-fixing antibodies (antigen virion).

Cytomegalovirus isolation. Samples of urine, saliva, cervical secretions, and amniotic fluid were filtered through a 0.45 μm Minisart; 0.2 ml of the sample was inoculated in duplicate on human embryonic lung cells (MRC5 cell line, Biomerieux, Lyon, France), centrifuged at 3000 rpm for 45 minutes in macroplates (Nunclon, Roskilde, Denmark), and incubated at 37° C. After 48 hours, replication of cytomegalovirus was detected by immunoperoxidase staining with a monoclonal antibody to cytomegalovirus immediate early antigen (Biosoft, Paris, France).

The same samples were cultured on tubes to detect characteristic cytopathic effect.

Results

Seroconversion occurred in 20 of 861 seronegative pregnant women (2.3%). Seven of 20 agreed to cordocentesis and amniocentesis. The mean age of the seven patients was 27.5 years. They were all asymptomatic, except for the one who presented with clinical and hematologic signs of mononucleosis. In five cases (Table I, cases 1 to 5), amniotic fluid culture yielded a high titer of virus (up to 10^7 plaque-forming units per milliliter).

The fetal blood test results were positive in three cases (1, 2, 5) for specific IgM antibodies and negative in the two other cases (3, 4).

Brain microcalcifications were visualized in two cases (4, 5) by ultrasonography.

Our ethical committee approved the termination of pregnancies requested by these five patients. Therapeutic abortions were achieved by intraamniotic injection of prostaglandin E_2 and intravenous injection of oxytocin. Afterward the placenta was systematically manually separated and removed.

After the pregnancies were terminated, evidence of infection was confirmed either by positive culture or by demonstrating cytomegalovirus antigen or inclusions on histologic sections of various organs (brain, eye, thyroid, heart, lungs, liver, spleen, pancreas, adrenal glands, kidneys) (Table II).

In all five cases microscopic cerebral lesions consisted of inflammatory changes with perivascular infiltrates, focal areas of ependymal disruption, and glial nodules (Fig. 1, *B*). Calcified necrotic areas (Fig. 1, *A*) were observed in the periventricular region in cases 4 and 5. Microglial and neuronal cells containing cytomegalovirus inclusions were identified with immunohistochemical stain (Fig. 1). These cells were widely distributed, more abundantly in the brain stem, cerebellum, and entorhinal regions. In addition, discrete cortical abnormalities were observed (case 4) with microgyric-like cortical foldings.

In the two remaining pregnancies (cases 6 and 7) no virus was isolated from amniotic fluid culture and no specific IgM antibodies could be found in cord blood. After delivery at term, the newborns were free of infection: no specific IgM antibodies were detected in their serum, and they did not shed virus from urine or saliva within the first 2 weeks of life.

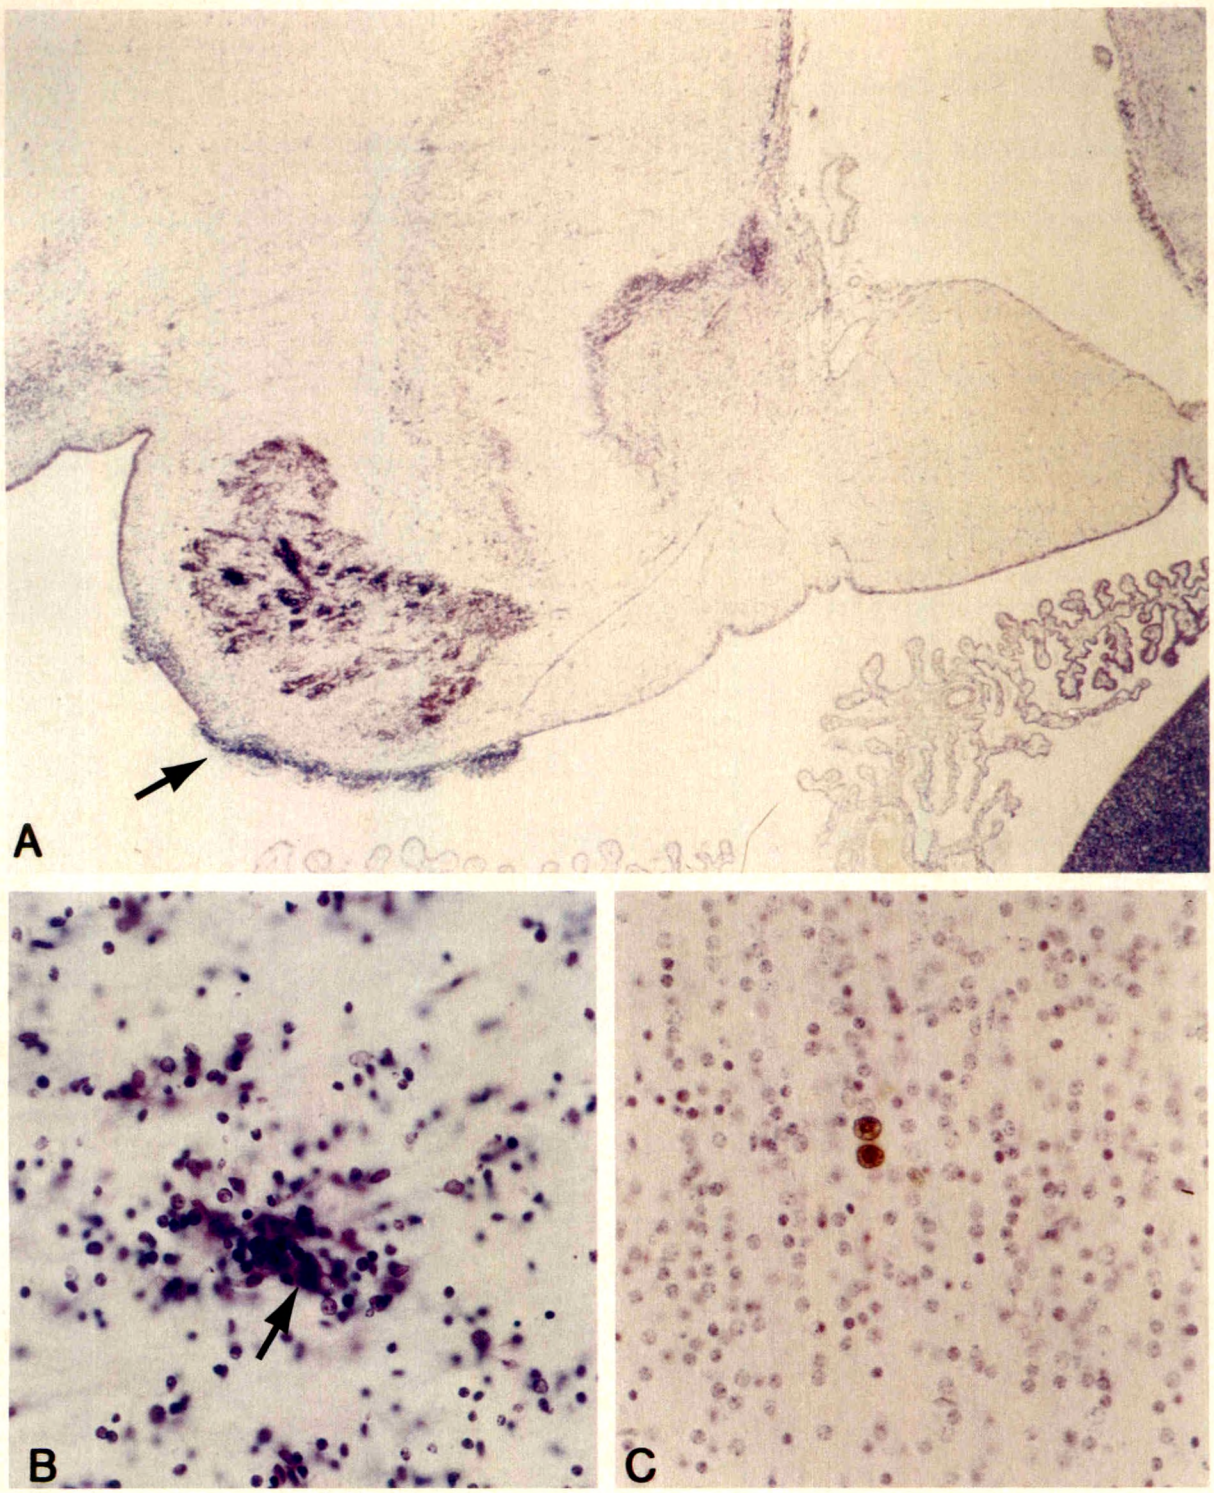

Fig. 1. Brain lesions in cytomegalovirus-infected fetuses. **A**, Perivascular calcified necrotic area and focal ependymal disruptions *(arrows)* by inflammatory cells; coronal section through the entorhinal region. (Hematoxylin-eosin stain; ×12.) **B**, Inflammatory nodule with intracytoplasmic cytomegalic inclusion *(arrows)*, subcortical region. (Hematoxylin-eosin stain; ×150.) **C**, Nuclear cytomegalic inclusions revealed by using an immunoperoxidase staining with anticytomegalovirus monoclonal antibody. Neocortical region. (Hematoxylin-eosin counterstain; ×180.)

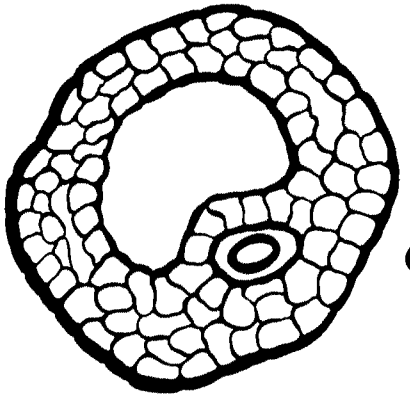

Comment

Detection of specific IgM in fetal blood was considered to be the best marker for prenatal diagnosis of cytomegalovirus infection.[3-7] These antibodies are detected only after 20 weeks of pregnancy.[8] Furthermore, an immature immune system or insufficient test sensitivity could lead to a false-negative result of IgM.[9] We found amniotic fluid culture to be a particularly sensitive indicator of cytomegalovirus transmission. It succeeded in predicting infection in five fetuses, confirmed by viral isolation from various organs and histologic lesions, which included the central nervous system; whether these lesions are responsible for neurologic sequelae requires further studies. Amniotic fluid culture also proved its specificity by showing negative results in the two cases free of infection at birth. We advocate that amniotic fluid culture be used in any case of suspected congenital infection. Two recently published reports dealing with amniocentesis corroborate our observations[10,11]; however, more amniocenteses performed before 22 weeks are needed to assess how early a marker amniotic fluid culture can be.

We thank M. Pirenne, M. Lebyn, M. Peers, L. Croonen, and B. Van De Put for their skillful technical assistance.

"All dressed up and no place to go."

DEMULEN® 1/35

(ethynodiol diacetate 1 mg, ethinyl estradiol 35 mcg)

Where protection begins

The physician should become familiar with the prescribing information (labeling) for this product, which discusses reported risks, such as thromboembolic disorders (including strokes and heart attacks), risk of estrogen dose, and hepatic lesions, as well as the need to monitor patients for early symptoms of any diseases or medical conditions, so use can be discontinued when appropriate.

Please see adjoining page for a brief summary of prescribing information.

The OC innovator **SEARLE**

DEMULEN® 1/35 Where protection begins

(ethynodiol diacetate 1 mg, ethinyl estradiol 35 mcg)

BRIEF SUMMARY

Demulen® 1/35: Each white tablet contains ethynodiol diacetate 1 mg and ethinyl estradiol 35 mcg. Each blue tablet in Demulen 1/35-28 is a placebo containing inert ingredients. **Demulen® 1/50:** Each white tablet contains ethynodiol diacetate 1 mg and ethinyl estradiol 50 mcg. Each pink tablet in Demulen 1/50-28 is a placebo containing inert ingredients.

Indication and usage: For prevention of pregnancy. Pregnancy rate for products with ≥35 mcg ethinyl estradiol or ≥50 mcg mestranol is ≤1/100 woman-years. With ≤35 mcg ethinyl estradiol, rate is slightly higher; with progestogen-only oral contraceptives (OCs), rate is about 3. Precise comparisons cannot be made. Rates for other methods have been published. *Dose-related Thromboembolic Risk:* Studies showed positive association between OC estrogen dose and thromboembolic risk. It is in keeping with good therapeutics to minimize estrogen exposure. Prescribe product containing least amount of estrogen compatible with acceptable pregnancy rate and patient acceptance. Start new users on ≤50 mcg estrogen.

Contraindications: Thrombophlebitis, thromboembolic disorders, past history of deep vein thrombophlebitis or thromboembolic disorders; cerebrovascular disease, myocardial infarction or coronary artery disease, or past history of these; known or suspected breast carcinoma, estrogen-dependent neoplasia, or pregnancy; undiagnosed abnormal genital bleeding; past or present, benign or malignant liver tumors developing during use of estrogenic products.

Warnings:

Cigarette-smoking increases risk of serious cardiovascular side effects from OC use. Risk increases with age and heavy smoking (15 or more cigarettes/day) and is quite marked in women over 35. OC users should be strongly advised not to smoke. OCs are associated with increased risk of several serious conditions including venous and arterial thromboembolism, thrombotic and hemorrhagic stroke, myocardial infarction, visual disorders, hepatic tumors, gallbladder disease, hypertension, fetal abnormalities. Practitioners should be familiar with the available information relating to these and other risks.

1. *Thromboembolic disorders and other vascular problems:* Increased risk of thromboembolic and thrombotic disease associated with OCs is well established. A British study showed increased risk for fatal venous thromboembolism (TE). British and U.S. studies showed increased risk for nonfatal disease. U.S. studies showed increased risk for stroke. OC users were 2-11 times more likely to manifest these diseases without evident cause. In a study of idiopathic deep vein thrombosis and pulmonary embolism (PE), projected hospitalization rates for ages 16-40 were 47/year/100,000 users and 5 for nonusers. Overall excess mortality from PE or stroke was 1.3-3.4 deaths/year/100,000 users and increased with age. *Cerebrovascular Disorders:* In a study of stroke with and without predispositions, risk of hemorrhagic stroke was 2 times greater and thrombotic stroke 4.0-9.5 times greater in users. Mortality trends in 21 countries indicate that changes in cardiovascular mortality were associated with changes in OC prevalence. The Royal College of GPs (RCGP) reported on its prospective study: "A statistically significant higher rate of reporting of cerebrovascular accidents in Takers is evident, but the numbers are too small to justify an estimation of the degree of risk." A 1981 analysis showed a 4-fold increased mortality in users from circulatory diseases, mainly myocardial infarction (MI) and hemorrhagic stroke. Excess mortality was associated with age and smoking. A 1983 analysis showed elevated cerebrovascular disease, increasing with use to 8 yrs, including cerebral thrombosis or embolism and TIA. Peripheral arterial disease and MI were increased. Women over 30 had more arterial disease, being greatest in smokers. Arterial case-fatality was 2-3 times greater for users who smoked. Family Planning Assoc. (FPA) found significant association between OC use and stroke; increased risk for venous thrombosis and PE was 4-fold and statistically significant. Mortality from nonrheumatic heart disease was greater in ever-users. In the Walnut Creek Study, subarachnoid hemorrhage risk was associated with smoking, age, and OC use. *Myocardial Infarction:* Increased risk of MI associated with OCs was reported in Britain, as previously suspected. The morbidity study found the greater the number of risk factors for coronary artery disease (smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk, regardless of OC use. OCs were an additional risk factor. Excess rate of fatal MI was 3.5/year/100,000 users aged 30-39 and 20 for ages 40-44. (These are based on British statistics with acute MI death rates 2-3 times less than the U.S. Similar estimates for the U.S. are 25.7 for users aged 30-39 with predispositions vs 1.5 without; for ages 40-44, 86.2 vs 5.1.) Excess hospitalization rate for nonfatal MI in Britain was 3.5/year/100,000 users aged 30-39 and 47 for ages 40-44. Smoking is a major predisposing condition to MI. In terms of relative risk, nonsmoking OC users are twice as likely to have fatal MI as nonsmoking nonusers. Smoking users have a 5-fold greater risk than nonsmoking users, but a 10-12-fold greater risk than nonsmoking nonusers. Amount of smoking is an important factor. In determining importance of these risks, give serious consideration to rates in table below. Importance of other predispositions cited above in determining relative and absolute risks has not been quantified; it is likely the same synergism exists, but perhaps to a lesser extent. U.S. studies similarly relate MI, OCs, smoking, and age.

Estimated Mortality Rate from Myocardial Infarction per 100,000 Women/Year

	Aged 30-39:	*Users*	*Nonusers*	*Aged 40-44:*	*Users*	*Nonusers*
All smokers		10.2	2.6		62.0	15.9
≥15 cigarettes daily		13.0	5.1		78.7	31.3
<15 cigarettes daily		4.7	0.9		28.6	5.7
Nonsmokers		1.8	1.2		10.7	7.4
Smokers and nonsmokers		5.4	1.9		32.8	11.7

Risk of Dose: Reports of TE after use of OCs with ≥50 mcg estrogen received by drug safety committees in Britain, Sweden, and Denmark were compared with distribution expected from market research sales estimates. A positive correlation was found between estrogen dose and reporting of TE, including coronary thrombosis, in excess of that predicted by sales. OCs with ≥100 mcg estrogen were associated with higher TE risk than those with 50-80 mcg. Estrogen quantity may not be the sole factor; influence of progestogens was not considered, which may be responsible for certain discrepancies in the data. No significant differences were noted between OCs containing same estrogen dose nor between ethinyl estradiol and mestranol. In Britain certain TE conditions were associated with progastogen or estrogen dose. In Sweden reports of TE decreased when higher estrogen doses were no longer prescribed. Studies on TE risk with progestogen-only OCs have not been done. Cases have been reported for these; they are not presumed free of risk. In a U.S. case-controlled study, relative risk of OC use 1 month before hospitalization for various types of TE was calculated. If relative estrogenic potency and possible influence of different progestogens are ignored, OCs may be divided into those with <100 mcg and those with ≥100 mcg estrogen. For all cases combined, larger doses were associated with only slightly higher risk; for idiopathic cases risk was doubled with larger doses, but confidence limits overlapped and differences were not significant. Apparently there was less increased risk for cases with predispositions. In FPA study no nonhemorrhagic strokes occurred with <50 mcg estrogen, vs 13 with higher doses. Latter group also had more venous TE. TE risk in users and nonusers increases with age. OCs have been considered an independent risk factor. Decreased HDL, which relates to increased myocardial ischemia, occurs with high progestational activity. Consider amount of both steroids in choosing OC. *Persistence of Risk* after OC discontinuation was reported for circulatory disease, nonrheumatic heart disease, and cerebrovascular disease, including subarachnoid hemorrhage, cerebral thrombosis, and TIA. *Excess Mortality from Circulatory Diseases:* A U.K. prospective study estimated annual mortality from circulatory diseases for OC users and nonusers by age, smoking, and duration of use. Excess mortality was 23/100,000 users (2 and 10 for ages 25-34, 15 and 48 for ages 35-44, 41 and 179 for ages >44, for nonsmokers and smokers, respectively). Risk was significant only for smokers over 34. Most deaths were due to subarachnoid hemorrhage or ischemic heart disease. Risk for ever-users rose with parity. One study estimated risk of death with various contraceptive methods, each estimate including risk of method (eg, TE for OCs) plus risk due to pregnancy or abortion in cases of method failure. This latter risk varies with effectiveness. It concluded mortality with all methods is low and below that of childbirth, except for OC users over 40 who smoke. Heavy smokers have double the risk of smokers, light smokers about half. Mortality with OC use in nonsmokers over 40 is higher than with any other method in that age group. Lowest mortality is with condom or diaphragm backed up by early abortion. Risk of TE and thrombotic disease with OCs increases with age after 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia, and especially cigarette smoking. Based on current data, the chart gives gross estimates of risk of death from circulatory disorders associated with OCs:

Risk is: A—very high; B—high; C—moderate; D—low.	Age:	<30	30-39	≥40
Heavy smokers (≥15/day)		C	B	A
Light smokers (<15/day)		D	C	B
Nonsmokers, no predispositions		D	C,D	C
Nonsmokers, with predispositions		C	C,B	B,A

Be alert to earliest manifestations of TE disorders (eg, thrombophlebitis, PE, cerebrovascular insufficiency, coronary artery disease, MI, retinal thrombosis, mesenteric thrombosis). Should any be suspected, discontinue OCs immediately. A 4-7-fold increased risk of postsurgery TE was reported in users; if feasible discontinue OCs at least 4 weeks before surgery or in prolonged immobilization. Before resuming OCs, weigh risks of postsurgery TE complications against contraceptive needs. RCGP reported higher incidence of superficial and deep vein thrombosis in users, the former correlated with progestogen dose. Varicose veins have little effect on development of deep vein thrombosis. **2.** *Ocular lesions:* Neuro-ocular lesions such as optic neuritis or retinal thrombosis have been associated with OCs. Discontinue if there is unexplained, gradual or sudden, partial or complete loss of vision; proptosis or diplopia; papilledema; or evidence of retinal vascular lesions. Institute diagnostic and therapeutic measures. **3.** *Carcinoma:* Long-term estrogen in certain animals increases carcinomas and/or nonmalignant neoplasms, such as those of breast, uterus, cervix, vagina, ovary, liver, pituitary. Some synthetic progestogens, none currently in OCs, increase incidence of benign and malignant mammary nodules in dogs. Estrogens increase risk of human endometrial carcinoma. In case-controlled studies, increased risk (2.2-13.9 times) associated endometrial carcinoma with prolonged estrogen for menopausal symptoms. Risk was independent of other known risk factors and depended on duration of use and dose. This is supported by increased endometrial cancer incidence since 1969 in areas with cancer-reporting systems, which may be related to expanding estrogen use. There is no evidence that natural estrogens are more or less hazardous than synthetics. Of the first 30 cases of endometrial carcinoma in OC users under 40, those without predispositions occurred nearly always with no-longer-marketed sequential OCs. No statistical association is reported suggesting increased endometrial cancer with combination or progestogen-only OCs. Studies show no increased breast cancer with OCs or estrogens. However, greater risk was noted in OC users with benign breast disease or long-term (2-4 years) use. One study found greater risk of breast cancer with >4 years OC use prior to first full-term pregnancy. Risk of breast cancer with menopausal estrogens rose and further increased with duration of follow-up. OCs or estrogen were related to breast cancer in connection with other risk factors and in various subgroups. Decrease in benign breast tumors in OC users is well known. Some studies suggested increased risk of cervical dysplasia, CIN, erosion, and carcinoma in long-term users. Cervical microglandular hyperplasia has been reported. In summary, there is no consistent evidence from human studies of increased cancer risk with OCs. Close surveillance is, however, essential. In undiagnosed persistent or recurrent abnormal vaginal bleeding, consider nonfunction causes and take diagnostic measures to rule out malignancy. Carefully monitor users with strong family history of breast cancer or with breast nodules, fibrocystic disease, recurrent cystic mastitis, abnormal mammograms, or cervical dysplasia. **4.** *Hepatic adenomas, etc,* have been associated with OCs. In 1 study OC formulations with high "hormonal potency" were associated with higher risk, as was age over 30. Though benign, these lesions may rupture and cause fatal hemoperitoneum in short- or long-term users. Two studies related risk to duration of use, being much greater after ≥4 years. Long-term OC users have an estimated adenoma incidence of 3-4/year/100,000. Consider such lesions in users with abdominal pain, tenderness, mass, or shock. About 25% present with abdominal masses, up to half with acute hemoperitoneum. Radiology and lab studies may not be helpful; liver scans may show local defect. Hepatic arteriography or CAT may be useful. Hepatocellular carcinoma risk is increased 7-20 times in users for 8 or more years. Bile duct cancer may occur with OC use. **5.** *Use in or immediately preceding pregnancy, birth defects, malignancy in offspring:* Estrogens or progestogens during early pregnancy may seriously damage offspring. Females exposed in utero to DES and other nonsteroidal estrogens may have increased risk of vaginal or cervical cancer. Though OCs may not enhance this risk, monitor such patients carefully. From 30-90% of DES-exposed women develop benign vaginal or cervical adenosis, which could be premalignant. DES-exposed daughters have more unfavorable pregnancy outcomes. Males so exposed may develop urogenital and sperm defects. Other estrogens may mimic DES. Reports relate fetal exposure to female sex hormones and congenital anomalies, eg, VACTERL (of vertebral, anal, cardiac, tracheoesophageal, renal, and limb defects. There appears preferential expression by males. There was a 4.7-fold increased risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal pregnancy tests, or treatment for threatened abortion). Some exposures were very short, being only a few days. Cardiovascular defects in children exposed to female hormones, including OCs, during early pregnancy occurred in 18.2/1,000 births compared to 7.8 for those unexposed ($P<.05$). Female hormone exposure in utero was associated with testicular and ovarian cancer. More twinning was reported in conceptions shortly after OC discontinuance. Female sex hormones were used for threatened or habitual abortion, but there is considerable evidence estrogens are ineffective and no evidence progestogens are effective. Triploidy and possibly other polyploidy may be increased in abortuses from women becoming pregnant soon after post-OC. These almost always abort spontaneously. It is unknown if spontaneous abortion is increased soon after stopping OCs. Increased chromosome aberrations have been reported. Safety of OCs in pregnancy has not been demonstrated. Rule out pregnancy in using OCs and always consider it if withdrawal bleeding does not occur. If 2 consecutive periods are missed rule out pregnancy before continuing. If user deviates from regimen, consider pregnancy at first missed period and withhold OCs. If pregnancy is confirmed, stop OC and apprise patient of potential fetal risks and discuss continuation of pregnancy. Users discontinuing for pregnancy should use alternative contraception for 3 months before attempting to conceive, though this is not based on precise information. Do not use progestogen-only or progestogen-estrogen drugs as pregnancy tests. **6.** *Gallbladder disease* risk, surgically confirmed, appeared after 2 years' use and doubled after 4-5 years in 1 study; appeared in 6-12 months' use in another. Bile duct cancer has been reported. **7.** *Carbohydrate and lipid metabolism:* Decreased glucose tolerance occurs in a significant number of users; carefully observe diabetic and prediabetic patients. Triglycerides, total phospholipids, and lipoproteins may increase. **8.** *Elevated blood pressure* (BP) occurs in some users in a few months and degree may relate to progestogen dose. Hypertension prevalence in users is not higher in the first year, but increase with longer exposure; in the 5th year it is 2½-3 times the first year. Age is strongly correlated with hypertension in users. Those with history of elevated BP (hypertension), preexisting renal disease, history of toxemia or elevated BP in pregnancy, familial tendency to hypertension or its consequences, or history of excessive weight gain or fluid retention during menstrual cycles may be more likely to develop elevated BP on OCs and should be monitored closely. Even though elevated BP may be in "normal" range, do not ignore implications. Follow closely, particularly those with other risk factors for cardiovascular disease or stroke. High BP may or may not persist after stopping OCs. **9.** *Headache:* Onset or exacerbation of migraine or development of headache of a new pattern that is recurrent, persistent, or severe requires stopping OCs and evaluating cause. **10.** *Bleeding irregularities:* Breakthrough bleeding (BTB), spotting, and amenorrhea are frequent reasons for discontinuing. If BTB, as in all cases of irregular bleeding, consider nonfunctional causes. In undiagnosed persistent or recurrent bleeding, rule out pregnancy or malignancy. If pathology is excluded, time or change to another product may suffice. Change to a higher estrogen OC only when necessary as this may increase thromboembolic risk. Those with history of oligomenorrhea or secondary amenorrhea or without established regular cycles may be anovulatory or amenorrheic after discontinuing. Those with such problems should be so informed and other methods encouraged. Post-use anovulation, possibly prolonged, may occur in women without previous irregularities. Higher incidence of galactorrhea and of pituitary tumors has been associated with postpill amenorrhea. One study reported 16-fold increased prevalence of pituitary prolactin-secreting tumors in patients with postpill amenorrhea when galactorrhea was present. **11.** *Ectopics:* In failures with combination OCs, the ratio of ectopic to intrauterine pregnancies is no higher than in nonusers. **12.** *Breast feeding:* OCs may decrease quantity and quality of milk. A small fraction of OC steroids appears in milk. Effects if any on child are unknown. If feasible defer OCs until after weaning. **13.** *Infertility* may occur after discontinuing OCs. While impairment diminishes with time, there is still an appreciable difference in nulliparas aged 25-29 after 30 months; difference is negligible after 48 months. In nullips aged 30-34 impairment persists to 72 months and is more severe for 2-year users. In paras aged 25-34, difference is negligible after 30 months. **Precautions:** Conduct complete history and physical prior to OC use and annually thereafter. Include breasts, abdomen, and pelvis, with BP, Pap, and lab tests. Preexisting uterine leiomyomata may enlarge. Mental depression may occur; with positive history observe carefully and discontinue if serious recurrence. Fluid retention may occur; prescribe cautiously and monitor carefully in convulsive disorders, migraine, asthma, or cardiac, hepatic, or renal dysfunction. History of jaundice in pregnancy increases risk of recurrence on OCs; observe carefully and discontinue if it occurs. Cholestatic jaundice occurred after OC and troleandomycin use. OC/cyclosporine combination may be hepatotoxic. Steroids may be poorly metabolized in liver dysfunction and should be given cautiously. Tryptophan metabolism may be disturbed and result in pyridoxine deficiency; megaloblastic anemia has been reported. Serum folate may be depressed and may be exacerbated in post-OC pregnancy. Advise pathologist of OC use when submitting specimens. Endocrine and liver function tests may be altered; repeat abnormal tests after stopping for 2 months. These have been observed: increased BSP retention and other abnormalities in liver function tests; increased prothrombin and coagulation factors VII, VIII, IX, X; decreased antithrombin III, increased platelet aggregability; increased thyroid-binding globulin leading to increased circulating total thyroid hormone (PBI, T^4); decreased T^3 uptake, unaltered free T^4, decreased pregnanediol excretion; reduced metyrapone response; increased blood transcortin, corticosteroid, triglyceride phospholipid, reduced serum folate; impaired glucose tolerance; altered plasma trace minerals. Influence of prolonged OC use on pituitary, ovarian, adrenal, hepatic, or uterine function, or on immune response not established. OCs may mask onset of climacteric. Cervical chlamydial and gonorrheal prevalence is increased; do not assume OC protects against chlamydial PID. HIV seropositivity was associated with OC use. *Information for patients.* See patient labeling. *Drug Interactions.* OC effectiveness may be decreased and more BTB occur with rifampin, isoniazid, ampicillin, neomycin, penicillin V, tetracycline, chloramphenicol, sulfonamides, nitrofurantoin, griseofulvin, barbiturates, phenytoin, carbamazepine, primidone, phenylbutazone, analgesics, tranquilizers, antimigraines. OCs may alter effectiveness of oral anticoagulants, anticonvulsants, tranquilizers, tricyclic antidepressants, antihypertensives, theophylline, caffeine, vitamins, hypoglycemics, clofibrate, glucocorticoids, acetaminophen. **Adverse reactions:** Increased risk of the following serious adverse reactions has been associated with OCs: thrombophlebitis and thrombosis; pulmonary embolism; arterial thromboembolism; Raynaud's disease, myocardial infarction; coronary thrombosis; cerebral thrombosis; cerebral hemorrhage; hypertension; gallbladder disease; Budd-Chiari syndrome; benign adenomas and other hepatic lesions, with or without intra-abdominal bleeding, liver cancer, congenital abnormalities. There is evidence of association between the following and OCs, though confirmatory studies have not been done: mesenteric thrombosis; neuro-ocular lesions, eg, retinal thrombosis and optic neuritis. The following are believed drug related: nausea, vomiting, gastrointestinal symptoms, BTB, spotting, change in menstrual flow, dysmenorrhea, amenorrhea during and after use, infertility post-OC, edema, chloasma or melasma, which may persist post-OC, breast changes (tenderness, enlargement, secretion), weight changes, change in cervical erosion and secretion, endocervical hyperplasia, lactation decrease, cholestatic jaundice, migraine, enlarged uterine leiomyomata, allergic rash, mental depression, reduced carbohydrate tolerance, vaginal candidiasis, change in corneal curvature (steepening), intolerance to contact lenses. Association not confirmed or refuted for premenstrual-like syndrome, cataracts, libido changes, chorea, appatite changes, cystitis-like syndrome, headache, paresthesia, nervousness, dizziness, auditory disturbances, rhinitis, fatigue, backache, hirsutism, scalp hair loss, erythema multiforme or nodosum, hemorrhagic eruption, herpes gestationis, hidradenitis suppurativa, hemolytic uremia, malignant hypertension, impaired renal function, acute renal failure, sometimes irreversible, itching, vaginitis, porphyria, PVCs, abnormal EKG, pulmonary hypertension, TTP, anemia, pancreatitis, hepatitis, colitis, Crohn's disease, gingivitis, dry socket, lupus erythematosus, rheumatoid arthritis, pituitary tumors (eg, adenoma) with amenorrhea and/or galactorrhea after use, malignant melanoma, endometrial, cervical, breast, and bile duct carcinoma. **Acute overdosage:** Serious ill effects have not been reported after large acute doses of OCs in young children. Nausea and withdrawal bleeding might occur. **Important note: Complete prescribing information should be consulted prior to use and is available on request.**

Endothelin-1,2 levels are increased in the amniotic fluid of women with preterm labor and microbial invasion of the amniotic cavity

Roberto Romero, MD,[a,c] Cecilia Avila, MD,[a] Samuel S. Edwin, MS,[b] and Murray D. Mitchell, DPhil[b]

New Haven, Connecticut, Detroit, Michigan, and Salt Lake City, Utah

The purpose of this study was to determine the effect of gestational age, labor, and microbial invasion of the amniotic cavity on amniotic fluid concentrations of endothelin-1,2. Amniotic fluid was retrieved by amniocentesis from 148 women: patients at term with and without labor, patients with preterm labor with and without intraamniotic infection, and women in the second trimester of pregnancy. Endothelin-1,2 was measured by a sensitive and specific radioimmunoassay. Immunoreactive endothelin-1,2 was detectable in all samples of human amniotic fluid. Advancing gestational age and spontaneous term labor did not result in changes in amniotic fluid concentrations of endothelin-1,2. Women with preterm labor and positive amniotic fluid cultures for microorganisms had higher amniotic fluid concentrations of endothelin-1,2 than did those without microbial invasion of the amniotic cavity ($p < 0.05$). These results support a role for endothelins in the mechanisms responsible for preterm delivery associated with intraamniotic infection. (AM J OBSTET GYNECOL 1992;166:95-9.)

Key words: Endothelins, intraamniotic infection, preterm labor, chorioamnionitis

Endothelins are a family of small proteins that were originally isolated from the culture supernatants of porcine aortic endothelial cells.[1] The first member of this family to be characterized was endothelin-1. Expression of the endothelin-1 gene is regulated by several vasoactive agents, and the peptide is a potent vasoconstrictor. Subsequently, this family of peptides has expanded to include endothelin-1 (porcine/human), endothelin-2, and endothelin-3 (rat endothelin).[2-4] These 21-residue peptides are formed from a preproendothelin (−200 residues) by way of a 38/39-residue intermediate.[1, 2] It is thought that endothelins act as endogenous agonists of dihydropyridine-sensitive calcium channels.[1] Endothelins can induce two types of contractions of the rat uterus,[5] activate phospholipase A_2,[6] and activate phospholipase C.[7, 8] Endothelins have recently been found to be synthesized not only by endothelial cells but also by kidney cells.[9] Moreover, it has been suggested that endothelin-1 is synthesized by amnion.[10, 11]

A role for endothelins in the control of human parturition can be postulated on the basis of their effect on myometrial contractility and on phospholipase A_2 and C. This study was undertaken to determine the effect of labor and microbial invasion of the amniotic cavity on amniotic fluid concentrations of endothelin-1,2.

Material and methods

Patient population and study design. Amniotic fluid was collected from 155 women. Patients were subdivided into four groups: group 1, women in the second trimester of pregnancy (gestational age of 16 to 18 weeks) undergoing amniocentesis for genetic indications (maternal age >35 years) ($n = 22$); group 2, women in the third trimester (gestational age of 38 to 39 weeks) who had amniocentesis for the assessment of fetal lung maturity before elective cesarean section ($n = 25$); group 3, women with spontaneous active labor at term and negative amniotic fluid cultures ($n = 44$). Amniotic fluid was obtained at the time of repeat or primary cesarean section or by amniocentesis in patients who were thought to have preterm labor but who subsequently were delivered of babies weighing >2800 gm and considered term by pediatric examination. Group 4 consisted of women admitted with

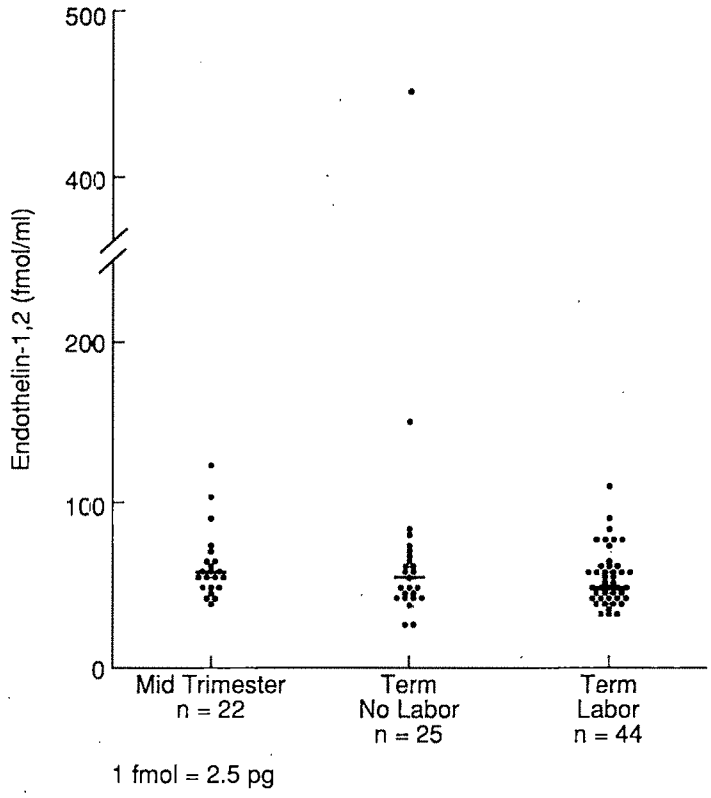

Fig. 1. Amniotic fluid endothelin-1,2 concentrations in women in midtrimester, at term without labor, and at term in active labor. Midtrimester: median 57.5 fmol/ml, range 38 to 125 fmol/ml; term no labor: median 56 fmol/ml, range 26 to 450 fmol/ml; term labor: median 50.5 fmol/ml, range 32 to 110 fmol/ml. No differences among groups ($p > 0.05$).

preterm labor and intact membranes ($n = 57$). Amniocentesis was performed in this group for microbiologic assessment of the amniotic cavity and fetal lung maturity studies. To study the relationship between intraamniotic infection, preterm labor, and amniotic fluid endothelin-1,2 concentrations, a cross-sectional study of patients in group 4 (preterm labor) was constructed. Patients with preterm labor were subdivided into three subgroups according to their response to tocolysis and the results of their amniotic fluid culture: subgroup 4a, women with preterm labor and negative amniotic fluid cultures who were responsive to tocolysis ($n = 21$); subgroup 4b, women with preterm labor and negative amniotic fluid cultures who were unresponsive to tocolysis and were delivered of preterm neonates ($n = 19$); subgroup 4c, women with preterm labor and intraamniotic infection who were delivered of preterm neonates ($n = 17$).

Preterm labor was defined as the presence of regular uterine contractions with a frequency of at least two every 10 minutes for at least 60 minutes' duration. Amniocentesis was performed before the initiation of tocolytic therapy with intravenous ritodrine or terbutaline. Failure of tocolysis was diagnosed when cervical dilatation progressed beyond 5 cm and/or delivery occurred. Informed consent was obtained from all patients according to the guidelines of the Yale University Human Investigations Committee.

Microbiologic studies. Amniotic fluid was transported to the laboratory in a capped plastic syringe immediately after collection and plated within 30 minutes of collection. Fluid was cultured for aerobic and anaerobic bacteria and for *Mycoplasma hominis* and *Ureaplasma urealyticum*, as previously described.[12]

Endothelin-1,2 determinations. Endothelin-1,2 was measured with radioimmunoassay kits from Amersham Corporation (Arlington Heights, Ill.). The assay was performed directly on duplicate 100 μl amniotic fluid samples. We have found that purification of liquor samples before assay has a limited effect on measured values, in marked contrast to its significant impact on plasma measurements. The sensitivity of the assay (2 SD of the zero point binding) is 1.03 fmol. Intraassay and interassay coefficients of variation are 4.1% and 10.4%, respectively.

Statistical analysis. Comparisons of endothelin-1,2 concentrations in amniotic fluid samples from different groups were conducted with a Kruskal-Wallis one-way

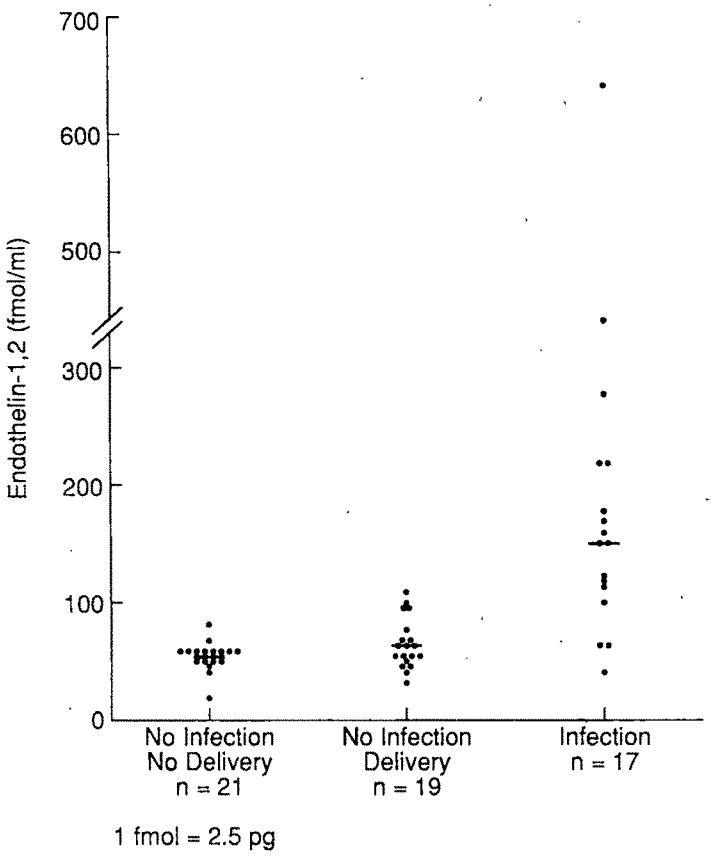

Fig. 2. Amniotic fluid concentrations of endothelin-1,2 in women in preterm labor according to response to tocolysis and amniotic fluid culture results. Subgroup 4a, women with negative amniotic fluid cultures who responded to tocolysis: median 55 fmol/ml, range 17 to 83 fmol/ml; subgroup 4b, women with negative amniotic fluid cultures who did not respond to tocolysis and were delivered of preterm neonates: median 62 fmol/ml, range 31 to 110 fmol/ml; subgroup 4c, women with positive amniotic fluid cultures who were delivered of preterm neonates: median 150 fmol/ml, range 41 to 640 fmol/ml. No difference was found between subgroups 4a and 4b; concentration in subgroup 4c was greater than that in subgroups 4a and 4b ($p < 0.05$).

analysis of variance. The Dunn test was used for post hoc multiple comparisons among groups (True Epistat, Epistat Services, Richardson, Tex.).

Results

Immunoreactive endothelin-1,2 was detected in all amniotic fluid samples from patients in the second and third trimesters of pregnancy (groups 1 and 2, Fig. 1). No changes were observed with gestational age in the amniotic fluid concentrations of endothelin-1,2. Spontaneous labor at term was not associated with an increased concentration of immunoreactive endothelin-1,2 in amniotic fluid ($p > 0.05$) (Fig. 1).

Patients in preterm labor with positive amniotic fluid cultures for microorganisms (group 4c) had significantly greater concentrations of amniotic fluid endothelin-1,2 than did women without intraamniotic infection (subgroups 4a and 4b, Fig. 2) ($p < 0.05$). Failure to respond to tocolysis in women with preterm labor was not associated with higher amniotic fluid concentrations of endothelin-1,2 when compared with those of women in preterm labor who were responsive to tocolysis. Table I displays the clinical and microbiologic information for patients with preterm labor and microbial invasion of the amniotic cavity.

Comment

This study documents the presence of immunoreactive endothelin-1,2 in normal amniotic fluid from women in the second and third trimesters of pregnancy. It is interesting to note that amniotic fluid concentrations of endothelin-1,2 were approximately tenfold higher than those observed in peripheral blood or in the umbilical circulation.[13, 14] No change in the amniotic fluid concentration of endothelin-1,2 was observed with gestational age.

The role of these endothelins is uncertain. Since endothelin can induce smooth muscle contraction, we pos-

tulated that it might play a role in the control of human parturition. Indeed, myometrium is extremely sensitive to the action of endothelin with a contractile effect demonstrated at very low concentrations of the peptide.[15] This action is mediated by an increase in intracellular calcium concentration and phosphorylation of the myosin light chain.[15] Additionally, endothelin-1 can stimulate uterotonic prostaglandin output by myometrium[16] and thus induce contractions indirectly. Our data, however, do not indicate a change in amniotic fluid concentrations of endothelin-1,2 with spontaneous parturition at term.

In contrast, women with preterm labor and microbial invasion of the amniotic cavity have higher amniotic fluid concentrations of endothelin-1,2 than do those with negative amniotic fluid cultures for microorganisms. These results are consistent with a role for endothelin-1,2 in the mechanism of preterm labor associated with intraamniotic infection. Alternatively, the increased availability of endothelin-1,2 in amniotic fluid could be an epiphenomenon associated with parturition in the setting of infection. Further investigation of the intrauterine sources and local regulation of the production of endothelin is required. It is unknown whether bacteria could be a source of endothelin. It has been documented, however, that human amnion produces endothelin[17] and that cytokines such as interleukin-1β can increase endothelin production by amnion.[18] Interleukin-1β is found in the amniotic fluid of women with preterm labor and intraamniotic infection[19, 20] and is produced by human decidua in response to bacterial products.[21] Therefore cytokines produced during the host response to intraamniotic infection may be responsible for the increased availability of endothelin-1,2. Endothelins may play a role in the regulation of myometrial contractility in infection-associated preterm labor. Further studies are required to determine whether amniotic fluid endothelin can cross intact chorioamniotic membranes and reach the myometrium to exert this biologic action.

Incidence of pelvic inflammatory disease after first-trimester legal abortion in women with bacterial vaginosis after treatment with metronidazole: A double-blind, randomized study

Per-Göran Larsson, MD,[a] Jens-Jörgen Platz-Christensen, MD,[b] Henning Thejls, MD,[c] Urban Forsum, MD, PhD,[d] and Carl Påhlson, PhD[e]

Skövde, Gothenburg, Gävle, Linköping, and Uppsala, Sweden

OBJECTIVE: The purpose of this study was to evaluate the effect of metronidazole treatment on the incidence of postoperative pelvic inflammatory disease after first-trimester abortion in women with bacterial vaginosis.

STUDY DESIGN: A double-blind, randomized, multicenter study was conducted on 231 women undergoing first-trimester legal abortion and fulfilling the criteria for bacterial vaginosis. The women were randomized to either metronidazole 500 mg three times daily for 10 days or placebo. Treatment was started at the outpatient visit the week before the operation.

RESULTS: Among the 174 women who could be evaluated, pelvic inflammatory disease developed in 14 after the abortion. In the treatment group there were three infections (3.8%) compared with 11 (12.2%) in the placebo group ($p < 0.05$).

CONCLUSION: These data suggest that patients with bacterial vaginosis should be treated in conjunction with first-trimester abortion because treatment with metronidazole reduces the postoperative infection rate more than three times. (Am J Obstet Gynecol 1992;166:100-3.)

Key words: Bacterial vaginitis, endometritis, pelvic infection, abortion

The incidence of pelvic inflammatory disease after first-trimester abortion is 4% to 12%.[1-3] Many attempts have been made to identify risk groups. Patients considered to be at risk are women with previous pelvic inflammatory disease, cervical infection with either *Chlamydia trachomatis* or *Neisseria gonorrhoeae,* and women with pregnancy of advanced gestational age.[4, 5] Screening for *C. trachomatis* with subsequent treatment does not, however, reduce the infection rate, indicating to us that other factors might predominate in some patient groups.[6, 7]

Prophylactically administrated antibiotics, i.e., penicillin-ampicillin,[8] metronidazole,[9, 10] tinidazole,[11, 12] and doxycycline,[13, 14] have been tried to reduce the incidence of postabortion pelvic inflammatory disease. With the exception of one study with metronidazole,[10] no risk groups were selected for prophylactic antibiotic treatment. Women with a history of pelvic inflammatory disease received metronidazole, but no reduction in the infection rate could be demonstrated.

In a recently published study we showed that women with clue cells in Gram-stained smears may be a group at risk for postabortion pelvic inflammatory disease.[6] The presence of clue cells is one of the accepted signs of bacterial vaginosis and alone is highly discriminative between bacterial vaginosis and normal status.[15] In our study postabortion pelvic inflammatory disease developed in 10.8% of women with clue cells compared with 4.5% of women without clue cells.[6] The aim of this study

was to evaluate whether treatment with metronidazole in women with bacterial vaginosis lowers the rate of postabortion pelvic inflammatory disease after first-trimester abortion.

Material and methods

A double-blind, randomized, placebo-controlled, multicenter study was performed in three different hospitals in Sweden (Sahlgrenska Hospital, Gothenburg; Central Hospital, Skövde; Central Hospital, Gävle). All women >16 years old and without language difficulties visiting our outpatient clinics during the study period for first-trimester legal abortion underwent investigation for the presence of bacterial vaginosis. Bacterial vaginosis was diagnosed if three of the following four criteria were fulfilled: characteristic discharge, pH >4.5, positive amine test, and clue cells in a wet smear.[16] To ascertain uniform diagnosis of bacterial vaginosis at the three hospitals, clue cells were also evaluated on air-dried smears.[17]

All smears were investigated by culture or with Chlamydiazyme (Abbott Scandinavia) for *C. trachomatis*. Culturing for *N. gonorrhoeae* was done in one hospital (Gothenburg). None of the *N. gonorrhoeae* cultures were positive, and because of the low incidence in Sweden culturing was not done at the other two hospitals.[18]

Patients fulfilling the criteria for bacterial vaginosis were invited to take part in the study. After giving verbal consent, the patients were treated with either metronidazole tablets, 500 mg three times daily for 10 days, or placebo tablets. If any complications occurred, the patients were asked to return to the clinic. A vacuum aspiration was done within a week after the outpatient visit and before the twelfth completed week. Preoperative ripening of the cervix was performed in primiparous women with intravaginally administered prostaglandins, Cervagem dilators (Skövde), intracervical laminaria tents (Gävle), or Dilapan dilators (Gothenburg). The medical records of all patients were evaluated at follow-up 1 month later.

Postabortion pelvic inflammatory disease was defined as two or more of the following six criteria fulfilled within 28 days of the operation: (1) abnormal or purulent vaginal discharge after 1 week, (2) abnormal bleeding after the third day, (3) temperature >38.0° C (100.4° F) for >24 hours, (4) palpable adnexal masses, (5) tenderness over the uterus or adnexa on pelvic examination, or (6) erythrocyte sedimentation rate >30 mm.

The metronidazole tablets and identical placebo tablets were supplied by Dumex Ltd., Copenhagen. All data were fed into a computer before the code indicating placebo or metronidazole treatment was broken. The study was approved by the regional ethics committee. The one-tailed z test was used for statistical evaluation. A p value >0.05 was considered nonsignificant.

Results

During the study period 1202 women visited our outpatient clinics for first-trimester abortion. Of these, 231 (19.2%) fulfilled the criteria for bacterial vaginosis and were accepted in the study. The mean age of the study group was 25.2 years. Fifty-seven patients were excluded from the study group, 23 because of *C. trachomatis* infection; all of these received antibiotics before operation. Three women received other antibiotics before operation (two because of *Trichomonas vaginalis* infection). Three women did not undergo the abortion procedure until after 13 weeks of gestation (second-trimester abortion), and seven women continued the pregnancy. Reexeresis was done in five women, six had received postoperative antibiotics, and six did not follow the prescribed medication. The medical records of four patients could not be found (Table I).

The treatment trial thus consisted of 174 women. During the study period 14 cases of postoperative pelvic inflammatory disease occurred. The breakdown of the individual pelvic inflammatory disease criteria were as follows: 10 women had tenderness over the uterus or adnexa on pelvic examination in combination with fe-

ver and the other four women had tenderness over the uterus or adnexa in combination with abnormal bleeding ($n = 2$) or discharge ($n = 2$) and one of them had palpable adnexal masses. Three (3.6%) of the 84 patients in the metronidazole group and 11 (12.2%) of the 90 patients in the placebo group ($p < 0.05$; Table II) had postoperative pelvic inflammatory disease. Treatment of bacterial vaginosis lowers the incidence of post abortion pelvic inflammatory disease by 8.7% (95% confidence limits 0.9% to 16.6%); thus treatment lowers the infection more than 3 times.

The median time from abortion to infection were 5.5 days. The time to infection did not exceed 16 days, and the women treated with metronidazole have the infections in the first 4 days. The infection rates in the three hospitals are listed in Table II. Statistically there were no significant differences.

The investigation of air-dried smears according to the described method[17] was done after the completion of the study. Of the 174 women in the study, eight smears could not be examined because of either interfering blood or little material for correct diagnosis. Thus it was possible to examine 166 air-dried smears. Of these, 158 contained clue cells (95.2%). None of the eight patients without clue cells in air-dried smears had a postoperative infection.

Comment

In an attempt to reduce the risk for postoperative infection associated with first-trimester elective abortion, several studies have been performed to define criteria for prophylactic treatment with antibiotics. The only risk groups identified so far are women with a positive culture for *N. gonorrhoeae* or *C. trachomatis*.[5, 14, 19] Screening is therefore often performed for *C. trachomatis* infection among (all or) selected groups of women undergoing first-trimester abortion.[2, 19, 20]

Bacterial vaginosis signifies a disturbed or abnormal vaginal flora, with suppression of lactobacilli and an increase in the number of other bacteria such as *Mycoplasma hominis*, bacteroides, anaerobes, and *Gardnerella vaginalis*.[21] It is conceivable that during abortion these microorganisms can ascend into the endometrial cavity[7] and in some cases cause infection. Many postabortion infections occur within 1 week after the operation, and it has been questioned whether these early infections are caused by *C. trachomatis*.[2, 11] Early infections that mostly occur in the endometrial cavity may not be as hazardous to future fertility as salpingitis that develops after 2 to 4 weeks.[22] Such salpingitis is probably more often caused by *C. trachomatis*.[2, 11] The early infections, however, will still cause a great deal of discomfort and morbidity for the patients, with an increase in hospitalization. Studies published on the role of *C. trachomatis* in postabortion pelvic inflammatory disease have not divided the infections into early and late.[1-4, 14, 19, 20] Metronidazole treatment is effective only against anaerobic bacteria associated with bacterial vaginosis and not against *C. trachomatis;* therefore the reduction in infection rate in our study is most probably not due to undetected *C. trachomatis* infections, although *C. trachomatis* is associated with bacterial vaginosis. The incidence of *C. trachomatis* was 10.0% in our study group but only 2.6% among the other women not having bacterial vaginosis. This association between bacterial vaginosis and *C. trachomatis*–infected patients attending sexually transmitted disease clinics has been shown previously.[23, 24] The results of previous studies[1, 14, 20] demonstrating a reduction in postabortion pelvic inflammatory disease if *C. trachomatis*–positive women are treated with tetracyclines could thus be because tetracyclines are also effective against bacterial vaginosis.

It is also known that the experience of the surgeon is of importance, but since all colleagues taking part in the study at the three departments were either attending surgeons or resident surgeons under training and were supervised by attending surgeons, this should not have interfered with our results.

Our results indicate that patients with bacterial vaginosis should be treated in conjunction with first-trimester elective abortion to reduce the risk of postabortion infection. These results are partly supported by other studies that have found connections between preterm birth,[25] postcesarean endometritis, and bacterial vaginosis diagnosed by vaginal Gram-stained smears.[26] Recently a connection has been shown between bacterial vaginosis and postoperative infection after abdominal hysterectomy,[27] a connection that we have also found.[28]

We thank all colleagues for assistance in conducting the study.

Depressive symptoms in women in the six months after miscarriage

Richard Neugebauer, PhD, MPH,[a, b] Jennie Kline, PhD,[b, d] Patricia O'Connor, PhD,[b, f] Patrick Shrout, PhD,[a, b, e] Jim Johnson, PhD,[b] Andrew Skodol, MD,[c] Judith Wicks, BA,[b] and Mervyn Susser, MB, BCh, DPH[b, d]

New York, New York

This study, the first systematic investigation of the psychiatric impact of miscarriage, tests whether miscarriage markedly increases depressive symptoms in the 6 months after loss. We interviewed 382 miscarrying women entering the study at 2 weeks, 6 weeks, or 6 months after loss and, for comparison, 283 pregnant women and 318 community women not recently pregnant. Among women interviewed 2 weeks after miscarriage the proportion highly symptomatic on the Center for Epidemiologic Studies–Depression scale was 3.4 t mes that of pregnant women (95% confidence limits 2.0 and 5.0) and 4.3 times that of community women (95% confidence limits 3.0 and 5.8). Among women first interviewed 6 weeks and 6 months after miscarriage the proportion highly symptomatic was three times that of the community women. Women reinterviewed at 6 weeks and 6 months did not have elevated symptom levels, a result attributed to the unintended therapeutic and test effects of study interviews. Interviews were fully structured, readily administered by telephone by nonmedical personnel. The possibility that such interviews afford miscarrying women substantial psychologic benefits merits future investigation. (AM J OBSTET GYNECOL 1992;166:104-9.)

Key words: Spontaneous abortion, depression, grief counseling, miscarriage, pregnancy

Twelve percent to 15% of clinically recognized pregnancies end in spontaneous abortion.[1] For many women miscarriage represents death of a future child, dislocates reproductive plans, and may engender doubts about procreative competence. Nonetheless society lacks established rituals for mourning such loss.[2, 3]

In spite of repeated calls for studies of the psychiatric sequelae of reproductive loss[2, 4-6] relevant investigations are rare, and methodologic shortcomings cloud their findings. Only three investigations focused solely on miscarriage[7-9]; an additional six included miscarriage (loss usually at >20 weeks' completed gestation) in investigations of perinatal death.[10-15] These studies lacked a comparison group unexposed to recent reproductive loss, thereby precluding estimation of its effect on depressive symptoms. Wide variation in the timing of subject assessment ranging within a given study from a few weeks to months or even years after loss,[11, 12, 15] small samples, and absence of data on response rates[11, 13] further complicate evaluation and interpretation of research findings.

Material and methods

Study design. The study comprised three cohorts: miscarrying women, pregnant women, and women in the community not pregnant in the preceding year. Levels of depressive symptoms in the miscarrying women were compared with those in these two other groups.

Miscarriage cohort. Miscarriage was defined as the involuntary termination of a nonviable, intrauterine pregnancy before 28 completed weeks of gestation with the conceptus dead on expulsion. The miscarriage cohort was derived from the cases of an antecedent hospital-based case-control study of risk factors for miscarriage[16] in which 77% of all women attending a New York City medical center for miscarriages from late 1984 to 1986 were interviewed. This antecedent case-control study interviewed approximately 75% of these cases within 2 weeks of miscarriage, 95% within 8 weeks, and the remainder by 6 months.

Pregnant cohort. The pregnant cohort was derived from the controls of the case-control study and consisted of women registered for prenatal care before 22 weeks' gestation selected to be similar to the miscarrying women in age and whether they were receiving medical

care privately or in a public, clinic setting. Eighty-five percent of identified controls were interviewed for the case-control study. Of identified cases and controls, participants and nonparticipants in the case-control study were similarly distributed on sociodemographic and reproductive characteristics.[16]

At the conclusion of the case-control interview all participants who were 18 years of age or older, English or Spanish speaking, and accessible by telephone were invited to participate in our study. For pregnant women we also required that the case-control interview occur before 28 weeks' completed gestation.

We aimed to assess miscarrying women at three time points: the second week after miscarriage (2 weeks), weeks 6 through 8 (6 weeks), and weeks 26 through 35 (6 months). Overall, 73% (n = 382) of eligible miscarrying women were evaluated at least once; 232 were first interviewed at 2 weeks, 114 at 6 weeks, and 36 at 6 months. This staggered recruitment arises largely from the timing of the antecedent case-control study interview and logistic difficulties encountered by the current study in scheduling women for assessments within narrow, fixed time intervals after loss.

Seventy-two percent (n = 283) of eligible pregnant women were interviewed on a single occasion

Community cohort. Recruits for the community cohort were located by randomly dialing telephone numbers based on the telephone area codes and exchanges of the interviewed miscarrying women. The eligibility of household residents was established for 92% of working telephone numbers. Community women were frequency matched to the women in the miscarriage cohort on language of interview, age (in 5-year intervals), education (less than high school, high school graduate, college graduate, postgraduate training), and season of interview. Of (known) eligible community women, 82% (n = 318) were interviewed on a single occasion.

Comparability of interviewed and uninterviewed subjects. Within each cohort interviewed and uninterviewed women were similar in age, ethnicity, education, language, and season of interview. Interviewed and uninterviewed miscarrying and pregnant women also did not differ on private-public status, marital status, parity, or prior reproductive loss. For miscarrying women mean length of gestation at loss was slightly greater (8 to 9 days) for interviewed women compared with those not interviewed. Mean scores on a measure of depressed mood[17] did not differ between interviewed and uninterviewed women.

Study measures

The presence and duration of depressive symptoms in the week before the interview were evaluated with the 20-item Center for Epidemiologic Studies-Depression (CES-D) scale.[18] This scale measures affective, cognitive, and somatic components of depression. Each item is scored from 0 to 3 depending on the frequency of the symptom and is summed to produce an overall index. The CES-D correlates well with other self-report

Table II. Selected reproductive history characteristics of women in miscarriage, pregnant, and community cohorts

Characteristic	Cohort

measures of depressive symptoms, distinguishes clinically depressed patients from the general population, and has been used previously with samples of pregnant women.[19] A CES-D mean of 24.4 has been reported for heterogeneous samples of psychiatric inpatients.[18] The CES-D was administered by telephone[20] and preceded an extensive interview covering the woman's sociodemographic characteristics, social supports, attitude toward the pregnancy, and reproductive history, including history of the current pregnancy and miscarriage. Interviewers were not required to have clinical training or experience.

Sample characteristics. The three cohorts were similarly distributed on the majority of sociodemographic variables (Table I). Overall mean age was 30 years; 40% were Hispanic; a quarter had not graduated from high school; approximately 30% had incomes of <$10,000. As expected, the two hospital-based cohorts contained fewer single and childless women and had more reproductive loss (Table II). Half of index miscarriages occurred at <12 weeks' gestation; the majority of pregnant women were interviewed after the first trimester.

Analytic strategy. A first set of analyses tested differences in symptom levels within the miscarriage co-

*Proportions are adjusted with maximum likelihood logistic regression analysis.

†Odds ratios (95% CL) for miscarriage-community comparisons in descending-column order: 6.2 (3.6, 10.5); 3.1 (1.5, 6.2); 1.4 (0.7, 2.7); 3.6 (1.3, 10.2); 1.6 (0.9, 2.9).

‡Odds ratio (95% CL) for this comparison is 4.9 (2.4, 10.0).

hort across time points. A second set tested differences in symptom levels between the miscarriage cohort and the two comparison groups. At 2 weeks after loss the miscarriage cohort was compared with both the pregnant and community cohorts. Thereafter, because the pregnant cohort offered an estimate of symptom levels among miscarrying women immediately before loss, it lacked pertinence beyond the 2-week mark. Depressive symptom levels did not vary with length of gestation at loss. Consequently early and late miscarriages were combined in these analyses.

CES-D symptom levels were treated as continuous and categorical variables. The categorical approach tested whether findings based on the entire range of CES-D scores hold for extreme symptom levels. Subjects were dichotomized so that women receiving CES-D scores of ≥30, that is, those who reported at least half of the 20 symptoms in the CES-D for at least 1 week, were categorized as highly symptomatic. Approximately two thirds of these individuals would be expected to meet diagnostic criteria for major depressive disorder.[21] Analyses were conducted with ordinary least-squares multiple regression and maximum likelihood logistic regression to permit adjustment for potentially confounding variables. Comparisons of miscarrying with community women controlled for maternal age, ethnicity, marital and socioeconomic status, number of living children, and prior reproductive loss. Comparisons with pregnant women, as well as those within the miscarriage cohort, also controlled for private-public status, length of gestation (at time of miscarriage at interview), and pregnancy attitude. Results from logistic regression analyses are presented in terms of ratios of proportions scoring ≥30 and odds ratios, the latter reserved for notes to the relevant tables. Statistical significance was assessed at $p < 0.05$.

Results

Comparisons within the miscarriage cohort. In the miscarriage cohort at 2 weeks after loss the observed symptom mean is 23.9 (Table III), with 36.2% of the subjects being highly symptomatic (Table IV). At 6 weeks and 6 months after loss, depressive symptom levels are lower than at 2 weeks but substantially so only among reinterviewed women. Between miscarrying women first interviewed at 2 weeks and those first interviewed at later time points, adjusted differences in means at 6 weeks are 4.0 points and at 6 months 3.3 (Table III). Between women first interviewed and those reinterviewed at the same times, the differences are considerable. At 6 weeks their adjusted symptom means differ by 6.1 points and at 6 months by 6.3 points. The same pattern of results holds in analyses based on proportions highly symptomatic.

Comparisons between study cohorts. In the miscarriage cohort at 2 weeks after loss the adjusted symptom mean exceeds those in the pregnant and community cohorts by 7.5 to 9.1 points, respectively (Table V). Among miscarrying women receiving their first interviews at 6 weeks and 6 months symptom means were still significantly greater than that in the community cohort (5.2 and 5.9, respectively). Similarly, at 2 weeks after loss the proportion of highly symptomatic subjects in the miscarriage cohort is 3.4 times that in the pregnant cohort and 4.3 times that in the community cohort (Table IV). Among miscarrying women first inter-

*Means are adjusted by ordinary least-squares multiple regression analysis.

viewed at 6 weeks and 6 months, the proportions that are highly symptomatic are 2.6 and 3 times that in the community cohort, respectively. Among women reinterviewed at 6 weeks or 6 months, symptom levels do not differ from those in the community cohort.

The pattern of findings described persisted after controlling for the contribution of somatic symptoms to the overall CES-D score. Hence symptom levels reported by study subjects do not reflect simply somatic complaints arising from the physical sequelae of the miscarriage (or of the pregnancy). In addition, while one third of miscarrying women were hospitalized overnight and another third for ≥2 nights, hospital stay was not associated with symptom levels. Women who had dilatation and curettage procedures (approximately 85%) and those who did not also did not differ on level of depressive symptoms. Finally, women with early and late miscarriages reported similarly elevated symptom levels. For example, 34.1% of women with first-trimester miscarriages (12 completed weeks' gestation) were highly symptomatic, as were 39.8% of women with later loss ($p < 0.40$).

Comment

Among miscarrying women depressive symptoms are elevated fourfold over those in the community women in the second week after miscarriage and 3.4-fold over those in pregnant women. These results document for the first time the magnitude of the early effect of miscarriage on maternal psychologic status. Levels remain high at 6 weeks and at 6 months among women first interviewed at these time points but not among the reinterviewed. This difference in symptom levels between women first interviewed at 6 weeks and 6 months and those being reinterviewed suggests a strong therapeutic effect of study interviews. However, alternative explanations for this finding need to be considered first.

Selection bias in the form of selective departure or selective deferment of participation by more depressed study subjects is unlikely to contribute substantially to these results. First, as to selective departure, women interviewed at 2 weeks or at 6 weeks after loss who thereafter left the study did not differ on symptom levels from women who remained. Second, as for selective deferment, adjusted scores on the depressed mood scale administered at the time of the case-control interview did not differ among women first interviewed at 2 weeks, 6 weeks, and 6 months. Furthermore, women first interviewed at 2 weeks and 6 weeks had nearly identical symptom levels at 6 months (13.6 and 14.1, respectively). Similarly, in a large community survey of depressive symptoms, subjects interviewed in the calendar week targeted for study assessment and those deferring to a later time point did not differ on CES-D symptom levels.[22]

The lower scores of reinterviewed women are more easily explained as a consequence of unintended benefits of study participation, together with a possible test effect arising from scale repetition. Our initial interview afforded each subject an opportunity to discuss her pregnancy, the circumstances of the miscarriage, and its psychologic aftermath. In this respect it inadvertently resembled grief counseling.[7, 23] The efficacy of such counseling, often propounded, has been rigorously demonstrated in at least one randomized, controlled trial.[23] After a perinatal death women in the treatment group received a modal number of two counseling sessions. At 6 months after loss, the rate of psychiatric disorder in the treated group was one quarter that in the untreated group (12.5% and 52.6%, re-

spectively). The first interview with miscarrying women in our study lasted from 1.5 to 3 hours and was generally given in two parts on separate days.

Our estimates of a twofold to threefold elevation in depressive symptoms at 6 weeks and 6 months after loss were based on miscarrying women receiving their first interview; these estimates accord well with the previous controlled investigation of reproductive loss. Clarke and Williams[24] compared depressive symptoms in women experiencing perinatal death with depressive symptoms in women having live births. (The study protocol did not involve extended personal interviews with subjects.) At 6 weeks and 6 months thereafter the proportions of depressed women were 2.9 and 2.4 times those of women with live births, respectively. The results from the study of grief counseling cited above[23] also argue for at least a fourfold elevation in psychiatric symptoms at 6 months after loss in the absence of intervention. Given the preceding evidence based on both our own data and those of these other reports, we take symptom levels at first interview at each time to represent a better estimate of the true magnitude of the effect of miscarriage than levels at reinterview.

Previous authors have suggested that the "conspiracy of silence"[2] surrounding reproductive loss or the part of hospital staff, family, and friends exacerbates depressive reactions. It would not be at all surprising therefore if our interview, with its direct focus on the miscarriage, proved to be psychotherapeutic. Although we had anticipated some drop in the subjects' reported symptoms as a result of study interviews, the magnitude of the observed decline was unexpected. The efficacy of this proposed method of intervention requires rigorous a priori testing. Nonetheless, on the basis of these initial findings, structured telephone interviews administered by lay personnel should have strong clinical and budgetary appeal for medical institutions unable to offer formal bereavement counseling. These results should also prompt obstetricians to meet with a miscarrying patient soon after loss simply to afford her a potentially therapeutic opportunity to review the circumstances of the pregnancy and the miscarriage.

Alloimmune thrombocytopenia may be associated with systemic disease

Helen H. Kay, MD,[a] Marvin L. Hage, MD,[a] Joanne Kurtzberg, MD,[b] and Kimberly P. Dunsmore, MD[b]

Durham, North Carolina

Adverse outcome was encountered in a case of neonatal alloimmune thrombocytopenia after in utero platelet transfusion. This may have resulted from generalized systemic vascular endothelial damage, because several cell types, including umbilical endothelial cells, have been shown to contain surface molecules similar to the receptor containing the PI^{A1} antigen. (Am J Obstet Gynecol 1992;166:110-1.)

Key words: Neonatal alloimmune thrombocytopenia, in utero platelet transfusion

Neonatal alloimmune thrombocytopenia resulting from material antiplatelet antibodies against the PI^{A1} surface antigen on fetal platelets may cause fetal intracranial hemorrhage. Suggested therapies have included fetal in utero platelet transfusions and maternal intravenous γ-globulin infusion. Here we present a case from our institution in which platelet transfusion and immunoglobulin therapy were associated with significant fetal acidosis and subsequent infant death.

Case report

Our patient was seen during her seventh pregnancy (three miscarriages before 12 weeks, one ectopic pregnancy, and two elective abortions). The diagnosis of alloimmune thrombocytopenia was made after her delivery of a term female infant with multiple petechiae and severe thrombocytopenia with a normal maternal platelet count. That infant had neonatal seizures after platelet transfusions. She subsequently had slow gross and fine motor development and an attention deficit disorder. No head ultrasonographic examination was done at birth, but computed tomographic scans obtained at 6 years of age excluded structural lesions. During the current pregnancy, the patient was offered enrollment in the protocol of Bussel et al.[1] for exogenous immunoglobulin therapy. However, the patient did not wish to undergo multiple cordocenteses, and empiric weekly immunoglobulin injections were begun at 21 weeks' gestation. At 35 weeks the patient underwent amniocentesis and cordocentesis for determination of fetal lung maturity, need for further therapy, and route of delivery. Cordocentesis was performed, and an in utero platelet transfusion of 10 ml irradiated maternal platelets (collected by pheresis the day before the procedure) was administered while fetal platelet count results were awaited. This was terminated after approximately 5 minutes when the count was reported as 90,000/mm³. Shortly after, a fetal bradycardia was noted and, although it eventually resolved (within approximately 20 minutes), there were additional variable decelerations. Three hours later a cesarean section was performed, and a female infant was delivered. External fetal monitoring within 5 minutes of delivery showed a fetal heart rate >110 beats/min. The initial platelet count of the baby was 120,000/mm³, which was what we had anticipated on the basis of our calculations from the known amount of platelets transfused. The amniotic fluid was clear, and examination of cord and placenta failed to reveal a thrombosis or abruptio placentae. Computed tomographic and magnetic resonance imaging scans of the infant's brain on days 3 and 5 after birth did not show any focal intracranial lesions. The infant was neurologically impaired and eventually died of bronchopneumonia at 6 months of age. Autopsy examination revealed gliosis and multifocal neuronal loss consistent with perinatal hypoxia-ischemia.

Comment

The cause of this adverse outcome is uncertain because the procedure was performed without obvious technical complications. Interestingly, Giltay et al.[2] have reported that fibroblast cells of the umbilical endothelium, umbilical artery smooth muscle, and human foreskin express a surface molecule that is similar, if not identical, to the endothelial fibronectin receptor that contains a β-subunit carrying the PI^{A1} antigen. This suggests that other cells, aside from platelets, may be involved in the pathophysiologic characteristics of alloimmune thrombocytopenia and that systemic vascular damage could result in this disease. Such damage could cause early in utero intracranial microhemorrhages. Similar damage in the umbilical vessels could predispose to vasospasms which, in turn, could aggravate the underlying neurologic impairment. Alternatively, infusing platelets and associated products could

aggravate impaired vascular endothelium, causing vasospasms. It is interesting to note that the first child had seizures after platelet transfusion and now has a learning disability. Of note, an ultrasonographic examination of the current fetus had shown a −1.9 SD in the head circumference at 29 weeks, but follow-up scan showed a less significant lag. Although unproved, it is also possible that some earlier in utero event, i.e., hemorrhage, had taken place before therapy was initiated.

There is still much unknown regarding the pathophysiology of this disease and the effects of therapy, such as exogenous immunoglobulins and platelet transfusions, on the long-term outcome of these infants. Platelet transfusions would be the most reliable way to elevate the platelet count. However, they need to be performed with caution. Immunoglobulin treatment may be a better alternative, as our patient's platelet count was 90,000/mm^3 with weekly intravenous doses of immune globulin. Although studies of long-term immune globulin therapy in patients with immunodeficiency syndrome have failed to reveal any significant risks to date, the long-term consequences of maternal-fetal intravenous immune globulin therapy have yet to be defined.

Spontaneous abortion and subsequent adverse birth outcomes

David H. Thom, MD, PhD, Lorene M. Nelson, PhD, and Thomas L. Vaughan, MD, MPH
Seattle, Washington

OBJECTIVE: Our purpose was to evaluate the association between spontaneous abortion and subsequent adverse birth outcomes.
STUDY DESIGN: Washington State birth certificate records for 1984 to 1987 were used to examine the association between spontaneous abortion and adverse outcomes in the subsequent live birth. Adverse birth outcomes were examined for women with one spontaneous abortion before the index pregnancy (n = 2146) and for women with three or more prior spontaneous abortions and no other prior pregnancies (n = 638); compared with women with no prior spontaneous abortions (n = 3099). Logistic regression was used to estimate the relative risk associated with prior spontaneous abortion of each adverse outcome.
RESULTS: Women with three or more prior spontaneous abortions were at higher risk for delivery at <37 weeks' gestation (relative risk 1.5, 95% confidence interval 1.1 to 2.1), placenta previa (relative risk 6.0, 95% confidence interval 1.6 to 22.2), having membranes ruptured >24 hours (relative risk 1.8, 95% confidence interval 1.2 to 2.9), breech presentation (relative risk 2.4, 95% confidence interval 1.6 to 3.6), and having an infant with a congenital malformation (relative risk 1.8, 95% confidence interval 1.1 to 3.0).
CONCLUSION: These findings suggest that common causes may underlie recurrent spontaneous abortion and certain adverse birth outcomes. They may also help guide clinical management of pregnancies in women with a history of recurrent spontaneous abortions. (Am J Obstet Gynecol 1992;166:111-6.)

Spontaneous abortion before the 20th week of gestational age is reported to occur in 15% to 20% of recognized pregnancies.[1, 2] Approximately 1% of women experience three or more spontaneous abortions before the first live birth.[1] In spite of the frequency of this problem, the subsequent birth outcomes of women with prior spontaneous abortions have not been extensively studied. Previous studies have suggested

that women with a history of spontaneous abortion are at increased risk for preterm delivery,[3-5] placenta previa,[6] and having an infant with intrauterine growth retardation (IUGR)[7, 8] or congenital malformation.[9, 10] These studies have been limited by small sample sizes[5-9] and a lack of consideration of possible confounding variables.[3-10]

The current study sought to examine the incidence of adverse birth outcomes among women with one prior spontaneous abortion and women with three or more prior spontaneous abortions, compared with the incidence among women with no prior spontaneous abortions. We used a large data base that includes information on maternal age, parity, gravidity, smoking status during pregnancy, race, and prenatal care.

Material and methods

Data were taken from Washington State birth certificate records for the years 1984 through 1987. Obstetric ward clerks are generally responsible for abstracting information from the medical chart into the birth certificate form. Handbooks describing procedures for birth certificate completion are provided by the State of Washington. Additional instruction is provided by each hospital. A state field representative makes periodic visits to review completion procedures. Most adverse birth outcomes are represented by a checklist format. The completeness of reporting birth complications on the Washington State birth certificate was the subject of a recent study.[11] With the checklist format, reporting was 80% or better for most birth complications (e.g., preeclampsia, breech presentation, and cesarean section). Congenital malformations were reported less frequently, as judged by hospital discharge diagnoses. Reporting rates for congenital malformations ranged from 32% for polydactyly to 57% for cleft lip and palate. The birth certificate defines spontaneous abortion as fetal loss occurring before 20 weeks' gestation; first- and second-trimester spontaneous abortions are not differentiated.

Two "exposure" groups were constructed. The group of women with one prior spontaneous abortion consisted of all women having a live singleton birth in 1987 who had one prior spontaneous abortion and no other prior pregnancies. A second group of women with recurrent spontaneous abortions consisted of all women having a live singleton birth in 1984 to 1987, who had three or more prior spontaenous abortions and no other prior pregnancies. Births ending in fetal death were not included because of their small numbers (<0.7% of all pregnancies >20 weeks' gestation).

The unexposed comparison group consisted of 3099 randomly selected women having a live singleton birth in 1987 with no pregnancies prior to the index pregnancy. Use of this primigravid group thus controlled for the potential confounding effects of parity.

The adverse birth outcomes of interest were: low birth weight (<2500 gm), IUGR, preterm birth (<37 weeks' gestational age, calculated from the first day of the last menstrual period), congenital malformations, prolonged rupture of membranes (>24 hours), breech presentation, low 1-minute (<6) and 5-minute (<7) Apgar scores, abruptio placentae, placenta previa, and preeclampsia. The definition of a low Apgar score was chosen to allow comparison of the results with those of a previous study.[10] Intrauterine growth retardation was defined as birth weight <10th percentile for gestational age as determined by last menstrual period. The 10th percentile of birth weight by menstrual weeks' gestation was taken from a widely cited nomogram and table of birth weights.[12]

Maximum likelihood logistic regression[13] was used to estimate the relative risk associated with prior spontaneous abortion for each adverse birth outcome while controlling for confounding variables.

Results

The characteristics of women with one prior spontaneous abortion, three or more prior spontaneous abortions, and the primagravid comparison group are shown in Table I. Women with three or more spontaneous abortions were older and more likely to smoke, compared with the primigravid group. Women with one prior spontaneous abortion were intermediate for these characteristics. The differences in the proportion of smokers among women with one prior spontaneous abortion and women with three or more prior spontaneous abortions, compared with the proportion among women with no prior spontaneous abortions, were highly significant ($p < 0.001$) after controlling for age. The differences by maternal race, marital status, urban residence (living in an incorporated area), and prenatal care were relatively small.

Information was missing on <3% of the outcome variables examined, except for gestational age, congenital malformations, and preeclampsia. Gestational age was missing for 7% of the group with one prior spontaneous abortion, 9% of the group with the three or more prior spontaneous abortions, and 9% of the primigravid group. The totals missing for those with malformations were 14%, 13%, and 16%, respectively. All three groups had 10% of the preeclampsia data missing.

The frequencies of adverse outcomes by group are presented in Table II. Differences were found for low birth weight, IUGR, preterm delivery, congenital malformation, placenta previa, prolonged rupture of membranes, breech presentation, 1-minute and 5-minute Apgar scores, and preeclampsia, but not for abruptio placentae.

Table III displays the relative risk estimates with 95% confidence intervals for the adverse outcomes in Table

Table I. Characteristics of women during their index pregnancy by number of prior spontaneous abortions

Characteristic	*Women with no prior pregnancies (n = 3099)*	*Women with one prior spontaneous abortion (n = 2146)*	*Women with three or more prior spontaneous abortions (n = 638)*
Maternal age			
Mean (yr)	23.9	25.0	26.3

II. Maternal age, smoking status, race, marital status, place of residence, and prenatal care were evaluated for confounding effects on all outcomes. Gestational age was evaluated as a potential confounder for all outcomes except IUGR. Only those variables that resulted in a meaningful change in the estimated relative risk were adjusted for in the analysis.

After adjustment for maternal age and smoking status, women with three or more prior spontaneous abortions had twice the risk of having a low-birth-weight infant (relative risk = 2.0, 95% confidence interval = 1.4 to 2.8) compared with that of women with no prior pregnancies. This association appears to primarily reflect an increased risk of preterm birth among women with recurrent abortions (relative risk = 1.5, 95% confidence interval = 1.1 to 2.1), rather than an increased risk of IUGR (relative risk = 1.2, 95% confidence interval = 0.9 to 1.7). The estimated relative risk for prematurity among women with three or more prior spontaneous abortions increased with increasing prematurity, from 1.2 (95% confidence interval = 0.8 to 1.8) for mild prematurity (34 to 36 weeks' gestation) to 2.7 (95% confidence interval = 1.0 to 7.3) for severe prematurity (<30 weeks' gestation).

Women with recurrent spontaneous abortions had an increased risk of delivering an infant with a congenital malformation (relative risk = 1.8, 95% confidence interval = 1.1 to 3.0). Ductus arteriosus was not included in congenital malformations because of its strong association with prematurity, which was already known to be associated with prior spontaneous abortions. Analysis by individual type of malformation was not possible because of small numbers. Analysis by major organ systems (genitourinary, cardiac, central ner-

Breech presentation	1.3	0.9-1.8	2.4	1.6-3.6
1 min Apgar score <6	1.3	1.0-1.6	1.2	0.8-1.6
5 min Apgar score <7	0.9	0.6-1.4	0.6	0.3-1.6
Preeclampsia	1.0	0.8-1.3	0.8	0.5-1.3
Abruptio placentae	1.2	0.6-2.3	1.2	0.4-3.1

*Low birth weight, IUGR, gestational age, and preeclampsia were adjusted for maternal age and smoking status. Placenta previa, prolonged rupture of membranes, and breech presentation were adjusted for maternal age and gestational length. One- and 5-minute Apgar scores were adjusted for maternal age, smoking status, and gestational length.

vous system, and limb defects) did not show a significantly elevated relative risk of malformation within any organ system.

Women with three or more prior spontaneous abortions also had elevated risks of placenta previa (relative risk = 6.0, 95% confidence interval = 1.6 to 22.2), prolonged rupture of membranes (relative risk = 1.8, 95% confidence interval = 1.2 to 2.9), and breech presentation (relative risk = 2.4, 95% confidence interval = 1.6 to 3.6), after adjustment for maternal age and gestational length. Additional adjustment for other variables, including smoking and prenatal care, did not alter these estimates.

After adjustment for maternal age, smoking status, and gestational length, women with recurrent spontaneous abortions had a relative risk of 1.2 (95% confidence interval = 0.8 to 1.6) of having an infant with a low 1-minute Apgar score. Women with one prior spontaenous abortion had a relative risk of 1.3 (95% confidence interval = 1.0 to 1.6) of having an infant with a low 1-minute Apgar score. There was no evidence of an increased risk of preeclampsia or abruptio placentae in either group.

Comment

Investigating the association between prior spontaneous abortion and subsequent adverse birth outcomes is complicated by the interrelationship between parity, gravidity, maternal age, smoking, number of prior spontaneous abortions,[14] and the interrelationship between adverse outcomes such as low birth weight, IUGR, prematurity, and low Apgar scores. The current study first simplified the examination of prior spontaneous abortion by limiting the study to women with prior spontaneous abortions who had experienced no other prior pregnancies. Women with one prior spontaneous abortion and women with three or more prior spontaneous abortions were examined separately because previous studies have suggested that women with three or more prior spontaneous abortions may be at higher risk for subsequent adverse pregnancy outcomes than women with only one prior spontaneous abortion,[2, 4, 6] The finding that smoking and maternal age were positively associated with the number of prior spontaneous abortions was expected, as both smoking[15, 16] and advanced maternal age[14, 17] have been associated with spontaneous abortion and women who reported smoking in the index pregnancies would be likely to have smoked during previous pregnancies. In this data set, maternal race, marital status, and prenatal care were similar among women with and without prior spontaneous abortions, and adjustment for these variables did not change the associations reported.

In the current study the adjusted relative risk of IUGR was 1.2 (95% confidence interval = 0.8 to 1.7) in women with three or more prior spontaneous abortions. This result is in contrast to a previous study that reported an increased unadjusted risk for severe IUGR in term infants (calculated relative risk = 2.2, 95% confidence interval = 1.6 to 2.9) in women whose previous

pregnancy ended in a spontaneous abortion when compared with women whose previous pregnancy ended in a live birth.[7]

The current study found only a slightly elevated adjusted relative risk of 1.2 (95% confidence interval = 0.9 to 1.4) for preterm birth in women with one prior spontaneous abortion but an adjusted relative risk of 1.5 (95% confidence interval = 1.1 to 2.1) for women with three or more prior spontaneous abortions. These results are similar to results reported from previous studies.[3, 4, 10]

Previous studies have suggested that prior spontaneous abortion is associated with an increased incidence of congenital malformation in a subsequent pregnancy.[9, 10] The rate of congenital malformation reported in the current study is less than that reported in previous studies.[10, 18] This difference probably reflects an underreporting of congenital malformations on the birth certificate. The current study found no evidence of an increased risk of congenital malformation in infants of women with one prior spontaneous abortion. However, women with three or more prior spontaneous abortions had a relative risk of 1.8 (95% confidence interval = 1.1 to 3.0) of having an infant with a congenital malformation. A larger study would be needed to evaluate the association between prior spontaneous abortions and specific malformation types.

A strong association was found in the current study between three or more prior spontaneous abortions and placenta previa (relative risk = 6.0, 95% confidence interval = 1.6 to 22.2) after adjusting for maternal age, smoking status, and gestational length. A previous study, which examined the combined risk of placenta previa and abruptio placentae in women with one prior spontaneous abortion, reported data that gave a calculated reltive risk of 2.3 (95% confidence interval = 0.7 to 7.9).[10] A more recent case-control study of 80 cases of placenta previa found calculated odds ratios of 1.5 for one prior spontaneous abortion (95% confidence interval = 0.5 to 4.1) and 4.9 (95% confidence interval = 0.3 to 88.4) for three or more prior spontaneous abortions.[6] The suggested explanation for this association was that curettage, commonly performed after a spontaneous abortion, may be a risk factor for subsequent placenta previa.

The current study found a moderate association between prolonged rupture of membranes and three or more prior spontaneous abortions, which was independent of gestational age and early prenatal care. This finding has not been previously reported. It is possible that this result reflects an association between delay in seeking medical care at the time of membrane rupture and other, unmeasured factors related to spontaneous abortion.

Another, apparently new finding is an elevated relative risk for breech presentation among women with three or more prior spontaneous abortions (relative risk = 2.4, 95% confidence interval = 1.6 to 3.6) after adjustment for maternal age, smoking status, and gestational length. The explanation for this finding is not apparent, although it could reflect underlying morphologic uterine abnormalities that predispose to both spontaneous abortion and breech presentation.

Women with one prior spontaneous abortion had a relative risk of 1.3 of having an infant with a 1-minute Apgar score <6, after adjustment for smoking, maternal age, and gestational age. This is less than the relative risk of 1.8 (95% confidence interval = 1.1 to 2.9) calculated from data reported in a previous study for a 1-minute Apgar score <6 among women with one prior spontaneous abortion.[10]

There are a number of limitations in the current study that should be noted. The use of birth certificate data to ascertain prior spontaneous abortion undoubtedly results in some misclassification of the number of prior spontaneous abortions. Because the information on prior spontaneous abortion is taken from the medical record, where it is usually recorded before the birth outcome, it is unlikely that prior spontaneous abortions were preferentially recorded for women with adverse outcomes. As long as such misclassification is not related to the outcomes of interest, the reported relative risk would be a conservative estimate of the true relative risk.

It is also possible that the associations reported may be the result of an unmeasured external variable, such as poor nutrition or alcohol or drug abuse, rather than a shared biologic mechanism. Socioeconomic status was not adjusted in the current study; however, mother's household income did not confound the associations in a pilot analysis with the same data. Moreover, adjustment for race, marital status, and first-trimester prenatal care, all of which would be expected to be related to socioeconomic status, did not affect any of the associations reported.

It is possible that the association between the adverse outcomes reported and three or more prior spontaneous abortions actually reflects an association with second-trimester spontaneous abortions,[19] which would be more common among women with three or more prior spontaneous abortions, rather than an association with the number of prior spontaneous abortions per se. This possibility could not be addressed in the current study because the data did not distinguish between first-trimester and second-trimester spontaneous abortions.

Multiple, nonexclusive causes have been suggested for spontaneous abortion, including chromosomal aberrations,[2, 20] maternal immunologic[21, 22] or hormonal[23] abnormalties, infection,[24] incompetent cervix,[25] and uterine malformations.[2] One or more of these factors may also result in an adverse birth outcome, creating an association between prior spontaneous abortion and

specific adverse birth outcomes. IUGR, for example, could plausibly result from immunologic, implantation, infection, or hormonal defects. Prematurity and IUGR have been associated with both maternal infection[26] and immunologic abnormalities.[21] Congenital malformations, while possibly related tc chromosomal aberrations, may also be the result of infection or of immunologic or hormone factors.[27] In spite of these complexities in the interpretation of the relation between prior spontaneous abortion and subsequent adverse birth outcomes, it is hoped that the results of the current study will provide clues to unraveling the etiology of spontaneous abortion.

The findings from the current study suggest that women whose first pregnancy ended in a spontaneous abortion are at little, if any, increased risk for an adverse outcome in a subsequent live-birth pregnancy. However, women with recurrent (three or more) spontaneous abortions and no other prior pregnancies are at increased risk for several adverse outcomes, including placenta previa, preterm delivery, and breech presentation. These results may be useful in guiding the clinical management of pregnancies in women with recurrent abortions.

We thank Dr. Margaret Karagas and Dr. Janet Daling for their help and support.

Prolonged effects of a novel, low-dosage continuous progestin–cyclic estrogen replacement program in postmenopausal women

Earl R. Plunkett, MD, and Bernard M. Wolfe, BM, BCh(Oxon)
London, Ontario, Canada

OBJECTIVE: Our objective was to ascertain long-term tolerability and effects of a novel, low-dosage continuous progestin–cyclic estrogen regimen on vasomotor flushing, vaginal bleeding patterns, bone density, and plasma lipoprotein lipids.
STUDY DESIGN: Eighteen postmenopausal women with climacteric symptoms received low doses of *dl*-norgestrel (0.075 mg/day) continuously and 17β-estradiol (1 mg/day) intermittently (25 of 28 days) for 3 years. The results were compared with baseline values.
RESULTS: The hormonal regimen was well tolerated. Vaginal bleeding, vaginal spotting, and vasomotor flushing occurred in only 0.4%, 4.2%, and 7.7% of cycles, respectively. Bone density was stable. Mean fasting plasma total cholesterol concentration fell 19%, low-density lipoprotein cholesterol 23%, high-density lipoprotein cholesterol 13%, and triglycerides 31% ($p < 0.01$) over the 3-year period, while the ratios of low-density lipoprotein cholesterol/high-density lipoprotein cholesterol and total cholesterol/high-density lipoprotein cholesterol decreased by 14% and 10%, respectively.
CONCLUSION: Long-term compliance with female hormonal replacement is feasible once vaginal bleeding is essentially eliminated, allowing for potentially better prophylaxis against coronary heart disease, osteoporosis, endometrial cancer, and stroke. (Am J Obstet Gynecol 1992;166:117-21.)

Key words: Hormonal replacement therapy, cholesterol, triglycerides, osteoporosis, endometrium

Estrogen deficiency has been implicated in causing osteoporosis, vasomotor instability, insomnia, depression, dyspareunia, and urinary stress incontinence.[1] Twenty-five percent or more of women of postmenopausal age are sufficiently symptomatic of estrogen deprivation to warrant replacement on that basis alone, and progestin replacement may be warranted in more.[2, 3] Whereas two centuries ago <30% of women lived long enough to reach menopause, currently 90% do, including >30 million American women with an average postmenopausal life expectancy of 28 years.[4] In spite of the permanency of ovarian hormone deficiency, only about 2 to 3 million American women currently take estrogens,[5] and only 19% of physicians would prescribe them for ≥3 years.[6] When ovarian secretion of 17β-estradiol and progesterone declines, the concentration of serum cholesterol rises,[7] and women lose their relative immunity (as compared with men) from ischemic heart disease.[8] They then also experience increases in the incidence of endometrial, ovarian, and breast cancer[9] and increased morbidity and mortality from osteoporosis-related fractures.[10]

Prolonged estrogen therapy that is unopposed by a balance of natural progesterone or synthetic progestin can induce proliferative changes in the lining of the uterus, which can progress to hyperplasia, adenomatous hyperplasia, and frank endometrial adenocarcinoma.[11] The relative risk of 1.7 to 8.0 for endometrial cancer can be reduced below 1.0 by intermittently administering progestin together with estrogen.[12] However, this leads to scheduled induction of withdrawal bleeding in 90% of women with uteri in situ.[13] During the interruption of therapy, menopausal symptoms frequently relapse, and recurrence of bothersome, painful, and at times heavy vaginal bleeding induces anxiety about cancer and return of fertility. These concerns have hampered the long-term use of female hormones for the prevention of osteoporosis, coronary heart disease, and stroke.[3, 14] The purpose of the present pilot study was to assess the efficacy and long-term acceptability of a novel low-dosage progestin-estrogen combination for hormonal replacement in postmenopausal women.

Material and methods

Twenty-one women (mean age 53 ± 2 years, mean height 162 ± 2 cm, mean weight 64 ± 3 kg) were re-

From the Departments of Gynaecology and Medicine, University Hospital and The University of Western Ontario.
Supported in part by a grant from the Medical Research Council of Canada.

cruited from University Hospital Outpatient Clinics. Fifteen subjects had uteri in situ. Each subject met the following criteria: amenorrhea for at least 6 months, serum follicle-stimulating hormone level >70 mIU/ml (mean 129 ± 5 mIU/ml), typical menopausal symptoms, and absence of contraindications for estrogen therapy.[3] Three subjects had hypercholesterolemia (395, 350, and 294 mg/dl) and two had hypertriglyceridemia (272 and 282 mg/dl).[15] The nature and possible consequences of the studies were explained to each subject and informed consent was obtained.

Initial examination consisted of a complete medical history (including menopausal symptom assessment), physical examination, measurement of serum electrolyte levels, creatinine, blood urea nitrogen, albumin, globulin, calcium, phosphate, uric acid, total bilirubin, follicle-stimulating hormone, luteotropic hormone, alkaline phosphatase, alanine transaminase, γ-glutamyl transpeptidase, white blood cell count, hematocrit, and a chest roentgenogram. A dietitian instructed each subject before baseline lipid testing to maintain her weight and diet, except that the diet should contain <500 mg cholesterol per day. However, exercise level, intake of ethanol, and consumption of cigarettes were not monitored systematically.

17β-Estradiol was supplied by Bristol Laboratories of Canada, Ottawa, and *dl*-norgestrel by Wyeth Ltd., Downsview, Ontario. Compliance with the hormonal regimen was monitored by recording every pill taken, along with the daily record of flushing and vaginal spotting or bleeding. Mean baseline values for fasting plasma lipid and lipoprotein lipid fraction levels (after a 12-hour fast) and blood pressure were based on the average of three determinations from each subject after a 4-week washout period that followed administration of similar doses of each of 17β-estradiol for 8 weeks and *dl*-norgestrel for 8 weeks or 17β-estradiol and *dl*-norgestrel for 24 weeks in the antecedent randomized study, in which all of the present subjects had participated. After baseline testing each subject was placed on a regime of *dl*-norgestrel (0.075 mg/day) continuously and 17β-estradiol (1 mg/day) intermittently (25 of 28 days).

Eighteen of the 21 subjects who volunteered completed the 3-year study. One subject was excluded early because of noncompliance, another because of intercurrent illness, and one moved away in the third year. Nurses coordinated the clinic visits and testing and measured blood pressure at each semiannual visit. Fasting plasma concentrations of lipids and lipoprotein fractions and the bone density of the left radius were measured annually and blood pressure and weight

semiannually. Lipids and lipoprotein fractions were determined as previously described.[16] Comparisons between paired samples were carried out with either the two-tailed Student *t* test or χ^2 analyses according to Steel and Torrie.[17]

Results

Plasma lipids and lipoproteins. Fasting plasma lipid levels decreased significantly and progressively below the baseline control during 17β-estradiol and *dl*-norgestrel therapy (Table I). There was a trend toward greater lowering of low-density lipoprotein (LDL) cholesterol as a function of initial concentration, but the coefficient of correlation failed to be statistically significant ($r = 0.42, 0.05 < p < 0.10, n = 19$). The mean ratio of plasma LDL cholesterol/high-density lipoprotein (HDL) cholesterol, an index of atherosclerotic risk, decreased from 3.6 ± 0.5 to 3.1 ± 0.3 at 3 years (14%, $0.10 < p < 0.20$), whereas that of another indicator, the mean ratio of total cholesterol/HDL cholesterol, decreased from 4.85 ± 0.46 to 4.37 ± 0.24 (10%, $0.10 < p < 0.20$).

Symptoms (flushing, spotting, and bleeding). Virtually complete relief of flushing was achieved. Fourteen of the 15 subjects with uteri did not detect any type of flushing over the third year (95.8% of cycles free, Table II). However, one subject had frequent mild atypical sweating in all but two cycles (average of 11 ± 1 days per 28-day cycle). The findings were atypical of flushing, but the subject (166 cm tall, 94 kg) construed them as such.

Vaginal spotting not necessitating protection was not experienced by 11 of the 15 subjects with uteri in situ and was absent in 95.8% of all cycles ($n = 15$). (Unpublished findings of endometrial biopsy specimens during the antecedent randomized study showed atrophic or scanty endometrium in 10 subjects who underwent biopsy before treatment and in nine of the same subjects who underwent biopsy after receiving 17β-estradiol and *dl*-norgestrel for 24 weeks [six cycles]; in one of these 10 subjects there was weak evidence of proliferative endometrium after treatment.) Over the 3-year period two subjects reported spotting on 1 day only, one subject on 1 day of each of two cycles, and a third subject on 2 days during only one cycle. Only one subject had frequent spotting (average of 2 days per cycle in 17 of 37 cycles, followed by one episode of vaginal bleeding during each of two further cycles). The other 14 subjects with intact uteri had no vaginal withdrawal bleeding, except for one subject who transiently failed to take medication as prescribed. Overall, vaginal bleeding was virtually eliminated (in 99.6% of cycles).

Bone density. Forearm bone density was not significantly changed from baseline control (0.67 ± 0.02) after 1 year (0.68 ± 0.02 gm/cm²), 2 years (0.69 ± 0.02), or 3 years (0.68 ± 0.02 gm/cm²) of therapy ($n = 17$, $p > 0.5$).

Blood pressure. The significant mean increase in body weight of 1.7 kg over the 3-year study (67.4 ± 3.2 vs 65.7 ± 3.1 kg, $p < 0.01$) was associated with a slight rise in diastolic blood pressure above baseline control. This was statistically significant at 2 years (79 ± 2 vs 75 ± 1 mm Hg, $n = 19, p < 0.05$) but not at three years (79 ± 2 vs 76 ± 2, $n = 18$). The associated slight rise above baseline control in systolic blood pressure after 2 years (137 ± 4 vs 124 ± 4 mm Hg, $n = 19$) was also maintained after 3 years (135 ± 3 vs 125 ± 4 mm Hg, $n = 18, p < 0.025$).

Comment

The current studies demonstrate the feasibility of long-term patient compliance with low-dosage 17β-estradiol and *dl*-norgestrel hormonal replacement therapy, which virtually eliminated menstrual spotting and bleeding that constitute the main obstacle to continu-

ance of therapy.[14] Recurrence of flushing is frequently reported during the estrogen-free period with most postmenopausal hormone replacement regimens (7 estrogen-free days of a total of 28); however, this was not observed when 17β-estradiol was interrupted for only 3 days per cycle and *dl*-norgestrel was given continuously (Table II). The finding of effective control of vasomotor symptoms and vaginal bleeding through the combined use of continuous low-dosage progestin and cyclic estrogen is consistent with similar results with the use of continuous low dosages of conjugated equine estrogens and medroxyprogesterone acetate[19, 20] or comparably low doses of ethinyl estradiol (about 5 μg daily) combined with oral contraceptive dosages of norethindrone acetate.[21] Prior exposure to progestin in the antecedent study explains the low incidence of vaginal bleeding or spotting in the first year. The 3-day-per-cycle interruption of estrogen administration in this study has the benefit of reducing total estrogen dosage by about 10% and thereby reducing the occurrence of mastodynia (recognized estrogen side effect) without any detectable increase in vasomotor symptoms. Interruption of estrogen may also play a role in reducing breakthrough bleeding.

Long-term therapy could yield important benefits for prevention of ischemic heart disease, the major cause of death (and a major source of disability) among menopausal and postmenopausal women, which causes four to five and a half times more deaths among them than do cancer of the breast and endometrium combined.[22, 23] The 23% mean decrease in LDL cholesterol in this study exceeded the 13% decrease in HDL cholesterol, yielding a favorable decrease in the ratios of LDL cholesterol/HDL cholesterol and total cholesterol/HDL cholesterol, which are important indicators of risk of coronary heart disease. The androgenic effects of 19-nortestosterone-derived *dl*-norgestrel likely account for the observed reduction in HDL cholesterol but could also play a role in the significant reduction in LDL production and concentration obtained with combined low-dosage *dl*-norgestrel and 17β-estradiol.[16] Continuous estrogen-progestin combinations with various low doses of ethinyl estradiol and oral contraceptive dosages of norethindrone acetate also minimize menstrual spotting and bleeding, though no significant changes in serum lipids were reported.[21]

In contrast to the life-threatening hyperlipidemia that can develop during estrogen therapy of hypertriglyceridemia subjects,[24] a significant lowering of triglyceride levels was observed with combined 17β-estradiol and *dl*-norgestrel (Table I). Although estrogens are often contraindicated in patients with hypertriglyceridemia,[24] the combination of 17β-estradiol and *dl*-norgestrel could sometimes be beneficial under such circumstances. The reduction of triglyceride-rich lipoprotein levels may be useful for the prophylaxis of coronary heart disease, given the evidence implicating them in its genesis.[25]

We found no change in radial bone density over 3 years, in contrast to the expected reduction which is detectable within a year in postmenopausal women not receiving estrogen. However, vertebral bone density would likely have been a more sensitive test of bone loss. The risk of bone fracture is known to be reduced by prophylactic estrogens.[10]

The current study demonstrates the feasibility of using a low-dosage 17β-estradiol and *dl*-norgestrel postmenopausal replacement program for 3 years to relieve vasomotor symptoms, eliminate vaginal bleeding, maintain radial bone mass, and reduce lipoprotein-associated risk of coronary heart disease and nonhemorrhagic stroke by decreasing plasma LDL and triglyceride levels and the ratios of LDL cholesterol/HDL cholesterol and total cholesterol/HDL cholesterol.[3]

We thank J. Munn and H. Erskine for coordinating the study and M. Lougheed and C. Bichay for expert technical assistance with lipoprotein determinations. We also thank E. Wolfe, L. Constant, and D. Parkinson for assistance with the manuscript.

Attitudes toward reproduction in a nonpatient population

Marianne Wikman, MD,[a] Lars Jacobsson, MD,[b] and Bo von Schoultz, MD[c]

Umeå and Stockholm, Sweden

OBJECTIVE: A basic question to be answered in an attempt to understand human reproductive behavior as it manifests itself in clinical practice is, why do people want to have children?

STUDY DESIGN: A psychometric instrument for the assessment of reproductive attitudes was developed. A total of 746 men and women at 20, 30, and 40 years of age, who were randomly selected from a nonpatient population, answered. Data were analyzed by factor analysis. Reproductive profiles were constructed.

RESULTS: The two most important factors in both sexes were "children as existential satisfaction" and "children as lack of freedom," indicating a basic conflict. The third most important factor in both sexes was "the importance of one's own parents as examples in parenthood," supporting earlier findings that reproductive conflicts are transmitted from one generation to another. Reproductive profiles were uniform in the different age groups.

CONCLUSION: The element of ambivalence may be a clue to a deeper understanding of human reproductive behavior. (AM J OBSTET GYNECOL 1992;166:121-6.)

Key words: Attitudes toward parenthood, child wish, factor analysis, reproductive ambivalence

Present-day attitudes toward sexuality, the availability of effective and reliable contraceptives, legislation on abortion on request, and technical developments to hinder or promote fertility may give the superficial impression that whether to have a child is a decision based solely on rational choices.[1] However, the strong emotional reactions evoked in society by these subjects[2] and the multitude of physical and mental reactions linked to contraception,[1, 3, 4] wanted and unwanted

pregnancies,[5, 6] and infertility[7, 8] all tend to compound the complexity of this seemingly simple matter. In clinical practie we often find ourselves as observers of a reproductive drama. Adaptational difficulties in the spheres of reproduction, motherhood, and femininity have been suggested to be factors underlying various somatic and mental reproductive disorders.[6] In modern Western societies, traditional norms for reproductive behavior are rapidly changing, which will probably render role adaptation more complicated. One important basic question to answer seems to be: Why do people want to have children[1]?

The psychoanalytic and psychologic literature on motives for having or not having children is extensive.[5, 9, 10] Nevertheless, there are few investigations based on larger populations, and evidently such studies raise methodologic problems.[10] Most previous attempts in this field have focused mostly on specific groups of patients or pregnant women or on students.[11-13] Although the husband's attitudes are most important for his wife's well-being during pregnancy,[13] little has been written on the male wish for progeny. Clearly, it would be valuable to obtain more general information on the matter from nonpatient populations. How do ordinary men and women approach the issue of reproduction and its vicissitudes during the different phases of reproductive life? In Sweden the unique national registration system provides possibilities for population-based investigations. We report here the results of a large-scale study on attitudes toward reproduction among men and women of fertile age.

Material and methods

A psychometric instrument for the assessment of reproductive profiles in men and women was devised.[14] The inventory comprises 53 items, the content of which was based on previous research,[7, 12] psychologic and psychoanalytic literature,[5, 9, 10] and clinical experience (M.W.). Negative and positive statements toward pregnancy and parenthood are balanced. They focus on four main reasons for wanting a child, i.e., philosophic or existential, sociocultural, interpersonal, and intrapsychic. "Wish for pregnancy" and "wish for a child" are considered as two distinct and not necessarily related desires. Seven of the 53 items are sex specific. The items are to be answered in a five-point response format according to Likert.[15] The instrument has earlier been found very reliable (Cronbach's α 0.7888).[14]

The population studied comprised inhabitants within the catchment area for Umeå University Hospital. Umeå is an average-size city on the northern Baltic coast of Sweden. Originally a center in a rural area with a strong religious tradition, it has developed into a modern center for education, and culture. The population of 90,000 is comparatively young (mean age 36 years) and is growing by a thousand persons per year.

Men and women were randomly selected from the national registration records. Representative samples of the population in three different phases of fertile life were created.

A questionnaire was mailed with an accompanying letter explaining the purpose of the study to 1001 persons, 20, 30, or 40 years old. Two reminders were sent to nonresponders. Data from completed forms were computerized and analyzed by factor analysis type PA 2 with oblique rotation.[16] Men and women were analyzed separately. Factor analysis was used to reduce the large number of variables to describe a structure in a complicated pattern. The number of factors in this work was chosen from the interpretability of their content. For each sex six factors were extracted. The mean group response to the selected factors was assessed. For each factor an index, I, was calculated according to the formula:

$$I = x_{v1} \cdot f_1 + x_{v2} \cdot f_2 + \ldots x_{vn} \cdot f_n$$

where x is the average group response to item V, 1, 2 . . . n indicates the rank of each item within the factor, and f represents the value of the factor loading. Only items with a factor loading >0.38 were included. The number of items within each factor ranged between 2 and 10.

For each factor an I_{min} and an I_{max} were calculated, and a reproductive profile was constructed where $I_{min} = 0$ and $I_{max} = +10$. Indices were produced for each age group in both sexes.

Table II. The six most important factors achieved by factor analysis of 53 items answered by 416 women

Factor	*Variance (%)*	*Content*	*Important items*	*Factor loading*
1	33	Children—existential satisfaction	A child is a confirmation of a love relationship.	0.59
			Having children is a way to communicate your knowledge and life experience to future generations.	0.58
			The children around you enhance your faith in the future.	0.58
			It is the greatest happiness in life to watch a child grow up.	0.55
2	26	Children—lack of freedom and a burden	You become afraid to have children when you see how unfree parents of small children are.	0.63
			When you have children you can no longer travel around the world as you would like to.	0.56
			You lose your freedom when you have children.	0.54
3	14	Importance of own parents as an example	As a parent I want to be like my own mother was toward me.	0.76
			As a parent I don't want to be like my own mother was toward me	−0.73
4	11	Importance of the child's sex	To me it is important to have a daughter.	−0.70
			To me it is important to have a son.	−0.61
5	10	Children—the meaning of love and life?	You may feel like a perfectly complete woman without having experienced a pregnancy.	0.66
			A woman cannot feel quite satisfied in life until she has experienced a pregnancy.	−0.50
			A love relationship is not complete until you have a child together.	−0.42
6	7	The impact of ambivalence	Difficulties in tolerating contraceptives are expressions of a subconscious child wish.	0.65
			"Negligence" about contraception is due to a subconscious desire to become pregnant.	0.65

The relative importance of each factor is denoted by the percentage of variance.

Results

Of the 1001 forms distributed, 746 were completed and returned. Thus the average response was 75% (women 82%, men 67%). The response rates in different age groups are illustrated in Table I. The six factors are described in Tables II and III. Their relative importance is expressed by the percentage of variance, and a few items with a high factor loading are given. The overall response pattern was strikingly similar between men and women.

Thus the two most important factors for both sexes were "children as existential satisfaction" and "children as lack of freedom." Together these two factors were found to account for about 60% of the variance. Whereas women ranked "children as existential satisfation" the most important factor, "children as lack of freedom" was considered relatively more important by men. There were also other subtle differences between male and female attitudes, as indicated by the slightly different formulations of the factors. Restriction of freedom was more concretely expressed in the items highly loaded by the women, whereas the men had a more general and abstract approach to this issue. Having children as a way to find existential security in life had a high factor loading in the men's factor 2, whereas existential satisfaction expressed as "a child is a confirmation of a love relationship" appealed to the women.

Factor 3 concerns "the importance of one's own parents as examples in parenthood" and evoked virtually identical responses from both sexes. This factor comprised four items, all of which are about whether one wants (or does not want) to be like one's mother and

Table III. The six most important factors achieved by factor analysis of 53 items answered by 329 men

Factor	*Variance (%)*	*Content*	*Important items*	*Factor loading*
1	36	Children—lack of freedom	You lose your freedom when you have children.	0.61
			You become afraid to have children when you see how unfree parents of small children are.	0.60
			It is difficult to realize the meaning of life when you have parental responsibility.	0.55
2	25	Children—existential consolation and satisfaction	Having children is a way to find security in life.	0.57
			The children around you enhance your faith in the future.	0.56
			It is the greatest happiness in life to watch a child grow up.	0.53

			To me it is important to have a son.	−0.51
6	7	The impact of ambivalence	Difficulties in tolerating contraceptives are expressions of a subconscious child wish.	−0.65
			You become afraid to have children of your own if you got on badly with your mother.	−0.47
			"Negligence" about contraception is due to a subconscious desire to become pregnant.	−0.44

The relative importance of each factor is denoted by the percentage of variance.

father, respectively, when one becomes a parent. The men ranked their fathers as more important than their mothers; conversely, the women ranked their mothers as more important than their fathers. In the women's factor 3 there was an additional fifth item with a comparatively low factor loading, 0.42. This fifth item has the wording, "I was a burden to my parents."

The men's factor 4, "fecundity, gift or coercion," was not identified among the women, and likewise the women's factor 5, "children as a means for achievement," was not found in the male pattern. The importance of the child's sex emerged as factor 4 in the women's analysis and as factor 5 among the men with the identical two items. Factor 6 in both sexes could be comprehended as "the impact of ambivalence." The perception of the content of this factor may differ between men and women, as exemplified in the items in the tables.

The mean group attitudes to the dominant factors were calculated. The resultant reproductive profiles for the different age and sex groups are shown in Figs. 1 and 2.

There was a striking similarity between the different age groups. When calculating corresponding indices for men to the women's factors and vice versa, a strong conformity between the sexes was also found.

Comment

The current results indicate a high degree of concordance in reproductive attitudes between women and men and between young and middle-aged people in different phases of their fertile life. We feel that what we have perceived are collective attitudes to pregnancy, children, and parenthood rather than individual private motives. The impact of collective attitudes on the motivation for reproduction in individuals has been demonstrated previously,[9] and certainly the results could be valid also for individual patients in clinical practice. These attitudes are dominated by two conflicting forces, i.e., the view of children as an existential satisfaction and children as a restriction of freedom and a burden. These findings are in line with an earlier study by Gaughran et al.[17] The focus of their items was more of an ideologic nature, but nevertheless the two most important factors "concern with population growth" and "large family ideology" express the same basic conflict. Indeed, this antagonism seems to create the basis of the reproductive drama.

Although the men's and women's attitudes were quite similar in most respects, there were still interesting differences. In Sweden, and possibly in many Western countries, women provide most of the practical and daily care for their children, often at the cost of a professional career. Men seem to feel their responsibility is to provide for the economic well-being of the family. This may be reflected in the differences in the content of the factor "children as a burden." The sequence of order where women place the factor "children as existential satisfaction" first, whereas men place it second, may reflect a convention where women are less allowed than men to reject parenthood. An alter-

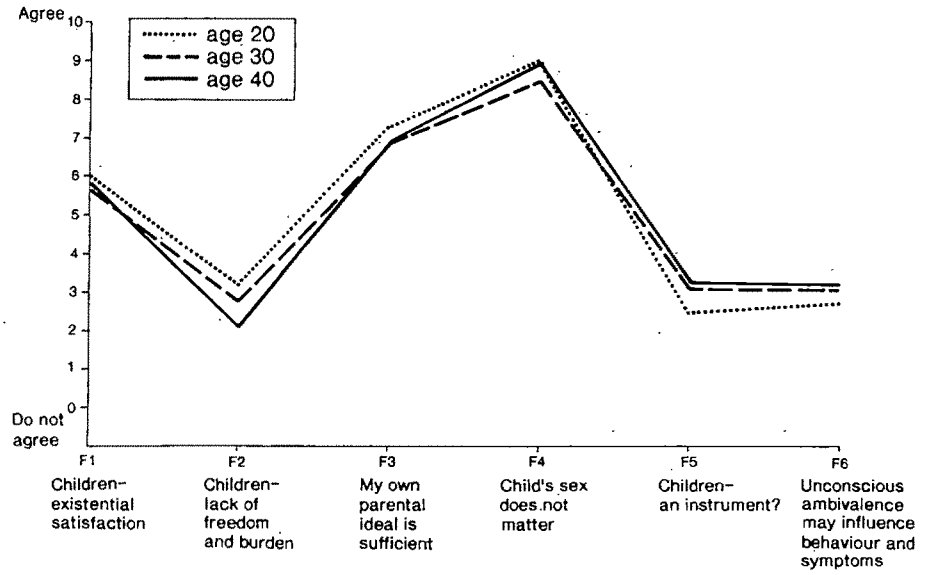

Fig. 1. Mean group attitudes toward six dominant factors about reproduction in 20-, 30-, and 40-year-old women.

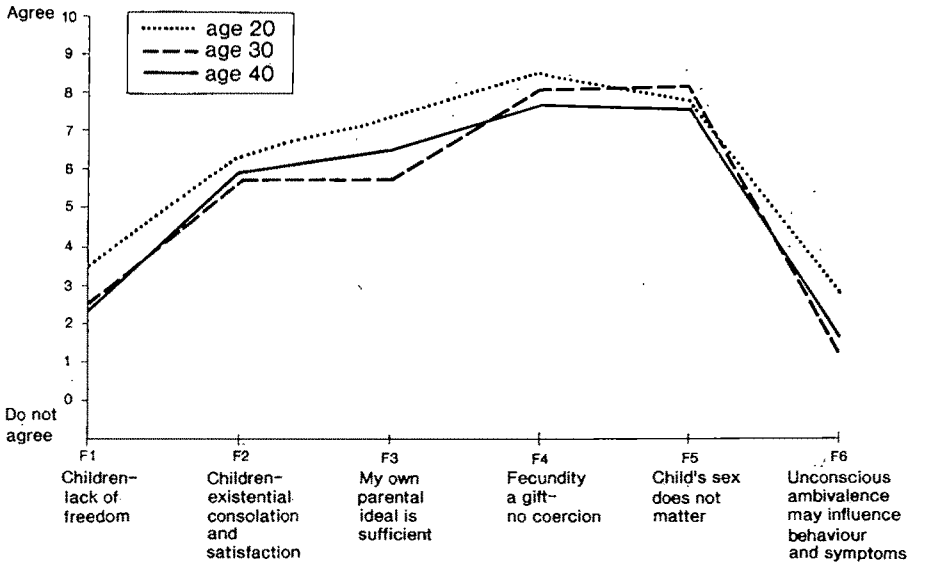

Fig. 2. Mean group attitudes toward six dominant factors about reproduction in 20-, 30-, and 40-year-old men.

native explanation might be that the biologic rhythm of women and men differs fundamentally—women's cyclicity perpetually and concretely reminds them of their reproductive potential.

The strong third factor dealing with the significance of one's own parents as an example in parenthood might be especially important for individual choice and behavior. Many authors[6, 18] have described how reproductional conflicts are transmitted from one woman-generation to another. This knowledge could be useful in clinical work with patients where reproductive conflicts are expressed, for example, as intolerance toward different contraceptives or repeated unwanted pregnancies. These women might benefit from consultations where realistic needs and possible hereditary conflicts are elucidated.

Little is known about reproductive conflicts in men. Previous studies have demonstrated that their attitudes markedly influence the well-being of their wives during pregnancy.[13, 18] Here the third factor about the significance of one's own parents as an example was similar in men and women, thus supporting the assumption that there is little difference between the sexes in this respect. To what extent male reproductive conflicts are transmitted through generations should be a theme for further research.

Although most subjects in our study answered that the child's sex was immaterial, this question was sufficiently loaded to emerge as a distinct factor in the analysis. In interviews with women about children, family, and work published by Statistics Sweden (1985),[19] mothers of two children were more inclined to have a third child if the first two children were of the same sex, regardless of whether they were boys or girls. In parents-to-be, Kihlbom et al.[18] found that the sex of the future child was extremely important, although there was a strong pressure to love the child whatever its sex. However, negative reactions were occasionally evoked when the child was born with the "wrong" sex.

When traditional roles are in a state of transition, it is noteworthy that the two most loaded items in the women's factor 5 concerned whether a pregnancy is necessary to make a woman feel a "real woman." The importance of sexual identity conflicts has been discussed previously.[3] Indeed, some insecure women may "want motherhood more than the child."[20] It is no doubt of clinical importance to perceive these attempts to buttress a fragile identity. The topic is subtle and delicate and respectful, empathic, and supportive listening in the consulting room is important.

Although most men and women in this population denied that ambivalence should exert any influence on either conscious or subconscious behavior (Figs. 1 and 2), the topic was loaded and found to constitute factor number 6. This finding again illustrates the basic conflict between opposing forces. In fact, ambivalence seems to be integral to collective attitudes toward reproduction. This may be a clue to a more complete understanding of the reproductive drama.

Our efforts to help women and men to enjoy sexuality without fear of unwanted pregnancies and to assist them when child wish is expressed may be even more successful if we recognize the element of ambivalence in human reproductive behavior.

Professional computer work was done by Birgitta Hammarström, UMDAC. Statistical advice was provided by Stig Uhlin, UMDAC. Valuable support was given by Ingemar Joelsson.

Acute posttraumatic fetal anemia treated with fetal intravascular transfusion

Gerardo O. Del Valle, MD, Gary M. Joffe, MD, Luis A. Izquierdo, MD, James F. Smith, MD, Tracey Kasnic, RNC, BSN, George J. Gilson, MD, Molly S. Chatterjee, MD, and Luis B. Curet, MD

Albuquerque, New Mexico

Fetal trauma resulting in acute anemia after maternal blunt abdominal trauma is a rare but potentially lethal condition. We recently managed such a case with the use of fetal intravascular transfusion. (Am J Obstet Gynecol 1992;166:127-9.)

Key words: Fetal trauma, fetal anemia, fetal intravascular transfusion

Maternal trauma during motor vehicle accidents is considered a significant contributor to perinatal morbidity and mortality in the United States. We report on the use of fetal intravascular transfusion in the management of posttraumatic fetal anemia in the early third trimester.

Case report

A 28-year-old woman, gravida 5, para 3-0-1-2, was transported to our institution at 27.5 weeks' gestation because of suspected fetal distress after a motor vehicle accident in which her abdomen hit the steering wheel. There was no history of drug or alcohol use. The prenatal course and medical history were unremarkable. On admission, the patient was alert, cooperative, and in no distress. Vital signs were stable. Abdominal examination revealed no ecchymoses, mild right upper-quadrant pain, and a soft uterus. Fundal height was 28 cm. There was no evidence of ruptured membranes, vaginal bleeding, or labor. Ultrasonographic examination did not show any fetal or placental anomalies. Results of umbilical artery Doppler studies were normal. External fetal heart monitoring demonstrated a persistent tachycardia of 170 to 180 beats/min with a sinusoidal pattern and no decelerations (Fig. 1). Biophysical profile revealed no fetal breathing, but adequate tone, movements, and amniotic fluid were present. Results of routine admission laboratory and coagulation studies were normal. Kleihauer-Betke test result was negative (<0.1% fetal cells), Rh status was positive, and antibody screening test result was negative. Urine toxicology screen was negative.

The fetus was monitored continuously, with the same

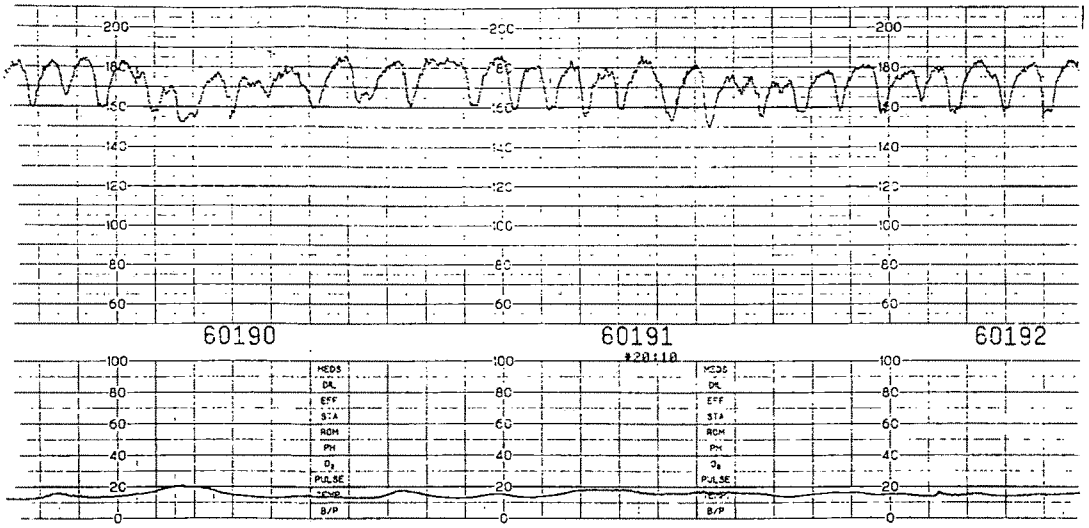

Fig. 1. Fetal monitoring strip before intravascular transfusion.

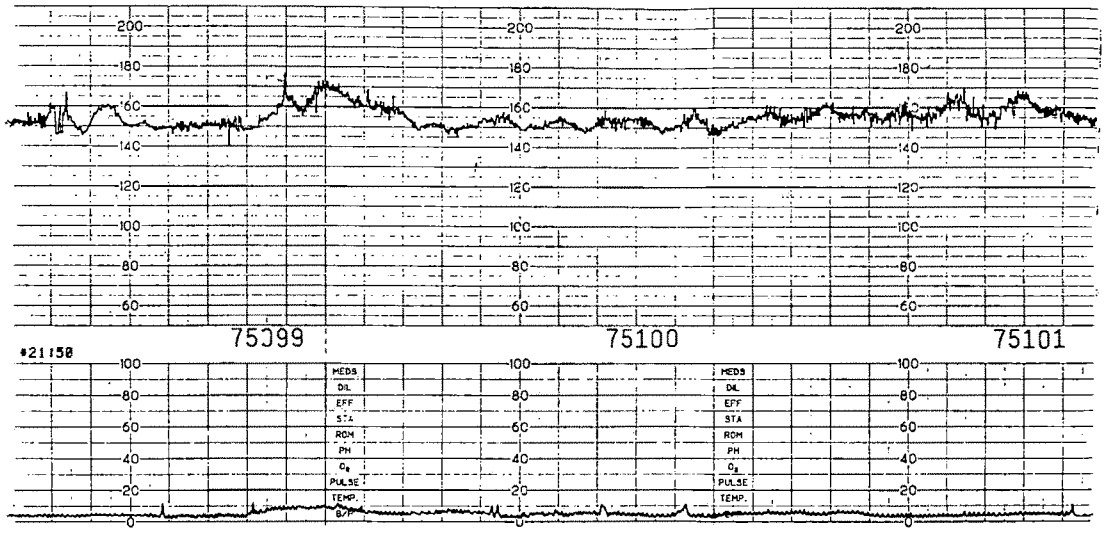

Fig. 2. Fetal monitoring strip after intravascular transfusion.

heart rate pattern always maintained. Serial biophysical profiles were not suggestive of hypoxia. To further investigate the cause of the abnormal heart rate pattern, amniocentesis and cordocentesis were performed. Amniocentesis revealed bloody amniotic fluid. Cordocentesis revealed a hematocrit of 17%, mean cell volume of 110.5, pH 7.4, Pco_2 38.0 mm Hg, bicarbonate 21.6 mEq/L, oxygen saturation 72.2%, and Kleihauer-Betke test >99% fetal cells. Subsequently, negative screens for toxoplasma and cytomegalovirus immunoglobulin M and normal female karyotype were reported. An intravascular fetal transfusion was performed with 70 ml packed, washed, irradiated, cytomegalovirus-negative, O-negative red blood cells. A posttransfusion hematocrit was not obtained because the needle dislodged and a second attempt at needle insertion failed. After the transfusion, fetal heart rate pattern showed a normal baseline and gradual disappearance of the sinusoidal pattern (Fig. 2). Daily fetal surveillance revealed reactive nonstress tests and normal biophysical profiles. The patient was discharged on the sixth hospital day. Further antepartum surveillance included fetal movement counts, nonstress testing, and ultrasonographic evaluations for growth.

The patient was admitted at 37 weeks with ruptured membranes. After augmentation of labor with oxytocin she was delivered vaginally without complications of a 3905 gm female infant with Apgar scores of 8 at 1 minute and 9 at 5 minutes. Cord hematocrit was 50%. The placenta had an area of old infarction covering 25% of the fetal surface. The neonate was diagnosed as having microcephaly (head circumference <3 SD). Results of neurologic evaluation were basically normal, and antibody titers for toxoplasma and cytomegalovirus were negative. Computed tomographic scan of the brain revealed evidence of parenchymal atrophy from a suspected resolving old hemorrhagic process in the left parietooccipital area. After initial problems with feeding, the baby was discharged on the sixth postpartum day.

Comment

Fetal injuries resulting from maternal blunt abdominal trauma may be due to abruptio placentae, cord rupture, fractures, intracranial hemorrhage, prematurity, uterine rupture, or maternal death.[1] Several of these may cause acute fetal anemia. Fetal anemia may be suspected from abnormal heart rate patterns. In the absence of the use of medications such as meperidine or anesthetics, sinusoidal patterns have been associated with fetal anemia, hypoxia, or asphyxia. In term or near term pregnancies the presence of a sinusoidal pattern after maternal trauma may be an indication for delivery. However, in the presence of prematurity further testing may be warranted to assess the need for delivery.

Recently, Fischer et al.[2] have reported a case of chronic fetomaternal hemorrhage managed with repeated fetal intravascular transfusions. The fetal anemia in our case was not due to fetomaternal hemorrhage as evidenced by the Kleihauer-Betke results. It may have been caused by a combination of hemorrhage from a ruptured vessel in the fetal side of the placenta and trauma-induced intracranial hemorrhage. This would explain the bloody amniotic fluid, the infarct in the fetal side of the placenta, and the neonatal brain findings.

This case demonstrates the possible adverse effects of blunt maternal abdominal trauma during pregnancy and the role that cordocentesis might play in the evaluation of abnormal fetal heart rate patterns. It also shows that delivery of a compromised fetus is not always the only management alternative. We were able to treat and resolve the fetal anemia with intravascular trans-

fusion and thus prolong this pregnancy. The unfortunate development of microcephaly secondary to the large parietooccipital brain lesion shows all too clearly that there are a number of unpredictable and unpreventable side effects of trauma during pregnancy.

We thank Dr. Lloyd Trujillo, Shiprock Public Health System, Shiprock, New Mexico, for his help in the management of this case.

VII. Microbial invasion of the amniotic cavity in spontaneous rupture of membranes at term

Roberto Romero, MD,[a, c] Moshe Mazor, MD,[a] Rafaella Morrotti, MD,[a] Cecilia Avila, MD,[a] Enrique Oyarzun, MD,[a] Alvaro Insunza, MD,[a] Manuel Parra, MD,[a] Ernesto Behnke, MD,[a] Francisco Montiel, MD,[a] and Gail H. Cassell, PhD[b]

New Haven, Connecticut, Detroit, Michigan, and Birmingham, Alabama

OBJECTIVE: The purpose of this study was to determine the frequency, microbiologic characteristics, and clinical significance of microbial invasion of the amniotic cavity in women with premature rupture of membranes at term.
STUDY DESIGN: Amniocentesis was performed in 32 women with term premature rupture of membranes and amniotic fluid cultured for aerobic and anaerobic bacteria and Mycoplasmas.
RESULTS: The prevalence of positive amniotic fluid cultures was 34.3% (11/32). The most common isolates were *Ureaplasma urealyticum, Peptostreptococcus* sp., *Lactobacillus* sp., *Bacteroides fragilis,* and *Fusobacterium* sp. Clinical chorioamnionitis occurred only in one patient with a positive amniotic fluid culture. Her neonate had ophthalmitis. Three patients (9.4%) had endometritis. Among women who were delivered vaginally, those with a positive amniotic fluid culture had a significantly higher rate of endometritis than those with a negative culture (33% [3/9] vs 0% [0/20], respectively, $p = 0.023$).
CONCLUSIONS: These data indicate that microbial invasion of the amniotic cavity occurs in approximately one third of patients with preterm premature rupture of membranes. Microbial invasion of the amniotic cavity is a risk factor for endometritis in women with term premature rupture of membranes. (AM J OBSTET GYNECOL 1992;166:129-33.)

Several studies have reported on the prevalence of microbial invasion of the amniotic cavity in preterm premature rupture of membranes.[1-7] However, there is no information available regarding the microbiologic state of the amniotic cavity during rupture of membranes at term. Previous studies addressing this issue have retrieved amniotic fluid with a transcervical intrauterine catheter from women in labor.[8] With this method, it is difficult to discern between positive cultures that are due to contamination of the fluid with cervicovaginal flora and true microbial invasion of the amniotic cavity. The purpose of this study was to de-

PROM, Premature rupture of membranes.

termine the prevalence and microbiologic features of microbial invasion of the amniotic cavity in women with term spontaneous rupture of membranes by transabdominal amniocentesis.

Material and methods

Patient population. A retrospective study was designed to identify women who had amniotic fluid retrieved transabdominally because of suspected preterm premature rupture of membranes but who subsequently were delivered of term neonates within 48 hours of amniocentesis. The diagnosis of rupture of membranes was made with sterile speculum examination and a combination of pooling, ferning, and Nitrazine tests. Amniocentesis for microbiologic studies is routinely offered in our institution to all patients admitted with suspected preterm premature rupture of membranes. The obstetric data base was searched to identify patients who had undergone amniocentesis but subsequently were delivered of neonates with birth weights >2500 gm, who were considered term infants by pediatric examination, and who had not undergone a digital examination before amniocentesis.

Microbiologic culture technique. Amniotic fluid was transported to the laboratory in a capped plastic syringe immediately after collection. These conditions precluded air contact with the specimen. Plating occurred within 30 minutes of collection in all cases. Amniotic fluid was cultured for aerobic and anaerobic bacteria by methods previously described.[9] The samples were plated on blood agar, MacConkey's agar, Columbia colistin–nalidixic acid agar, and chocolate agar (36° C in 8% carbon dioxide) for aerobic culture and on blood agar, BBE (*Bacteroides,* bile-esculin agar), LKV (laked kanamycin, vancomycin agar), and Martin-Lewis agar (all prereduced) for anaerobic culture. Amniotic fluid was also inoculated in thioglycollate broth. Anaerobic cultures were grown in an anaerobic chamber in the Forum Scientific anaerobic system (model 1024; Division of Mallinckrodt, Marietta, Ohio). For *Mycoplasmas,* an aliquot of fluid (1 ml) was inoculated into transport media and frozen at −70° C until culture with techniques previously described.[10, 11] Gram stain examinations were performed with commercial reagents (crystal violet, saffranin, and Gram's iodine [Difco Laboratories, Detroit]) under standard conditions.[12] The limulus amebocyte lysate assay was performed according to techniques previously described.[13]

Patient management. Patients were managed according to the results of the Gram stain of amniotic fluid. The results of the limulus amebocyte lysate test were blinded. Patients with positive Gram stains received antibiotics (ampicillin and gentamicin), and labor was induced. Patients with negative Gram stains were managed expectantly.

Criteria for the diagnosis of chorioamnionitis and puerperal endometritis. Clinical chorioamnionitis was defined by the criteria proposed by Gibbs et al.[14] Puerperal endometritis was defined as a temperature elevation to 38° C or higher on two occasions (4 hours apart, excluding the day of delivery) with uterine tenderness, foul-smelling lochia and no other apparent source of infection. Routine neonatal cultures were not performed.

Statistical analysis. Comparisons between proportions were performed with either a χ^2 or Fisher's exact test. An unpaired Student *t* test was used to compare gestational age between groups. Computations were performed with the Epistat program (Epistat Services, Richardson, Tex.).

Results

Thirty-two patients met the criteria for inclusion into this study. All amniotic fluid samples were retrieved by transabdominal amniocentesis. The prevalence of positive amniotic fluid cultures was 34.3% (11/32). Table I displays the clinical characteristics of patients with positive and negative amniotic fluid cultures. There were no significant differences between the two groups in maternal age, parity, rupture of membranes–to–amniocentesis interval, amniocentesis-to-delivery interval, mode of delivery, mean birth weight, and Apgar scores at 1 and 5 minutes.

Table II. Results of microbiologic and diagnostic tests in women with ruptured membranes at term

Patient No.	*Gram stain*	*Limulus amebocyte lysate*	*Microorganism*	*Puerperal infection*
1	Negative	Positive	*Lactobacillus* sp.	No
2	Negative	Negative	*Ureaplasma urealyticum*	Endometritis
3	Negative	Positive	*Ureaplasma urealyticum*	No
4	Negative	Negative	*Ureaplasma urealyticum*	No
5	Negative	Negative	*Peptostreptococcus* *Ureaplasma urealyticum*	Endometritis
6	Negative	Negative	*Ureaplasma urealyticum*	No
7	Positive	Negative	*Streptococcus*, group G *Bacteroides fragilis* *Peptostreptococcus* sp. *Fusobacterium* sp. *Ureaplasma urealyticum*	Endometritis
8	Negative	Negative	*Fusobacterium* sp. *Ureaplasma urealyticum*	No
9	Positive	Positive	*Gardnerella vaginalis* *Ureaplasma urealyticum*	No
10	Negative	Positive	*Peptostreptococcus* sp. *Ureaplasma urealyticum*	No
11	Negative	Negative	*Lactobacillus* sp. *Bacteroides fragilis*	No

Table II illustrates the results of Gram stain, limulus amebocyte lysate, and microbiologic analysis of amniotic fluid of patients with positive amniotic fluid cultures. The most frequent isolates were *Ureaplasma urealyticum* (n = 10), *Peptostreptococcus* sp. (n = 4) and *Lactobacillus* sp. (n = 2). The prevalence of polymicrobial invasion of the amniotic cavity was 45.4% (5/11). The Gram stain examination of amniotic fluid was positive in 18.1% (2/11) of cases with a positive amniotic fluid culture. There were no false-positive Gram stains of amniotic fluid. The limulus amebocyte lysate test was positive in five cases (15.6% [5/32]), and in four of these patients the amniotic fluid was positive for microorganisms.

Clinical chorioamnionitis was diagnosed in one patient who had a positive amniotic fluid culture for *Gardnerella vaginalis* and *Ureaplasma urealyticum*. The overall prevalence of puerperal endometritis was 9.4% (3/32). Among women who were delivered vaginally, those with positive amniotic fluid cultures had a significantly higher rate of endometritis than did those with negative cultures (33% [3/9] vs 0% [0/20], respectively; p = 0.023, Fisher's exact test). One patient had both clinical chorioamnionitis and endometritis. Her neonate had ophthalmitis but no other clinical or laboratory signs of sepsis. However, neonatal cultures for *Mycoplasmas* were not performed.

Three patients were delivered by cesarean section, two with positive amniotic fluid cultures and one with a negative amniotic fluid culture. The indication for cesarean section was failure to progress in labor in all cases. Only the two neonates born to mothers with a positive Gram stain of amniotic fluid had blood cultures performed; they were negative for microorganisms. Neonatal septicemia was not diagnosed on clinical grounds in this series.

Comment

This is the first study to report the prevalence of microbial invasion of the amniotic cavity in women presenting with ruptured membranes at term. The results are unexpected, in that the prevalence of microbial invasion of the amniotic cavity at term is similar to that found in preterm premature rupture of membranes (34.3% [11/32] vs 28.5% [178/625], respectively).[1-7, 15] These findings imply that one third of patients with rupture of membranes have microbial invasion of the amniotic cavity, regardless of whether this complication occurs in the preterm or term gestation. A limitation of the current study is that amniocentesis was performed on all patients because they were thought to have preterm gestations. Although all newborns had weights of >2500 gm and were term by pediatric examination, our population may not represent the entire term population.

The most common microbial isolates in this study were *Ureaplasma urealyticum*, *Lactobacillus* sp., *Peptostreptococcus* sp., *Bacteroides fragilis*, and *Fusobacterium* sp. Most of these microorganisms are frequent constituents of normal cervicovaginal flora; therefore an ascending route is the most likely pathway for microbial invasion. Further studies including quantitative microbiologic analysis are required to establish whether there are differences in microbial inoculum size and type between women with term and preterm rupture of membranes.

What is the temporal relationship between microbial invasion of the amniotic cavity and rupture of mem-

branes? The traditional view has been that microorganisms gain access to the amniotic cavity after rupture of membranes. An alternative view is that microbial invasion of the amniotic cavity precedes the rupture of membranes. The following evidence supports this view. First, 13.6% of women with preterm labor and intact membranes have a positive amniotic fluid culture for microorganisms, and they are more likely to have spontaneous rupture of membranes that are women with a negative amniotic fluid culture.[12, 16-24] Second, incubation of fetal membranes with bacterial products or activated neutrophils reduces the bursting tension of fetal membranes in vitro.[25] Third, the prevalence of acute histologic chorioamnionitis is significantly higher in women with premature rupture of membranes than in women without premature rupture of membranes.[26] This effect is present even when the duration of rupture of membranes is <4 hours, implying that the inflammatory process occurred before rupture of membranes. Fourth, neonates born to women with premature rupture of membranes have increased levels of immunoglobulin M or A_1, suggesting that the fetal immune system had time to respond to a preexisting insult (i.e., infection) of some duration.[27] Fifth, experimental studies indicate that bacteria can cross intact fetal membranes in vitro.[28] Microbial invasion of the amniotic cavity may then lead to rupture of membranes. Collectively, this evidence suggests that microbial invasion of the amniotic cavity in cases with premature rupture of membranes may occur before rupture. In this study the interval between rupture of membranes and amniocentesis was not different in women with positive and negative amniotic fluid cultures. However, the number of observations is insufficient to exclude the possibility that microbial invasion of the amniotic cavity is a time-dependent phenomenon.

An important question is why microbial invasion of the amniotic cavity occurs in some women with rupture of membranes and not in others. Premature rupture of membranes is probably a heterogeneous condition caused by several factors[29]; intraamniotic infection is merely one of these factors. A positive amniotic fluid culture may reflect both the contribution of infection to the etiology of premature rupture of membranes and secondary microbial infection. Susceptibility to microbial invasion of the amniotic cavity after premature rupture of membranes may vary. Host factors, such as the antimicrobial properties of the amniotic fluid, may play a role in determining an individual's susceptibility.[30-38]

Our data indicate that microbial invasion of the amniotic cavity often occurs without demonstrable clinical signs of maternal or neonatal infection. Indeed, only one of 11 patients with positive amniotic fluid cultures had clinical chorioamnionitis. This clearly demonstrates that the currently used definition of clinical chorioamnionitis is an insensitive indicator of microbial invasion of the amniotic cavity. This observation is in keeping with those made in the context of preterm labor with intact membranes[24] and of term labor with intact membranes.[39]

Although microbial invasion of the amniotic cavity at term is not often accompanied by clinical signs of chorioamnionitis, this condition is not innocuous. All cases of puerperal endometritis occurred in women with positive cultures. Furthermore, the rate of endometritis after a vaginal delivery was greater in women with a positive amniotic fluid culture than in those with a negative culture. Since there were only three cesarean sections in this study, we cannot determine whether microbial invasion of the amniotic fluid also increases the risk of post–cesarean section endometritis. Previous studies, however, have indicated that rupture of membranes is an important risk factor for post–cesarean section endometritis. The possibility must be strongly considered that the basis for this association is the high rate of microbial invasion of the amniotic cavity in women with term premature rupture of membranes.

Serum levels of macrophage colony-stimulating factor in patients with ovarian cancer undergoing second-look laparotomy

Steven A. Elg, MD,[a, b] Yin Yu, MD,[b] Linda F. Carson, MD,[a] Leon L. Adcock, MD,[a] Leo B. Twiggs, MD,[a] Konald A. Prem, MD,[a] and Sundaram Ramakrishnan, PhD[b]

Minneapolis, Minnesota

OBJECTIVE: The purpose of this study was to evaluate the prognostic significance of macrophage colony-stimulating factor serum levels in patients with ovarian cancer undergoing second-look laparotomy.

STUDY DESIGN: The presurgical serum levels of macrophage colony-stimulating factor from 33 consecutive patients with ovarian cancer undergoing second-look laparotomy were determined and compared with those of 50 healthy control subjects. Mean differences in groups were evaluated with the Student *t* test.

RESULTS: Sixteen of 33 patients had a positive result at second look and a mean serum macrophage colony-stimulating factor level of 2.31 ± 1.45 ng/ml. Seventeen of 33 patients had a negative result at second look and a mean macrophage colony-stimulating factor level of 1.90 ± 0.86 ng/ml ($p > 0.05$). The mean macrophage colony-stimulating factor level in the control group was 1.20 ± 0.51 ng/ml. This was statistically lower than the mean level found in patients with a negative second-look result ($p < 0.05$).

CONCLUSION: Regardless of tumor status, serum macrophage colony-stimulating factor levels tend to be elevated at the time of second-look laparotomy. (AM J OBSTET GYNECOL 1992;166:134-7.)

Key words: Ovarian cancer, tumor marker, macrophage colony-stimulating factor, second laparotomy

Tumor cells produce growth factors, some of which may regulate the proliferation of cancer cells by autocrine and paracrine pathways.[1-7] The aberrant production of trophic factors by cancer cells is due to either gene amplification or genetic translocation, which may bring the growth factor genes under the control of different regulatory elements. Interestingly, among the different growth factors studied thus far, colony-stimulating activity has been detected in many nonhematologic tumors.[6, 7] Concomitant with the presence of colony-stimulating factor activity, higher levels of circulating leukocytes have been seen in some of these patients.[4, 5] These results, along with studies using murine experimental model systems wherein human tumors were transplanted, indicate constitutive production of cytokines by malignant cells.[7] Although the importance of these factors remains uncertain at the present time, their levels in serum may prove useful as markers to monitor primary tumors or to detect metastases.

Table I. Patient age

Group	*No.*	*Age (yr, mean ± SD)*
Control	50	41 ± 11
Second-look laparotomy	33	52 ± 14
Positive	16	55 ± 12
Negative	17	49 ± 16

Table II. Initial diagnosis of patients undergoing second-look laparotomy

Initial diagnosis	*No.*
Adenocarcinoma (serous or mucinous)	28
Malignant endometrioid tumor	1
Clear cell carcinoma	4
TOTAL	33

In a recent study it was reported that each of six ovarian cancer cell lines secrete macrophage colony-stimulating factor into the culture medium in the absence of any external stimuli.[8] Whereas lymphoid and myeloid cell lines failed to show any detectable amount

Sera samples were analyzed in specific radioimmunoassay. Each value is mean of triplicate independent estimations from individual samples.

of macrophage CSF, a limited number of breast cancer cell lines produced the growth factor in significant quantities. Presence of the colony-stimulating factor was confirmed not only by immunologic (radioimmunoassay) and biologic assay (murine bone marrow cultures) but also by analysis of total cellular ribonucleic acid for macrophage CSF–related transcripts.[8] Kacinski et al.[9] have detected expression of macrophage CSF transcripts in ovarian carcinoma cells by in situ hybridization. Macrophage CSF is a dimeric glycoprotein of about 70 kd and belongs to a group of cytokines that regulate the ontogeny of blood cells. Macrophage CSF selectively stimulates proliferation and differentiation of the mononuclear phagocytic lineage and mature macrophages.[10, 11] Recently, macrophage CSF serum levels were reported to be elevated in patients with epithelial ovarian cancer.[9] It has been suggested that macrophage CSF may be useful as a potential tumor marker. The purpose of this study is to evaluate the prognostic significance of macrophage CSF levels in ovarian cancer patients undergoing second-look laparotomy.

Material and methods

Serum samples from 33 consecutive patients undergoing second-look laparotomy for epithelial ovarian cancer were retrieved from the serum bank of the University of Minnesota Women's Cancer Center. The sera, which had been drawn just before surgery, were obtained between Dec. 1, 1985, and June 1, 1988, and stored at −20° C until analysis.

Macrophage CSF levels in these samples were determined in the following way. A polyclonal antiserum against human recombinant macrophage CSF (provided by the Genetics Institute, Cambridge, Mass.) was generated in rabbits by hyperimmunization. The antiserum used in these studies has been well characterized and does not cross react with other growth factors or cytokines. Details of the assay conditions are published elsewhere.[8] This assay system can detect concentrations as low as 500 pg/ml. To minimize interassay variations, aliquots of individual sera samples from five normal subjects were used as internal controls. Macrophage CSF serum levels were determined in a similar manner in 50 healthy female controls.

All samples were also assayed for the presence of tumor marker CA 125 with an immunoradiometric method.[12] CA 125 levels were expressed in relative units per milliliter. Mean differences in groups were evaluated with the Student t test. A p value <0.05 was considered significant.

Results

No clinical evidence of infection was noted at the time of obtaining the serum. Mean ages of the study groups are given in Table I. A summary of initial pathologic diagnoses is shown in Table II. Macrophage CSF levels as determined by radioimmunoassay showed a wide

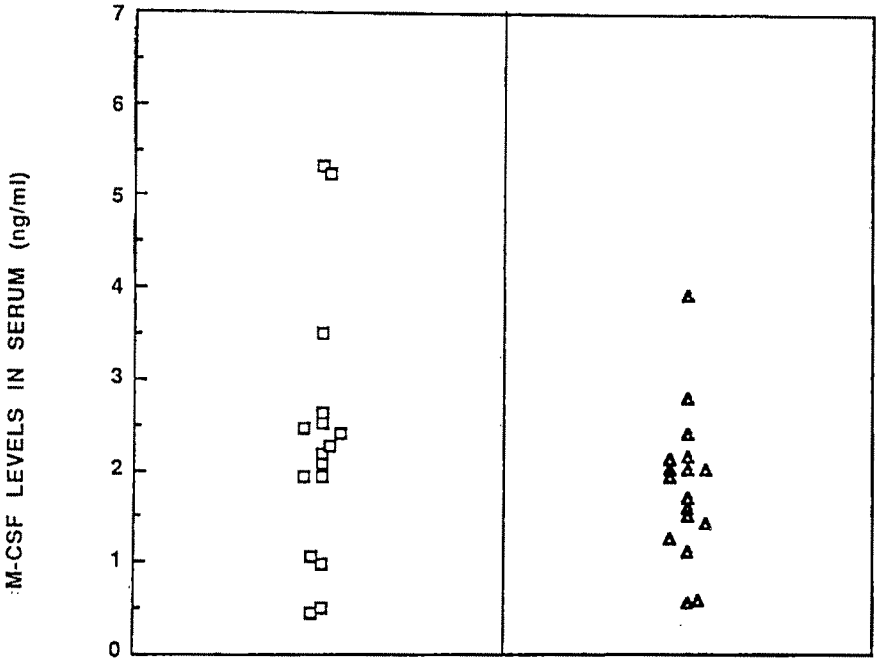

Fig. 2. Macrophage CSF levels in sera of patients with ovarian cancer. *Open squares,* Abnormal pathologic findings at second-look laparotomy; *open triangles,* normal pathologic findings at second-look laparotomy.

range between nondetectable levels and 5.3 ng/ml in one patient. The distribution of individual samples is shown in scatter plots (Figs. 1 and 2). Sixteen patients with positive pathologic studies at the time of second look had a mean serum macrophage CSF level of 2.31 ± 1.45 ng/ml. The mean level in the 17 patients with negative findings was 1.90 ± 0.86 ng/ml. The difference in these levels is not statistically significant ($p > 0.05$).

The mean macrophage CSF level in the control group was 1.20 ± 0.51 ng/ml. This is statistically lower than that found in patients with a negative second look ($p < 0.005$). Subsequently, macrophge CSF levels were compared with those of another tumor marker, CA 125. In all but five of the 33 patients, CA 125 levels were negative (<35 U/ml). Two of these five had a macrophage CSF level <3.62 ng/ml (mean ± SD 1.90 + 2) and a negative second look, one had a positive second look and a macrophage CSF level >3.62 ng/ml, and two had a positive second look and a macrophage CSF level <3.62 ng/ml (0.98 and 3.50 ng/ml). The variations seen in the levels of macrophage CSF might be attributed to tumor load. However, in the current study the sample size was too small to evaluate a possible correlation at second-look laparotomy.

Comment

Under normal conditions, macrophage CSF is produced constitutively by a variety of cells, including fibroblasts, endothelial and epithelial cells, and placental tissue.[8, 13, 14] Certain functionally differentiated cells such as monocytes do not secrete detectable quantities of macrophage CSF unless stimulated with tumor-promoting reagents (e.g., phorbol myristate acetate) or with bacterial lipopolysaccharides.[15-17] Normal serum will contain some basal amount of colony-stimulating factor. A recent report by Shaddle et al.[18] indicated that normal serum contained a mean level of 1.5 ng/ml of macrophage CSF, which is comparable to the levels observed in our study. The steady-state level of macrophage CSF in serum is governed by the rates of production and clearance. In normal individuals these two parameters are at equilibrium. Although the clearance rate and compartments involved in the clearance process have not been completely resolved for macrophage CSF, alveolar macrophages and Kupffer cells in the liver contribute to the removal of macrophage CSF from the circulation.[19] Macrophage CSF has a very short half-life, and injection of radioiodinated macrophage CSF is quickly cleared from circulation within 15 minutes. It has been noted that elevated macrophage CSF levels are associated with renal dysfunction.

In an earlier study Kacinski et al.[9] have shown that macrophage CSF levels in patients with ovarian cancer were significantly elevated. The increase had a positive correlation with CA 125 levels and showed a marked decrease after tumor debulking. These observations suggested that macrophage CSF levels could be used as an adjunct diagnostic parameter in ovarian cancer.

In this study we investigated the possible predictive value of macrophage CSF levels in patients undergoing second-look operation who had low CA 125 levels. All but one of the 33 patients studied received cisplatin before second look. One patient had a renal transplant before ovarian cancer developed. Although significant nephrotoxicity was documented in only two patients, subtle renal toxicity may also account for the elevated macrophage CSF levels found in patients with no evidence of disease at the time of second look. Renal function was not evaluated in the control group.

Macrophage CSF might be elevated simply because the patients in the study had been on a regimen of chronic leukocyte-suppressing chemotherapy. All patients, however, had normal white blood cell counts at the time of second-look surgery. Further study is warranted to see whether all patients undergoing chemotherapy have an elevated macrophage CSF level.

We conclude that, regardless of tumor status, macrophage CSF levels tend to be elevated at the time of second-look laparotomy. Further work is currently under way to determine if macrophage CSF levels may predict eventual recurrences in those patients with negative second-look laparotomy.

Population differences of fetal biophysical and behavioral characteristics

Mary Jo Johnson, MD, Lisa L. Paine, CNM, DrPH, Helma H. Mulder, MD, Carey Cezar, RNC, Carolyn Gegor, CNM, MS, and Timothy R.B. Johnson, MD
Baltimore, Maryland

Population differences in nonstress test reactivity have been reported with a threefold increase in the likelihood of nonreactive nonstress tests observed in black fetuses as compared with white fetuses. We analyzed fetal behavioral states and fetal heart rates in 14 black and 15 white fetuses at term to explain this observed difference in nonstress test reactivity. Two-hour Doppler and real-time ultrasonographic examination of each patient revealed no differences in percent time spent in the four behavioral states between the two populations. A 9.5 beats/min difference between black and white fetuses was found. The higher baseline heart rate of the black fetuses persisted in each behavioral state and may affect nonstress test reactivity because of rate-dependent decreases in short-term variability and rate-dependent limitations of maximal acceleration amplitude. (AM J OBSTET GYNECOL 1992;166:138-42.)

Key words: Heart rate, fetal, population differences, fetal surveillance

The nonstress test (NST) is an antepartum method of assuring fetal well-being in pregnancy. A "reactive" test is reassuring, indicating fetal heart rate (FHR) accelerations coincidental with fetal movement. It has recently been reported that maternal race may influence NST results, with black women noted to have nonreactive or nonreassuring tests three times more often than white women.[1] This large study determined the number and percentage of nonreactive NST results by demographic and behavioral characteristics. Fourteen percent (180/1263) of the blacks studied had nonreactive NSTs as compared with 4.3% of the whites studied (28/658). After controlling for gestational age, maternal medical complications, and behavioral characteristics such as substance abuse, this difference persisted. In a prospective study designed to evaluate auscultated FHR accelerations in conjunction with vibroacoustic stimulation, blacks were again significantly more likely to have a nonreactive NST.[2] Inherent racial variation in mean baseline heart rate could explain this observed population difference. The increased "nonreactivity" of the heart rate in black fetuses could also be attributed to racial variation in fetal behaviors such as movement and breathing. Fetal behavioral states have been described according to the parameters of FHR pattern, eye movements, breathing, and gross body movements.[3] The premise that black fetuses spent more time in states associated with "nonreactivity" (1F and 3F) than white fetuses could explain the increased incidence of nonreactive NSTs. The current study was undertaken to ascertain if this difference in reactivity could be attributed to differences in time spent by black and white fetuses in the four fetal behavioral states.

Methods

Patients. Informed consent was obtained from healthy, nonsmoking pregnant women who were between 38 and 41 weeks' gestation with uncomplicated pregnancies. The protocol was approved by the institutional review board at our institution. Women were recruited from the low-risk obstetric clinic, as well as from university-based private practices. The sample comprised 15 white and 14 black women.

The women were studied in our fetal testing unit after eating lunch. They were placed in a left lateral supine position and were monitored for 2 hours on the Toitu fetal actocardiograph model MT320. This monitor records both FHR and fetal movement; its reliability has been previously reported.[4] An Aloka real-time ultrasonographic transducer was positioned over the fetal head to observe fetal lens movement. This was simultaneously recorded on the heart rate strip with an event marker (Fig. 1).

The 29 women were monitored for an average of 120 minutes, with a range of 99 to 155 minutes. The FHR was determined for each fetus by visual inspection of the monitor strip (by M.J.J.). Changes in baseline of at least 3 minutes' duration were recorded and an average baseline for each subject was computed. A second observer (C.G.) reread the baseline on 10 randomly

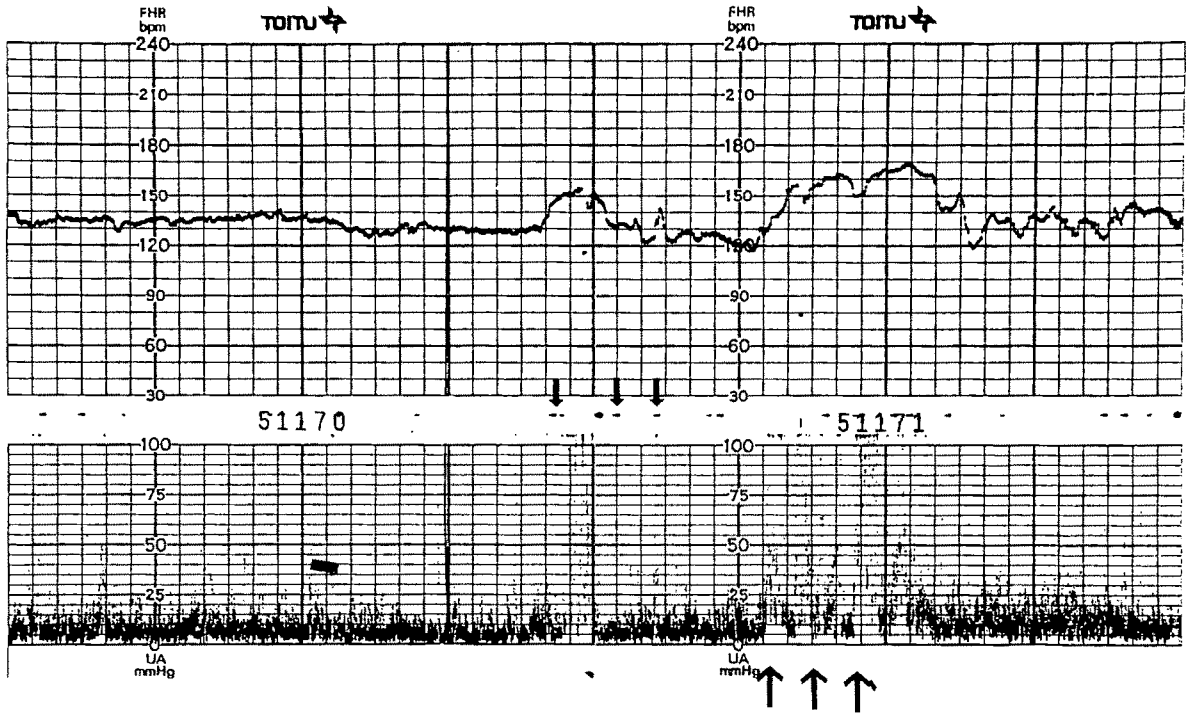

Fig. 1. Representative FHR recording. *Top line* is external FHR recording, with acceleration concomitant with fetal movement (depicted by ↑ on actograph). Fetal eye movements are recorded by event marker (↓).

selected strips. Pearson's correlation coefficient of these two readings was excellent at 0.984. The monitor strips were then evaluated for fetal state. FHRs were classified into patterns A, B, C, and D according to a previously described method.[5] Fetal body movements as depicted by the actograph were deemed present or absent. Fetal eye movements were likewise noted as present or absent. The three parameters of FHR pattern, body movement, and eye movements were then combined and fetal state assigned in a modification of Prechtl's criteria by a single investigator (T.J.).[5] Consensus on FHR patterns and states was provided by a second investigator (M.J.J.).

Percent time in each fetal state and mean baseline during each state were then computed for each fetus. Statistical significance was determined for demographic and clinical characteristics by means of χ^2, Fisher's exact test, and independent t tests as appropriate. Independent t tests were also used to evaluate mean percent time in the fetal behavior states and mean FHRs. The 0.05 confidence level was used to detect statistical differences throughout the analysis. The SYSTAT statistical package was used to analyze the data.

Results

Fetal outcome was good in all patients. The mean birth weight in the black fetuses was 3414 gm, which was not statistically different from the mean birth weight in the white fetuses, which was 3689 gm ($t = -1.513, p = 0.142$). There were no 5-minute Apgar scores <8.

Table I. Characteristics of study groups

	Black patients	*White patients*
Status		
Clinic	14	2*
Private	0	13*
Parity		
Primiparous	9	8
Multiparous	5	7
Mean maternal age (yr)	20.4	30.7*
Mean test gestational age (wk)	38.7	38.6

*$p < 0.05$.

The characteristics of the study groups are enumerated in Table I. The two racial groups were significantly different with regard to clinic status and maternal age. Parity was not significantly different. There were nine primiparous women in the black group and eight in the white group.

No significant differences in fetal state were found between the two groups (Table II). The black fetuses were in a "quiet-sleep" state 1F 28% of the monitored time; the white fetuses spent 22% of the monitored time in 1F. The FHR pattern in 1F shows minimal

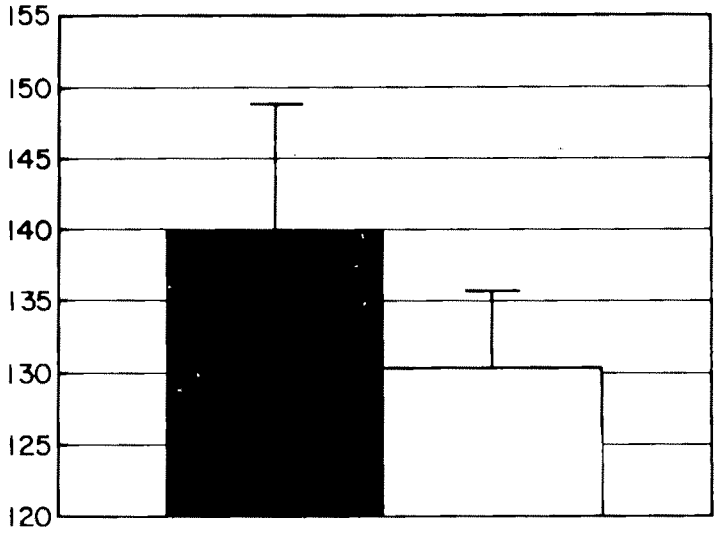

Fig. 2. Mean baseline FHR. ■, Black patients; □, white patients; $p = 0.003$.

Table II. Percent time in states 1F to 4F*

Behavioral state	*Time (%, mean ± SD)*	*Statistical significance*
1F		
Black patients	27.9 ± 18.7	$p > 0.05$
White patients	21.8 ± 17.1	
2F		
Black patients	51.8 ± 21.0	$p > 0.05$

White patients	11.2 ± 19.1	

*Insufficient data for state 3F.

variability and is "nonreactive," according to the usual definition of two accelerations of 15 beats/min and 15 seconds' duration in a 20-minute window. Both groups of fetuses spent the majority of the monitored time in the "active-asleep" state 2F (blacks 52%, whites 62%), again with no statistical racial difference noted. The fetal heart rate pattern in 2F is typically "reactive" with frequent heart rate accelerations coincidental with fetal body movements. The fetuses spent minimal time in state 3F, in agreement with other authors[7] (blacks 4%, whites 5%). The"active-awake" state 4F occurred in 16% of the monitored time in the black fetuses as compared with 11% of the monitored time in the white fetuses, a difference that was not statistically significant. Therefore black and white fetuses spent equal times in the four behavioral states; when the "reactive" states (2F and 4F) were combined and compared with the "nonreactive" states (1F and 3F), there was again no significant difference. When the overall mean FHRs were analyzed, a significant difference in baseline was found between the two groups (Fig. 2). Black fetuses had a mean baseline of 139.9 beats/min, which was 9.5 beats/min faster than that of white fetuses (130.4 beats/min). The FHR baseline was examined for each behavioral state for blacks and whites (Fig. 3). The higher baseline in black fetuses persisted in each state, reaching a difference of 13 beats/min in 4F.

The significant difference in mean FHR was evaluated after fetal sex was controlled for. No differences by race were observed; however, it should be noted that the sample sizes were small (Table III). Similarly, newborn birth weight did not correlate with baseline FHR ($r = -0.05$).

Comment

Multiple maternal behavioral variables and medical complications have been shown to directly affect antepartum fetal assessment test results. Variability in

	Black patients			*White patients*		
Sex of fetuses	*No.*	*FHR (beats/min, mean ± SD)*	*Statistical significance*	*No.*	*FHR (beats/min, mean ± SD)*	*Statistical significance*
Male	11	140.0 ± 10.1	$p > 0.05$	6	128.3 ± 4.9	$p > 0.05$
Female	3	139.7 ± 4.5		9	133.5 ± 4.7	

FHR reactivity, as well as various biophysical parameters, is influenced by gestational age, length of testing, and maternal ingestion of drugs, alcohol, cigarettes, and glucose.[6-9] The parameter of race, or ethnicity, has not been explored in this area although the literature is rich with heart rate and blood pressure data in children and adults of different races.[10, 11]

Our initial premise that the significant difference in NST reactivity between the black and white groups might be attributed to behavioral state differences could not be validated when 2-hour evaluations of 14 black and 15 white fetuses were undertaken. We did, however, find a significant difference in mean baseline heart rate, which has not been well described in research of the fetus. Schacter et al.[12] have consistently demonstrated a higher heart rate in black newborns as compared with white newborns. Seventy-four white and 67 black healthy term newborns to women of low socioeconomic status had heart rate measurements taken for three ½-hour periods of quiet, non-rapid-eye-movement sleep. Both the slowest heart rate and the mean heart rate were significantly faster for black newborns than for white newborns, with this difference averaging 8 beats/min. Schacter et al.[13] further evaluated the socioeconomic status in black and white newborns and verified that this heart rate difference persisted irrespective of socioeconomic status.

It is easily discerned that our two study groups differed by socioeconomic status, as well as by race. The black patients were recruited from the obstetric clinic. Nonsmoking white patients were difficult to recruit from this clinic; therefore the majority of the white patients were from private practices. In recognition of these differences, we refrained from attributing the observed heart rate difference to race alone. Population differences in our study in maternal anxiety or unrecognized drug use could contribute to the differences found.

Our observation of heart rate differences in different populations poses many questions. Inherent population variations in birth weight have been determined.[14] Earlier physical maturity of black newborns compared with white newborns of similar gestational ages has been described.[15] Racial differences in fetal behaviors are only now being explored. Further investigation into this area should include the Hispanic population, especially since much of the original fetal assessment data comes from this ethnic group. Patrick et al.[16] have discussed the association between maternal and fetal heart rates; we did not evaluate this association in our study.

The clinical significance of this heart rate difference is obvious when one considers its potential effect on maximal acceleration amplitude. It has been demonstrated that fewer accelerations of 15 beats/min are mounted when the FHR is ≥140 beats/min.[17] Eight of our 14 black subjects had a mean FHR ≥140 beats/min in comparison with 2 of 15 white subjects who had a mean FHR ≥140 beats/min. Therefore race may be an important variable when the sensitivity and specificity of the NST, as well as other antepartum tests, are ascertained.

In this analysis black and white fetuses spent equal time in the four fetal behavioral states when studied for 2 hours in the afternoon. A difference of 9.5 beats/min in mean baseline heart rate was found between the two populations, a finding well documented in the neonatal literature but previously underrecognized in the obstetric literature. Population differences and fetal physiologic variables need to be further studied to augment our current knowledge of antepartum fetal assessment and testing.

May-Hegglin anomaly: A rare case of maternal thrombocytopenia in pregnancy

Ashwin Chatwani, MD, Nancy Bruder, BS, Todd Shapiro, MD, and E. Albert Reece, MD
Philadelphia, Pennsylvania

The May-Hegglin anomaly, a rare cause of thrombocytopenia, is an autosomal dominant disorder that may have adverse maternal and fetal consequences. We present herein a case of May-Hegglin anomaly in pregnancy. The characteristic features of this anomaly, clinical presentation, and management options are discussed. (AM J OBSTET GYNECOL 1992;166:143-4.)

Key words: May-Hegglin anomaly

We describe a case of May-Hegglin anomaly in pregnancy.

Case report

A 28-year-old, white woman, gravida 4, para 0-0-3-0, with spontaneous rupture of the membranes at >39 weeks, was transferred from an outlying hospital to Temple University Hospital for tertiary care. The patient had been diagnosed with the May-Hegglin anomaly several years earlier. The patient had bleeding gums 1 week before admission but was otherwise asymptomatic. Physical and ultrasonographic examination revealed a nonfrank breech presentation of the fetus. The maternal platelet count at the time of admission was 34,000/mm³. Peripheral blood smear was characteristic of the May-Hegglin anomaly, showing giant platelets and cresent-shaped inclusions in the cytoplasm of neutrophils and monocytes. In view of fetal presentation and the 50% risk of inheritance of this disorder, a primary low-transverse cesarean section was performed. She received 12 U of platelets before surgery, and the preoperative platelet count was 90,000/mm³. A viable female infant weighing 7 pounds 3 ounces was delivered with Apgar scores of 6 at 1 minute and 9 at 5 minutes. The patient required no additional platelet transfusions. Repeat platelet count before discharge was 117,000/mm³. The patient's postoperative course was uncomplicated, and she was discharged on the fourth postoperative day. The baby's platelet count was normal and did not show any characteristics of the May-Hegglin anomaly.

Comment

The May-Hegglin anomaly is a rare hereditary platelet disorder transmitted in an autosomal dominant pattern. The disorder was first described in 1909 by May[1] when he noted the giant platelets and sky-blue, cresent-shaped inclusions in the cytoplasm of neutrophils, eosinophils, and monocytes. In 1945, Hegglin[2] observed thrombocytopenia and bleeding diathesis in three family members. The platelets in May-Hegglin anomaly are large, measuring up to 15 μm in diameter. They are elliptic, cigar-shaped, or rounded. Thrombocytopenia is usually mild, but platelet count may be as low as 10,000/mm³. The megakaryocyte level in bone marrow is normal, and it has been suggested that the basic defect may be impaired megakaryocyte fragmentation.[3] The inclusion bodies, measuring 1 to 2 μm in diameter, are best observed in neutrophils. Usually only one inclusion per cell is found, and on electron microscopy and histochemical staining, inclusions have been found to contain ribonucleic acid.

A computer-assisted search showed only four cases

Table I. Outcome of five cases of May-Hegglin anomaly in pregnancy

No.	Series	Platelet count (No./mm³)	Delivery route	Outcome	
				Maternal	Neonate
1	Landy et al.[4]	22,000	Cesarean section—placenta previa	Good	May-Hegglin anomaly
2	Duff and Jackson[5]	32,000	Cesarean section—May-Hegglin anomaly	Good	May-Hegglin anomaly
3	Gausis et al.[6]	50,000	Vaginal delivery	Good	Stillbirth
4	Kotelko[7]	24,000	Cesarean section—failure to descend	Good	May-Hegglin anomaly
5	Chatwani et al. (present case)	34,000	Cesarean section—nonfrank breech	Good	Normal

of this anomaly in pregnancy (Table I). Maternal diagnosis of this disease in pregnancy is established by characteristic peripheral smear and by excluding other causes of thrombocytopenia. Fetal diagnosis can be done in the same manner by periumbilical blood sampling. The obstetric management involves prevention of hemorrhage in both mother and fetus. At the time of delivery maternal hemorrhage can be avoided by transfusion of platelets as needed. Prenatal diagnosis will dictate route of delivery. In this case fetal diagnosis was not done because of the fetal presentation and because the information would not change the course of management. Failure to clearly assess fetal involvement may result in adverse fetal consequences, such as intracranial hemorrhage, during parturition. This case report simply documents a rare cause of maternal thrombocytopenia, which may have fatal consequences if such a diagnosis is not entertained and excluded.

Oral magnesium and the prevention of preterm labor in a high-risk group of patients

Rick W. Martin, MD, Kenneth G. Perry, Jr., MD, L. Wayne Hess, MD, James N. Martin, Jr., MD, and John C. Morrison, MD

Jackson, Mississippi

OBJECTIVE: The null hypothesis of this study is that treatment with oral magnesium gluconate 1 gm four times daily will not decrease the rate of preterm labor and delivery in a high-risk group of pregnant women.
STUDY DESIGN: Fifty-four women at risk for preterm delivery were selected randomly to receive magnesium gluconate 1 gm orally four times daily or placebo. These women were monitored prospectively for signs and symptoms of preterm labor. A subgroup of 31 women also received a home uterine activity monitor. The serum magnesium level was measured initially and again 2 weeks after study enrollment. The data were analyzed with Fisher's exact test and analysis of variance.
RESULTS: Preterm labor developed in 15 women in the placebo group and in 16 women in the magnesium group. There were no differences in birth weight or gestational age at delivery. The mean increase in serum magnesium level while the patients were taking magnesium gluconate was 0.10 mg/dl (p = not significant). Five women did not have an increase in serum magnesium level and preterm labor developed in all of them.
CONCLUSION: Magnesium gluconate in a dose of 1 gm four times daily is not effective for preventing preterm delivery in a high-risk group of patients. (Am J Obstet Gynecol 1992;166:144-7.)

Key words: Magnesium, preterm labor, tocolysis

Preterm birth occurs in approximately 9% of all deliveries and is accompanied by high rates of perinatal morbidity and mortality.[1] Factors that put women at risk for early delivery can be identified.[2] Monitoring women more extensively for preterm labor results in a reduction in preterm births.[3]

The use of oral magnesium gluconate for tocolysis

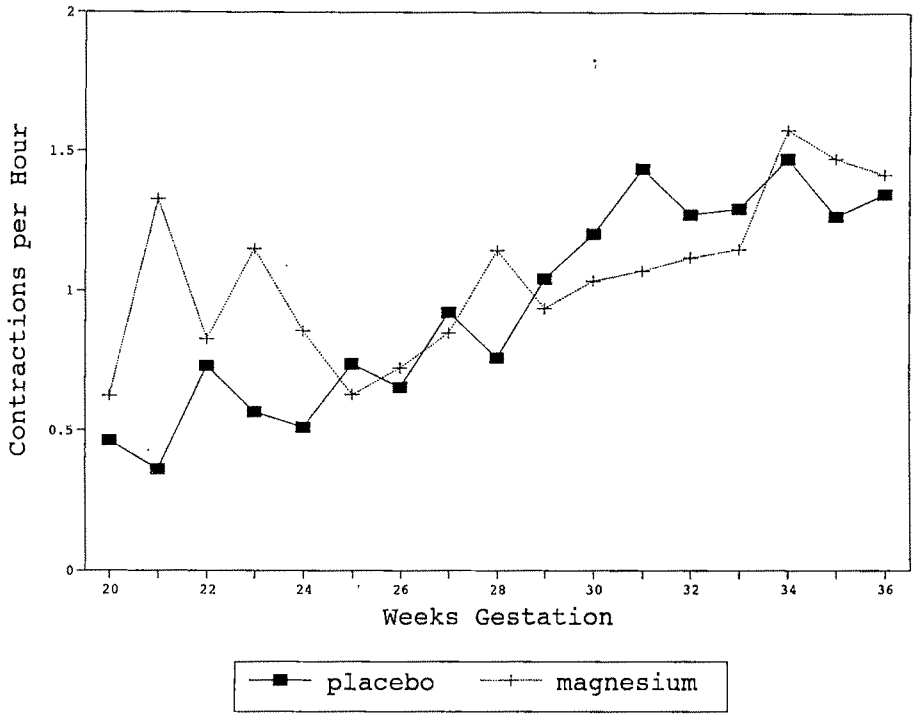

Fig. 1. Baseline uterine activity.

in ambulatory patients with preterm labor has been reported.[4] Magnesium is well tolerated with only minor gastrointestinal effects and is inexpensive compared with other oral tocolytic drugs. Finally, women who have low serum magnesium levels have a greater risk of preterm labor.[5] In uncontrolled studies supplementation of this ion has suggested a reduction in the incidence of early delivery.[6]

The purpose of this prospective study was to assess whether treatment with oral magnesium reduces the incidence of preterm labor and delivery in women at high risk for preterm birth.

Patients and methods

Fifty-four women with risk factors for preterm delivery were enrolled in the study, which was approved by the local institutional review board. After giving informed consent, the patients were randomly selected to receive either two 500 mg magnesium gluconate tablets four times daily or two placebo tablets four times daily. All tablets had the same physical appearance. Both groups were monitored prospectively in a high-risk clinic. The health care providers were blind as to which treatment each patient received. Patients were educated as to the signs and symptoms of preterm labor. A cervical examination was performed every 2 weeks. Preterm labor was diagnosed by the presence of regular, persistent uterine contractions with a change in cervical dilatation.

If preterm labor occurred, the study medication was discontinued and the patient was treated with standard tocolytic therapy (parenteral magnesium sulfate). Patients who completed 37 weeks' gestation returned to routine obstetric care. The gestational age at delivery, birth weight, and episodes of preterm labor were recorded.

After the study had begun, 31 consecutive patients (16 magnesium, 15 placebo) received home uterine ambulatory monitoring for 1 hour twice daily. The uterine activity data were transferred via telephone once daily to a perinatal nurse, who recorded the data and each patient's symptoms in a manner previously described.[7] The weekly uterine contraction rate was determined as an average of the uterine activity recorded during the monitored periods (2 hours daily, 7 days each week). Uterine activity increased markedly in the few days before the onset of preterm labor. To obtain a baseline contraction rate, we excluded the contraction data in the week before the onset of preterm labor.

The data were evaluated with the Fisher exact test and analysis of variance, as appropriate. A p value <0.05 was considered to be significant.

Results

Seven of the 54 women in the study were excluded from analysis because they moved from the area (4 women), experienced an early pregnancy loss (2), or violated the study protocol (1). Of the remaining 47

Table I. Risk factors for preterm labor

Risk factor	*Magnesium group*	*Placebo group*
Prior preterm delivery	17	19
Multiple gestation	1	5
Cerclage procedure	1	0
Uterine activity	3	0
Leiomyomas	0	1
TOTAL	22	25

patients, 25 were assigned to the placebo group and 22 were assigned to the magnesium group. The average maternal age was 26.5 years in the placebo group and 24.2 years in the magnesium group. The mean parity was 2.4 in the placebo group and 1.7 in the magnesium group. Gestational age at entry into the study was not different, with 23.4 and 23.7 weeks in the placebo and magnesium groups, respectively. There were no significant differences in the entry characteristics. Risk factors for preterm delivery were also similar in each group (Table I).

Fifteen women in the placebo group had preterm labor, compared with 16 in the magnesium group. The average gestational age (mean ± SD) at delivery was 35.6 ± 3.7 weeks for the placebo group and 35.6 ± 2.8 weeks for the magnesium group. Mean birth weights were similar: 2612 ± 828 gm in the placebo group and 2479 ± 684 gm in the magnesium group. Only two infants scored <7 on the Apgar scale at 5 minutes. Both infants were delivered of mothers in the placebo group.

No major side effects were reported among the 22 women in the magnesium group. Serum magnesium levels were obtained for 36 patients (21 placebo group, 15 magnesium group) initially and 2 weeks after they entered the study. The initial serum magnesium level was 1.68 ± 0.25 mg/dl for the placebo group and 1.64 ± 0.21 mg/dl for the magnesium group. Women taking magnesium gluconate responded with a rise in serum magnesium level of 0.10 ± 0.21 mg/dl from the initial measurement ($p < 0.09$, paired t test). The serum magnesium level fell by 0.01 ± 0.23 mg/dl in those not receiving magnesium.

The serial magnesium values obtained in 15 patients taking magnesium gluconate showed 4 of 10 patients with increased serum magnesium levels having preterm labor. It is interesting that all five women whose serum magnesium levels did not increase had preterm labor ($p < 0.15$).

Uterine activity data are presented in Fig. 1. The mean hourly uterine activity increased with gestational age in both groups. The data were analyzed with a two-factor analysis of variance (treatment, time), with one factor (time) repeated. The difference between the magnesium and placebo groups was not statistically significant ($p < 0.8$).

Comment

Magnesium exerts an effect on uterine contractility, presumably by its competition with intracellular calcium. In 1966 Rusu et al.[5] reported a decline in serum magnesium level with advancing gestation and a further fall before the onset of labor. They suggested a role for maternal administration of oral magnesium in the prevention of preterm birth. Later a retrospective study by Conradt et al.[6] established a decreased preterm delivery rate, from 11% to 4.9%, with the addition of oral magnesium to a standard treatment of cerclage and prophylactic β-sympathomimetic drugs. More recently in a prospective study Spatling and Spatling[8] were able to reduce the incidence of preterm labor from 9% to 4.3% in women treated with magnesium aspartate compared with women receiving placebos.

These initial results were encouraging. In other studies magnesium was found to be inexpensive and well tolerated when given to patients in preterm labor.[4] Many pregnant women, particularly women of lower socioeconomic status,[9] do not have adequate magnesium in their diets. This group of women has not always benefited from intervention with current risk-scoring systems to prevent preterm delivery.[10] A study to evaluate magnesium supplements for women at risk for preterm delivery would therefore be reasonable.

In our study prophylactic magnesium had no effect on the duration of pregnancy or infant birth weight. The study dosage of 216 mg of elemental magnesium was lower than the dosage used by Spatling and Spatling.[8] In our institution's earlier report of oral magnesium tocolysis, magnesium gluconate was given six times daily.[11] The four times per day regimen (30% lower than in the previous study) was designed to increase patient compliance. Whereas the increase in serum magnesium levels achieved statistical significance in the previous study, there was not a statistically significant rise in serum magnesium levels with the lower magnesium dosage. Sibai et al.[12] have also reported the use of prophylactic magnesium. Their study included primigravid women who were not at risk for preterm delivery. Although the focus of the study of Sibai et al. was to evaluate the effect of oral magnesium on pregnancy-induced hypertension, the incidence of preterm birth did not decrease in the magnesium-treated group.

There may be a subgroup of women who could benefit from a program of magnesium prophylaxis. The five women in this study whose serum magnesium levels did not increase may represent such a group. These women may have had relative magnesium deficiency despite normal initial serum magnesium levels. Palla et al.[13] described a magnesium load test in which pregnant women were given intravenous magnesium and the urinary excretion of this cation was measured. Retention of >20% of an intravenous magnesium load was consistent with magnesium deficiency. In our study, the

group of women with decreased serum magnesium levels may have been magnesium deficient and would perhaps benefit from a higher dosage of oral magnesium. A study with a larger number of patients is needed to investigate this aspect of magnesium replacement.

Although there was not a difference in gestational age at delivery or in birth weight in the two groups, it might be expected that the lower dose of magnesium would decrease uterine activity. In the 31 patients evaluated via home uterine activity monitoring the baseline hourly contraction rate increased with gestational age, as has been described in other studies.[14] There was, however, no difference in uterine activity between the placebo and treatment groups.

Oral magnesium gluconate did not change the incidence of preterm labor or infants with low birth weight in this high-risk group of women. Uterine activity was also not affected by this dosage of magnesium. Women with risk factors whose serum magnesium levels did not increase while on magnesium therapy may be at increased risk for preterm delivery.

Pelvic abscess complicating transcervical embryo transfer

Mark V. Sauer, MD, and Richard J. Paulson, MD
Los Angeles, California

A severe pelvic infection resulting in a tuboovarian abscess after transcervical embryo transfer is reported. The case is unique in that the recipient was an agonadal woman who had not undergone prior transvaginal aspiration. Although rare, pelvic infection after embryo transfer may occur in spite of normal precautions. (AM J OBSTET GYNECOL 1992;166:148-9.)

Key words: Embryo transfer, pelvic infection, embryo donation

Complications in women undergoing intrauterine catheterization for embryo transfer are exceedingly rare.[1] In most cases patients undergo ovarian aspiration before embryo transfer, which makes it difficult to determine the contribution of the prior procedure in the overall risk assessment. We report the occurrence of a severe pelvic infection resulting in a tuboovarian abscess after embryo donation to an agonadal woman. This case illustrates that infection may result from transcervical embryo transfer in spite of precautions taken in the performance of this procedure.

Case report

The patient was a 38-year-old, nulligravid, Asian woman who was previously diagnosed with premature ovarian failure. She was married and sexually active with her husband. Semen culture before oocyte donation was negative for pathogens. Fifteen years previously she underwent a right salpingo-oophorectomy after a pelvic infection. She had no history of pelvic infection, surgery, or abdominal pain since that time. A late luteal phase endometrial biopsy was performed 2 months before the planned oocyte donation while the patient was receiving exogenous sex steroid replacement as previously described.[2] The biopsy specimen was within normal limits, and the patient then underwent hormonal synchronization with the menstrual cycle of a 32-year-old woman who underwent controlled ovarian hyperstimulation and oocyte aspiration for the sole purpose of gamete donation. The donor provided 12 oocytes, resulting in the creation of five preembryos. Forty-eight hours after the aspiration the preembryos were transferred transcervically with a 3Fr tomcat catheter. This catheter has been extensively used in our program for this purpose and for the intrauterine insemination of washed sperm. It is flexible, easy to use, sterile, and known not to be embryo toxic. The transfer was performed with aseptic technique and proceeded without difficulty or incident. A tenaculum was not used on the cervix. Prophylactic antibiotics were not prescribed, nor are they routinely used by us for patients undergoing either intrauterine catheterization for insemination or for agonadal recipients needing embryo donation.

Approximately 72 hours after embryo transfer the patient experienced lower abdominal pain and fever. She was seen by her local doctor, who thought she might have a viral infection and sent her home. Her symptoms worsened and 6 days after transfer she returned to our office. Her temperature was 102° F, and she had severe lower abdominal pain and distention. Transvaginal ultrasonography noted a 6 cm × 6 cm left-sided pelvic mass, not previously noted on ultrasonography performed at the time of endometrial biopsy. The white blood cell count was 19,700/mm³ with a shift to the left. A diagnosis of tuboovarian abscess was made, and she was admitted to the hospital. Intravenous antibiotics consisting of ampicillin, gentamicin, and clindamycin were begun. After 36 hours of triple antibiotics she remained febrile to 102° F, and the abdominal distension worsened. The white blood cell count was 22,000/mm³, and it was elected to perform an operation for extirpation of the abscessed tissue. A left salpingo-oophorectomy was performed and a large abscess drained. Hormonal replacement medications were discontinued, and she menstruated. The patient did well, postoperatively, and she was afebrile 72 hours later. She was discharged on the sixth postoperative day and recovered uneventfully.

Comment

This case illustrates the potential for an atraumatic embryo transfer to result in severe pelvic infection. Although the likelihood of such an untoward outcome is exceedingly small, patients should be informed of such a complication before their consent to the procedure.

It remains uncertain whether the use of prophylactic antibiotics would prevent such an occurrence. At this time we cannot recommend routine antibiotic usage since this complication to date remains unreported.

However, as a result of our experience, we now offer prophylaxis to patients undergoing transcervical catheterization if the patient gives us a history of pelvic infection. Similarly, in cases of traumatic catheterization of the cervix during embryo transfer or intrauterine insemination procedures, antibiotic coverage should be considered.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1992 issues from the Publisher, at a cost of $68.00 for domestic, $95.76 for Canada, and $91.00 for international for Vol. 166 (January-June) and Vol. 167 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351, or (314) 453-4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Urinary excretion of prostacyclin and thromboxane metabolites in threatened preterm labor: Effect of indomethacin and nylidrin

Tapio Kurki, MD,[a] Lasse Viinikka, MD,[b] and Olavi Ylikorkala, MD[a]
Helsinki, Finland

OBJECTIVE: We studied the role of smooth muscle–relaxing prostacyclin and its endogenous antagonist, thromboxane A_2, in preterm labor by assessing the urinary output of the breakdown products of prostacyclin (6-keto-prostaglandin $F_{1\alpha}$ and 2,3-dinor-6-keto-prostaglandin $F_{1\alpha}$) and those of thromboxane A_2 (thromboxane B_2, 2,3-dinor-thromboxane B_2).
STUDY DESIGN: Thirty-three women in preterm labor between 25 and 34 weeks of gestation were studied before, during, and after treatment with indomethacin (n = 16) or nylidrin (n = 17). Urinary prostanoid levels were determined by high-performance liquid chromatography followed by radioimmunoassay, and the excretion was expressed as nanograms of prostanoids per millimole of creatinine. Statistical analyses were done by paired and unpaired Student t test, by Spearman's correlation, and by Wilcoxon signed-rank test.
RESULTS: Preterm labor was accompanied by a median 32% higher output of prostacyclin and thromboxane A_2 metabolites as compared with those in 25 controls. At 8 hours after the start of treatment indomethacin induced maximal drops in 6-keto-prostaglandin $F_{1\alpha}$ (70%), in dinor-6-keto-prostaglandin $F_{1\alpha}$ (60%), in thromboxane B_2 (85%), and in dinor-thromboxane B_2 (95%) excretion. Within 1 week after the cessation of indomethacin, output of prostacyclin metabolites had recovered to pretreatment values, whereas output of thromboxane A_2 metabolites was yet lower than the pretreatment value. Nylidrin induced no change in the output of prostacyclin and thromboxane A_2 metabolites.
CONCLUSION: Threatened preterm labor is associated with a rise in prostacyclin and thromboxane A_2 synthesis. Indomethacin inhibits more thromboxane A_2 than does prostacyclin synthesis. These findings may explain the fetal vascular changes during maternal indomethacin treatment. (AM J OBSTET GYNECOL 1992;166:150-4.)

Key words: Preterm labor, urinary prostaglandins, tocolysis

During the last decade it has become clear that antiaggregatory and vasodilatory prostacyclin (PGI_2) and its endogenous antagonist, thromboxane A_2 (TxA_2), play a significant role in the physiology of pregnancy.[1-3] Hypertensive pregnancies are characterized with PGI_2 deficiency or TxA_2 overproduction, and these changes may lead to vasoconstriction, microthromboses, and diminished blood flow in the fetoplacental unit.[1-3] Further support for the significance of the PGI_2/TxA_2 balance in pregnancy comes from a trial demonstrating that doses of aspirin so small that they inhibit only the synthesis of TxA_2, leaving PGI_2 unaffected, protect against the development of preeclampsia and other hypertensive pregnancy complications.[4]

Whereas the significance of PGI_2 and TxA_2 in hypertensive pregnancies appears clear, data are scanty on PGI_2 and TxA_2 in preterm labor. PGI_2 relaxes and TxA_2 constricts the human myometrium in in vitro study models.[5] Furthermore, it is known that labor is associated with the release of prostaglandins (PG) and prostanoids from the fetal membranes, the decidua, or the fetus itself.[6-8] Additional support for the role of prostanoids in labor comes from data indicating that PG synthesis inhibitors, such as indomethacin, arrest preterm labor.[9, 10] This treatment may, however, cause a transient constriction of the ductus arteriosus[11] and cerebral arteries,[12] and this could well be a result of PGI_2 suppression in the fetal vasculature, particularly because indomethacin is known to cross the placenta.[13] However, no direct data exist on the effect of indomethacin on PGI_2 and TxA_2 in pregnancy. Furthermore, the use of β-sympathomimetic agents, another tocolytic alternative, is accompanied by vascular

changes such as hypotension where changes in PGI_2 have been supposed to be significant.[10, 14] We therefore studied the production of PGI_2 and TxA_2 in preterm labor and the effect of indomethacin and nylidrin on these productions.

Material and methods

With the approval of the local ethical committee, 86 pregnant women were studied (Table I). Of these, 33 otherwise healthy women were admitted to the hospital because of an established threat of preterm labor between 25 and 34 gestational weeks of singleton pregnancy. They all had regular painful uterine contractions at <10-minute intervals, and the cervix was softened and opened (2 to ≤4 cm) (median Bishop score, 6; range, 2 to 8). The fetal membranes were intact.

As the control group for these women with threatened preterm labor, we studied 25 healthy pregnant women experiencing no uterine contractions who were matched for the gestational age (±3 days). To learn whether preterm and term uterine activity was differently associated with PGI_2 and TxA_2, we studied another control group of 28 women who had been in term labor for 3 to 12 hours and whose cervices were open 2 to 10 cm (median, 3 cm) (Table I).

The 33 women were threatened preterm labor were treated in randomized order (a sealed envelope) with indomethacin (16 women) or nylidrin (17 women). Three days of an indomethacin course consisted of an initial 100 mg rectal suppository followed by two 50 mg oral capsules at 8-hour intervals for the first day; on days 2 and 3 the dose was 50 mg orally, three times a day. Nylidrin was infused intravenously with an initial dose of 50 μg/min; this was increased within 30 minutes to the maximum of 150 μg/min and continued for 3 days. The double-dummy principle was followed so that all patients received both the intravenous infusion (containing placebo or nylidrin) or rectal suppositories and oral capsules (containing indomethacin or placebo).

Maternal blood pressure and pulse rate were recorded hourly up to 8 hours and then 12, 24, 48, and 72 hours after initiation of treatment. Fetal heart rate was monitored by continuous cardiotocography. Labor was halted for >24 hours in all 33 patients and postponed for 2 to 7 days in nine patients (four indomethacin, five nylidrin), for 1 to 2 weeks in four patients (1 indomethacin, 3 nylidrin), and for >2 weeks in 20 patients (11 indomethacin, 9 nylidrin). More detailed clinical data will appear in a subsequent article.[15]

Spot urinary samples (50 ml) were collected before the start of the indomethacin or nylidrin from women with preterm labor. Similar urine samples were collected 8 hours (from 12 women), 24 hours (from all women), 72 hours, 1 week, and 2 weeks (from 14 women each) after the onset of tocolysis. The distribution of the samples collected was equal between the indomethacin and nylidrin groups. Single urine samples were collected from the control groups.
